

Springer

Handbook of Robotics

Siciliano
Khatib
Editors

**Springer Handbook
of Robotics**

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Robotics

Bruno Siciliano, Oussama Khatib (Eds.)

With DVD-ROM, 953 Figures, 422 in four color and 84 Tables

Foreword

My first introduction to robotics came via a phone call in 1964. The caller was Fred Terman, the author of the world-famous *Radio Engineer's Handbook*, who was at the time Provost of Stanford University. Dr. Terman informed me that a computer science professor, John McCarthy, had just been awarded a large research grant, part of which required the development of computer-controlled manipulators. Someone had suggested to Terman that it would be prudent if the mathematically oriented McCarthy had some contact with mechanical designers. Since I was the only one on the Stanford faculty whose specialty was mechanism design, Terman decided to phone me, even though we had never met and I was a young assistant professor fresh out of graduate school with only 2 years at Stanford.

Dr. Terman's phone call led me to a close association with John McCarthy and the Stanford Artificial Intelligence Laboratory ([SAIL](#)) that he founded. Robotics became one of the pillars of my entire academic career, and I have maintained my interest in teaching and researching the subject through to the present day.

The modern history of robotic manipulation dates from the late 1940s when servo arms were developed in connection with master-slave manipulator systems used to protect technicians handling nuclear materials. Developments in this area have continued to the present day. However, in the early 1960s there was very little academic or commercial activity in robotics. The first academic activity was the thesis of H. A. Ernst, in 1961, at MIT. He used a slave arm equipped with touch sensors, and ran it under computer control. The idea in his study was to use the information from the touch sensors to guide the arm.

This was followed by the [SAIL](#) project and a similar project started by Professor Marvin Minsky at MIT, which were the only sizeable academic ventures into robotics at that time. There were a few attempts at commercial manipulators, primarily in connection with part production in the automotive industry. In the USA there were two different manipulator designs that were being experimented with in the auto industry; one came from American Machine and Foundry (AMF) and the other from Unimation, Inc.

There were also a few mechanical devices developed as hand, leg, and arm prosthetics, and, a bit later, some

exoskeletal devices to enhance human performance. In those days there were no microprocessors. So, these devices were either without computer control, or tethered to a remote so-called minicomputer, or even a mainframe computer.

Initially, some in the computer science community felt that computers were powerful enough to control any mechanical device and make it perform satisfactorily. We quickly learned that this was not to be the case. We started on a twofold track. One was to develop particular devices for [SAIL](#), so that hardware demonstrations and proof-of-concept systems were available for the fledgling robotics community to experiment with. The other track, which was more or less moonlighted from the work at [SAIL](#), was the development of a basic mechanical science of robotics. I had a strong feeling that a meaningful science could be developed, and that it would be best to think in terms of general concepts rather than concentrate exclusively on particular devices.

Fortunately, it turned out that the two tracks supported each other very naturally and, most importantly, the right students were interested in doing their research in this area. Hardware developments proved to be specific examples of more general concepts, and the students were able to develop both the hardware and the theory.

Originally, we purchased an arm in order to get started quickly. A group at Rancho Los Amigos Hospital, in Los Angeles, was selling a tongue-switch-controlled motor-driven exoskeleton arm to assist patients without muscular control of their arms. We purchased one of these, and connected it to a time-shared PDP-6 computer. The device was named *Butterfingers*; it was our first experimental robot. Several films demonstrating visual feedback control, block stacking tasks, and obstacle avoidance were made with *Butterfingers* as the star performer.

The first manipulator that we designed on our own was known simply as the *Hydraulic Arm*. As its name implies, it was powered by hydraulics. The idea was

Bernard Roth
Professor of Mechanical
Engineering
Stanford University

to build a very fast arm. We designed special rotary actuators, and the arm worked well. It became the experimental platform for testing the first ever dynamic analysis and time-optimal control of a robotic arm. However, its use was limited since the design speeds were much faster than required due to the limitations of the computational, planning, and sensing capabilities that were common at that time.

We made an attempt to develop a truly digital arm. This led to a snake-like structure named the *Orm* (the Norwegian word for snake.) The *Orm* had several stages, each with an array of inflatable pneumatic actuators that were either fully extended or fully contracted. The basic idea was that, even though only a finite number of positions in the workspace could be reached, these would be sufficient if there were a large number of positions. A small prototype proof-of-concept *Orm* was developed. It led to the realization that this type of arm would not really serve the **SAIL** community.

The first truly functional arm from our group was designed by Victor Scheinman, who was a graduate student at the time. It was the very successful *Stanford Arm*, of which over ten copies were made as research tools to be used in various university, government, and industrial laboratories. The arm had six independently driven joints; all driven by computer-controlled servoed, DC electric motors. One joint was telescoping (prismatic) and the other five were rotary (revolute).

Whereas the geometry of *Butterfingers* required an iterative solution of the inverse kinematics, the geometric configuration of the *Stanford Arm* was chosen so that the inverse kinematics could be programmed in any easy-to-use time-efficient closed form. Furthermore, the mechanical design was specifically made to be compatible with the limitations inherent in timeshare computer control. Various end-effectors could be attached to act as hands. On our version, the hand was in the form of a vise-grip jaw, with two sliding fingers driven by a servoed actuator (hence, a true seventh degree of freedom). It also had a specially designed six-axis wrist force sensor. Victor Scheinman went on to develop other important robots: the first was a small humanoid arm with six revolute joints. The original design was paid for by Marvin Minsky at the MIT **AI** Lab. Scheinman founded Vicarm, a small company, and produced copies of this arm and the *Stanford Arm* for other labs. Vicarm later became the West Coast Division of Unimation, Inc., where Scheinman designed the *PUMA* manipulator under General Motors sponsorship through Unimation. Later, for a company called Automatix, Scheinman developed the novel *Robot World* multirobot system. After Scheinman

left Unimation, his colleagues Brian Carlisle and Bruce Shimano reorganized Unimation's West Coast Division into Adept, Inc., which to this day is the largest **US** manufacturer of assembly robots.

Quickly, the modern trend of carefully detailed mechanical and electronic design, optimized software, and complete system integration became the norm; to this day, this combination represents the hallmark of most highly regarded robotic devices. This is the basic concept behind *mechatronic*, a word coined in Japan as a concatenation of the words mechanics and electronics. Mechatronics that relies on computation is the essence of the technology inherent in robotics as we know it today.

As robotics developed around the world, a large number of people started working on various aspects, and specific subspecialties developed. The first big division was between people working on manipulators and those working on vision systems. Early on, vision systems seemed to hold more promise than any other method for giving robots information about their environment.

The idea was to have a television camera capture pictures of objects in the environment, and then use algorithms that allowed the computer images of the pictures to be analyzed, so as to infer required information about location, orientation, and other properties of objects. The initial successes with image systems were in problems dealing with positioning blocks, solving object manipulation problems, and reading assembly drawings. It was felt that vision held potential for use in robotic systems in connection with factory automation and space exploration. This led to research into software that would allow vision systems to recognize machine parts (particularly partially occluded parts, as occurred in the so-called “bin-picking” problems) and ragged-shaped rocks.

After the ability to “see” and move objects became established, the next logical need had to do with planning a sequence of events to accomplish a complex task. This led to the development of planning as an important branch in robotics. Making fixed plans for a known fixed environment is relatively straightforward. However, in robotics, one of the challenges is to let the robot discover its environment, and to modify its actions when the environment changes unexpectedly due to errors or unplanned events. Some early landmark studies in this area were carried out using a vehicle named *Shakey*, which, starting in 1966, was developed by Charlie Rosen’s group at the Stanford Research Institute (now called SRI). *Shakey* had a TV camera, a trian-

gulating range finder, bump sensors, and was connected to DEC PDP-10 and PDP-15 computers via radio and video links.

Shakey was the first mobile robot to reason about its actions. It used programs that gave it the ability for independent perception, world modeling, and action generation. Low-level action routines took care of simple moving, turning, and route planning. Intermediate-level actions combined the low-level ones in ways that accomplished more complex tasks. The highest level programs could make and execute plans to achieve high-level goals supplied by a user.

Vision is very useful for navigation, locating objects, and determining their relative positions and orientation. However, it is usually not sufficient for assembling parts or working with robots where there are environmental constraining forces. This led to the need to measure the forces and torques generated by the environment, on a robot, and to use these measurements to control the robot's actions. For many years, force-controlled manipulation became one of the main topics of study at [SAIL](#), and several other labs around the world. The use of force control in industrial practice has always lagged the research developments in this area. This seems to be due to the fact that, while a high level of force control is very useful for general manipulation issues, specific problems in very restricted industrial environments can often be handled with limited, or no, force control.

In the 1970s, specialized areas of study such as walking machines, hands, automated vehicles, sensor integration, and design for hostile environments began to develop rapidly. Today there are a large number of different specialties studied under the heading of robotics. Some of these specialties are classical engineering subject areas within which results have been developed that have been particularized to the types of machines called robots. Examples here are kinematics, dynamics, controls, machine design, topology, and trajectory planning. Each of these subjects has a long history predating the study of robotics; yet each has been an area of in-depth robotics research in order to develop its special character in regard to robotic-type systems and applications. In doing this specialized development, researchers have enriched the classical subjects by increasing both their content and scope.

At the same time that the theory was being developed, there was a parallel, although somewhat separate, growth of industrial robotics. Strong commercial development occurred in Japan and Europe, and there was also continued growth in the USA. Industrial associa-

tions were formed (the Japan Robot Association was formed in March 1971, and the Robotic Industries Association (RIA) was founded in 1974 in the USA) and trade shows, together with application-oriented technical sessions, were introduced and held on a regular basis. The most important were the International Symposium on Industrial Robots, the Conference on Industrial Robot Technology (now called the International Conference on Industrial Robot Technology), and the RIA annual trade show, which is now called the International Robots and Vision Show and Conference.

The first regular series of conferences emphasizing research, rather than the industrial, aspects of robotics, was inaugurated in 1973. It was sponsored jointly by the International Center for Mechanical Sciences (CISM), based in Udine, Italy, and the International Federation for the Theory of Mechanisms and Machines (IFToMM). (Although IFToMM is still used, its meaning has been changed to the International Federation for the Promotion of Mechanism and Machine Science.) It was named the Symposium on Theory and Practice of Robots and Manipulators (RoManSy). Its trademark was an emphasis on the mechanical sciences and the active participation of researchers from Eastern and Western Europe as well as North America and Japan. It is still held biannually. On a personal note, it is at RoManSy where I first met each of the editors of this Handbook: Dr. Khatib in 1978 and Dr. Siciliano in 1984. They were both students: Bruno Siciliano had been working on his PhD for about one year, and Oussama Khatib had just completed his PhD research. In both cases, it was love at first sight!

RoManSy was quickly joined by a host of other new conferences and workshops; today there are a large number of research oriented robotics meetings that take place through the year in many countries. Currently, the largest conference is the International Conference on Robotics and Automation (ICRA), which regularly draws well over 1000 participants.

In the beginning of the 1980s, the first real textbook on robotic manipulation in the USA was written by Richard "Lou" Paul (Richard P. Paul, *Robot Manipulators: Mathematics, Programming, and Control*, The MIT Press, Cambridge, MA, 1981). It used the idea of taking classical subjects in mechanics and applying them to robotics. In addition there were several topics developed directly from his thesis research at [SAIL](#). (In the book, many examples are based on Scheinman's Stanford Arm.) Paul's book was a landmark event in the USA; it created a pattern for several influential future textbooks and also encouraged the creation of

specialized robotics courses at a host of colleges and universities.

At about this same time, new journals were created to deal primarily with research papers in the areas related to robotics. The *International Journal of Robotics Research* was founded in the spring of 1982, and three years later the *IEEE Journal of Robotics and Automation* (now the *IEEE Transactions on Robotics*) was founded.

As microprocessors became ubiquitous, the question of what is or is not a robot came more into play. This issue has, in my mind, never been successfully resolved. I do not think a definition will ever be universally agreed upon. There are of course the science fiction creatures-from-outer-space varieties, and the robots of the theater, literature, and the movies. There are examples of imaginary robot-like beings that predate the industrial revolution, but how about more down-to-Earth robots? In my view the definition is essentially a moving target that changes its character with technological progress. For example, when it was first developed, a ship's gyro auto-compass was considered a robot. Today, it is not generally included when we list the robots in our world. It has been demoted and is now considered an automatic control device.

For many, the idea of a robot includes the concept of multifunctionality, meaning the device is designed and built with the ability to be easily adapted or reprogrammed to do different tasks. In theory this idea is valid, but in practice it turns out that most robotic devices are multifunctional in only a very limited arena. In industry it was quickly discovered that a specialized machine, in general, performs much better than a general purpose machine. Furthermore, when the volume of production is high enough, a specialized machine can cost less to manufacture than a generalized one. So, specialized robots were developed for painting, riveting, quasiplanar parts assembly, press loading, circuit board stuffing, etc. In some cases robots are used in such specialized ways that it becomes difficult to draw the line between a so-called robot and an adjustable piece of "fixed" automation. Much of this practical unfolding is contrary to the dream of the pioneers in robotics, who had hoped for the development of general purpose machines that would do "everything", and hence sell in great enough volume to be relatively inexpensive.

My view is that the notion of a robot has to do with which activities are, at a given time, associated with people and which are associated with machines. If a machine suddenly becomes able to do what we normally associate with people, the machine can be upgraded in classification and classified as a robot. After a while,

people get used to the activity being done by machines, and the devices get downgraded from "robot" to "machine". Machines that do not have fixed bases, and those that have arm- or leg-like appendages have the advantage of being more likely called robots, but it is hard to think of a consistent set of criteria that fits all the current naming conventions.

In actuality any machines, including familiar household appliances, which have microprocessors directing their actions can be considered as robots. In addition to vacuum cleaners, there are washing machines, refrigerators, and dishwashers that could be easily marketed as robotic devices. There are of course a wide range of possibilities, including those machines that have sensory environmental feedback and decision-making capabilities. In actual practice, in devices considered to be robotic, the amount of sensory and decision making capability may vary from a great deal to none.

In recent decades the study of robotics has expanded from a discipline centered on the study of mechatronic devices to a much broader interdisciplinary subject. An example of this is the area called human-centered robotics. Here one deals with the interactions between humans and intelligent machines. This is a growing area where the study of the interactions between robots and humans has enlisted expertise from outside the classical robotics domain. Concepts such as emotions in both robots and people are being studied, and older areas such as human physiology and biology are being incorporated into the mainstream of robotics research. These activities enrich the field of robotics, as they introduce new engineering and science dimensions into the research discourse.

Originally, the nascent robotics community was focused on getting things to work. Many early devices were remarkable in that they worked at all, and little notice was taken of their limited performance. Today, we have sophisticated, reliable devices as part of the modern array of robotic systems. This progress is the result of the work of thousands of people throughout the world. A lot of this work took place in universities, government research laboratories, and companies. It is a tribute to the worldwide engineering and scientific community that it has been able to create the vast amount of information that is contained in the 64 chapters of this Handbook. Clearly these results did not arise by any central planning or by an overall orderly scheme. So the editors of this handbook were faced with the difficult task of organizing the material into a logical and coherent whole.

The editors have accomplished this by organizing the contributions into a three-layer structure. The first layer deals with the *foundations* of the subject. This layer consists of a single part of nine chapters in which the authors lay out the root subjects: kinematics, dynamics, control, mechanisms, architecture, programming, reasoning, and sensing. These are the basic technological building blocks for robotics study and development.

The second layer has four parts. The first of these deals with *robot structures*; these are the arms, legs, hands, and other parts that most robots are made up of. At first blush, the hardware of legs, arms, and hands may look quite different from each other, yet they share a common set of attributes that allows them to all be treated with the same, or closely related, aspects of the fundamentals described in the first layer.

The second part of this layer deals with *sensing and perception*, which are basic abilities any truly autonomous robotic system must have. As was pointed out earlier, in practice, many so-called robotic devices have little of these abilities, but clearly the more advanced robots cannot exist without them, and the trend is very much toward incorporating such capabilities into robotic devices. The third part of this layer treats the subject areas associated with the technology of *manipulation and the interfacing of devices*. The fourth part of this layer is made up of eight chapters that treat *mobile robots and various forms of distributed robotics*.

The third layer consists of two separate parts (a total of 22 chapters) that deal with advanced applications at the forefront of today's research and development. There are two parts to this layer; one deals with *field and service robots*, and the other deals with *human-centered and lifelike robots*. To the uninitiated observer, these chapters are what advanced robotics is all about. However, it is important to realize that many of these extraordinary accomplishments would probably not exist without the previous developments introduced in the first two layers of this Handbook.

It is this intimate connection between theory and practice that has nurtured the growth of robotics and become a hallmark of modern robotics. These two complementary aspects have been a source of great personal satisfaction to those of us who have had the opportunity to both research and develop robotic devices. The contents of this Handbook admirably reflect this complementary aspect of the subject, and present a very useful bringing together of the vast accomplishments which have taken place in the last 50 years. Certainly, the contents of this Handbook will serve as a valuable tool and guide to those who will produce the even more capable and diverse next generations of robotic devices. The editors and authors have my congratulations and admiration.

Stanford, August 2007

Bernard Roth

Foreword

Georges Giralt
Emeritus Research Director
LAAS-CNRS Toulouse

To open this Handbook and unfold the richness of its 64 chapters, we here attempt a brief personal overview to sketch the evolution of robotics in its many aspects, concepts, trends, and central issues.

The modern story of Robotics began about half a century ago with developments in two different directions.

First, let us acknowledge the domain of mechanical arms, ranging from teleoperated tasks on radiation-contaminated products to industrial arms, with the landmark

machine UNIMATE – standing for uni(versal)mate. The industrial development of products, mostly around the six-degree-of-freedom serial links paradigm and active research and development, associating mechanical engineering to the control specialism, was the main driving force here. Of particular note nowadays is the successfully pursued effort to design novel application-optimized structures, using powerful sophisticated mathematical tools. In a similar way, an important issue concerns the design and the actual building of arms and hands in the context of human-friendly robots for tomorrow's cognitive robot.

Second, and less well recognized, we should acknowledge the stream of work concerned with themes in artificial intelligence. A landmark project in this area was the mobile robot *Shakey* developed at Stanford International. This work, which aimed to bring together computer science, artificial intelligence, and applied mathematics to develop intelligent machines, remained a secondary area for quite some time. During the 1980s, building strength from many study cases encompassing a spectacular spectrum ranging from rovers for extreme environments (planet exploration, Antarctica, etc.), to service robots (hospitals, museum guides, etc.), a broad research domain arose in which machines could claim the status of intelligent robots.

Hence robotics researches could bring together these two different branches, with intelligent robots categorized in a solely computational way as bounded

rationality machines, expanding on the 1980s third-generation robot definition:

"(robot) . . . operating in the three-dimensional world as a machine endowed with the capacity to interpret and to reason about a task and about its execution, by intelligently relating perception to action."

The field of autonomous robots, a widely recognized test-bed, has recently benefited from salient contributions in robot planning using the results of algorithmic geometry as well as of a stochastic framework approach applied both to environmental modeling and robot localization problems (**SLAM**, simultaneous localization and modeling), and further from the development of decisional procedures via Bayesian estimation and decision approaches.

For the last decade of the millennium, robotics largely dealt with the intelligent robot paradigm, blending together robots and machine-intelligence generic research within themes covering advanced sensing and perception, task reasoning and planning, operational and decisional autonomy, functional integration architectures, intelligent human-machine interfaces, safety, and dependability.

The second branch, for years referred to as non-manufacturing robotics, concerns a wide spectrum of research-driven real-world cases pertaining to field, service, assistive, and, later, personal robotics. Here, machine intelligence is, in its various themes, the central research direction, enabling the robot to act:

1. as a human surrogate, in particular for intervention tasks in remote and/or hostile environments
2. in close interaction with humans and operating in human environments in all applications encompassed by human-friendly robotics, also referred to as human-centered robotics
3. in tight synergy with the user, expanding from mechanical exoskeleton assistance, surgery, health care, and rehabilitation into human augmentation.

Consequently, at the turn of the millennium, robotics appears as a broad spectrum of research themes both supporting market products for well-engineered industrial workplaces, and a large number of domain-oriented application cases operating in hazardous and/or

harsh environments (underwater robotics, rough-terrain rovers, health/rehabilitation care robotics, etc.) where robots exhibit meaningful levels of shared autonomy.

The evolution levels for robotics stress the role of theoretical aspects, moving from application domains to the technical and scientific area. The organization of this Handbook illustrates very well these different levels. Furthermore, it rightly considers, besides a body of software systems, front-line matters on physical appearance and novel appendages, including legs, arms, and hands design in the context of human-friendly robots for tomorrow's cognitive robot.

Forefront robotics in the first decade of the current millennium is making outstanding progress, compounding the strength of two general directions:

- short/mid-term application-oriented study cases
- mid/long-term generic situated research

For completeness, we should mention the large number of peripheral, robotics-inspired subjects, quite often concerning entertainment, advertising, and sophisticated toys.

The salient field of human-friendly robotics encompasses several front-line application domains where the robots operate in a human environment and in close interaction with humans (entertainment and education, public-oriented services, assistive and personal robots, etc.), which introduces the critical issue of human–robot interaction.

Right at the core of the field, emerges the forefront topic of personal robots for which three general characteristics should be emphasized:

1. They may be operated by a nonprofessional user;
2. They may be designed to share high-level decision making with the human user;
3. They may include a link to environment devices and machine appendages, remote systems, and operators; the shared decisional autonomy concept (co-autonomy) implied here unfolds into a large set of cutting-edge research issues and ethical problems.

The concept of the personal robot, expanding to robot assistant and universal companion, is a truly great challenge for robotics as a scientific and technical field,

offering the mid/long-term perspective of achieving a paramount societal and economical impact. This introduces, and questions, front-line topics encompassing cognitive aspects: user-tunable human–machine intelligent interfaces, perception (scene analysis, category identification), open-ended learning (understanding the universe of action), skills acquisition, extensive robot-world data processing, decisional autonomy, and dependability (safety, reliability, communication, and operating robustness).

There is an obvious synergistic effort between the two aforementioned approaches, in spite of the necessary framework time differences. The scientific link not only brings together the problems and obtained results but also creates a synergistic exchange between the two sides and the benefits of technological progress.

Indeed, the corresponding research trends and application developments are supported by an explosive evolution of enabling technologies: computer processing power, telecommunications, networking, sensing devices, knowledge retrieval, new materials, micro- and nanotechnologies.

Today, looking to the mid- and long-term future, we are faced with very positive issues and perspectives but also having to respond to critical comments and looming dangers for machines that are in physical contact with the user and may also be capable of unwanted, unsafe behavior. Therefore, there is a clear need to include at the research level safety issues and the topic of multifaced dependability and the corresponding system constraints.

The *Handbook of Robotics* is an ambitious and timely endeavor. It summarizes a large number of problems, questions, and facets considered by 164 authors in 64 chapters. As such it not only provides an efficient display of basic topics and results obtained by researches around the world, but furthermore gives access to this variety of viewpoints and approaches to everyone. This is indeed an important tool for progress but, much more, is the central factor that will establish the two first decades of this millennium as the dawn of robotics, lifted to a scientific discipline at the core of machine intelligence.

Toulouse, December 2007

Georges Giralt

Foreword

Hirochika Inoue
Professor Emeritus
The University of Tokyo

The field of robotics was born in the middle of the last century when emerging computers were altering every field of science and engineering. Having gone through fast yet steady growth via a procession of stages from infancy, childhood, and adolescence to adulthood, robotics is now mature and is expected to enhance the quality of people's lives in society in the future.

In its infancy, the core of robotics consisted of pattern recognition, automatic control, and artificial intelligence. Taking on these

new challenge, scientists and engineers in these fields gathered to investigate novel robotic sensors and actuators, planning and programming algorithms, and architectures to connect these components intelligently. In so doing, they created artifacts that could interact with humans in the real world. An integration of these early robotics studies yielded *hand–eye systems*, the test-bed of artificial intelligence research.

The playground for childhood robotics was the factory floor. Industrial robots were invented and introduced into the factory for automating spraying, spot welding, grinding, materials handling, and parts assembly. Machines with sensors and memories made the factory floor smarter, and its operations more flexible, reliable, and precise. Such robotic automation freed humans from heavy and tedious labor. The automobile, electric appliance, and semiconductor industries rapidly retooled their manufacturing lines into robot-integrated systems. In the late 1970s, the word *mechatronics*, originally coined by the Japanese, defined a new concept of machinery, one in which electronics was fused with mechanical systems, making a wide range of industrial products simpler, more functional, programmable, and intelligent. Robotics and mechatronics exerted an evolutionary impact on the design and operation of manufacturing processes as well as on manufactured products.

As robotics entered its adolescence, researchers were ambitious to explore new horizons. Kinematics, dynamics, and control system theory were refined and applied to real complex robot mechanisms. To plan and carry

out real tasks, robots had to be made cognizant of their surroundings. Vision, the primary channel for external sensing, was exploited as the most general, effective, and efficient means for robots to understand their external situation. Advanced algorithms and powerful devices were developed to improve the speed and robustness of robot vision systems. Tactile and force sensing systems also needed to be developed for robots to manipulate objects. Studies on modeling, planning, knowledge, reasoning, and memorization expanded their intelligent properties. Robotics became defined as the study of intelligent connection of sensing to actuation. This definition covered all aspects of robotics: three scientific cores and one synthetic approach to integrate them. Indeed, system integration became a key aspect of robotic engineering as it allows the creation of lifelike machines. The fun of creating such robots attracted many students to the robotics field.

In advancing robotics further, scientific interest was directed at understanding humans. Comparative studies of humans and robots led to new approaches in scientific modeling of human functions. Cognitive robotics, lifelike behavior, biologically inspired robots, and a psychophysiological approach to robotic machines culminated in expanding the horizons of robotic potential. Generally speaking, an immature field is sparse in scientific understanding. Robotics in the 1980s and 1990s was in such a youthful stage, attracting a great many inquisitive researchers to this new frontier. Their continuous explorations into new realms form the rich scientific contents of this comprehensive volume.

Further challenges, along with expertise acquired on the cutting edge of robotics, opened the way to real-world applications for mature robotics. The early-stage playground gave way to a workshop for industrial robotics. Medical robotics, robot surgery, and *in vivo* imaging save patients from pain while providing doctors with powerful tools for conducting operations. New robots in such areas as rehabilitation, health care, and welfare are expected to improve quality of life in an aging society. It is the destiny of robots to go everywhere, in the air, under water, and into space. They are expected to work hand in hand with humans in such areas as agriculture, forestry, mining, construction, and hazardous environments and rescue operations, and to find

utility both in domestic work and in providing services in shops, stores, restaurants, and hospitals. In a myriad of ways, robotic devices are expected to support our daily lives. At this point, however, robot applications are largely limited to structured environments, where they are separated from humans for safety sake. In the next stage, their environment will be expanded to an unstructured world, one in which humans, as service takers, will always live and work beside robots. Improved sensing, more intelligence, enhanced safety, and better human understanding will be needed to prepare robots to function in such an environment. Not only technical but also social matters must be considered in finding solutions to issues impeding this progress.

Since my initial research to make a robot turn a crank, four decades have passed. I feel both lucky and happy to have witnessed the growth of robotics from its early beginnings. To give birth to robotics, fundamental technologies were imported from other disciplines. Neither textbooks nor handbooks were available. To reach the present stage, a great many scientists and engineers have challenged new frontiers; advancing robotics, they have enriched this body of knowledge from a variety of perspectives. The fruits of their endeavors are compiled in this *Handbook of Robotics*. More than 100 of

the world's leading experts have collaborated in producing this publication. Now, people who wish to commit themselves to robotics research can find a firm foundation to build upon. This Handbook is sure to be used to further advance robotics science, reinforce engineering education, and systematically compile knowledge that will innovate both society and industry.

The roles of humans and robots in an aging society pose an important issue for scientists and engineers to consider. Can robotics contribute to securing peace, prosperity, and a greater quality of life? This is still an open question. However, recent advances in personal robots, robotic home appliances, and humanoids suggest a paradigm shift from the industrial to the service sector. To realize this, robotics must be addressed from such viewpoints as the working infrastructure within society, psychophysiology, law, economy, insurance, ethics, art, design, drama, and sports science. Future robotics should be studied as a subject that envelops both humanity and technology. This Handbook offers a selected technical foundation upon which to advance such newly emerging fields of robotics. I look forward to continuing progress adding page after page of robot-based prosperity to future society.

of Technology

environments but faster and faster in what they did in their carefully engineered world. Then in the mid 1970s in France, Japan, and the USA we started to see robots rising again in a handful of research laboratories, and now we have arrived at a world-wide frenzy in research and the beginnings of large-scale deployment of intelligent robots throughout our world. This Handbook brings together the current state of robotics research in one place. It ranges from the mechanism of robots through sensing and perceptual processing, intelligence, action, and many application areas.

I have been more than fortunate to have lived with this revolution in robotics research over the last 30 years. As a teenager in Australia I built robots inspired by the tortoises of Walter described in the *Scientific American* in 1949 and 1950. When I arrived in Silicon Valley in 1977, just as the revolution in the personalization of computation was really coming into being, I instead turned to the much more obscure world of robots. In 1979 I was able to assist Hans Moravec at the Stanford Artificial Intelligence Lab ([SAIL](#)) as he coaxed his robot “The Cart” to navigate 20 m in 6 hours. Just 26 years later, in 2005, at the same laboratory, [SAIL](#), Sebastian Thrun and his team coaxed their robot to autonomously drive 200,000 m in 6 hours: four orders of magnitude improvement in a mere 26 years, which is slightly better than a doubling every 2 years. However, robots have not

Robots have fascinated people for thousands of years. Those automata that were built before the 20th century did not connect sensing to action but rather operated through human agency or as repetitive machines. However, by the 1920s electronics had gotten to the stage that the first true robots that sensed the world and acted in it appropriately could be built. By 1950 we started to see descriptions of real robots appearing in popular magazines. By the 1960s industrial robots came onto the scene. Commercial pressures made them less and less responsive to their environments but faster and faster in what they did in their carefully engineered world.

When I arrived at [SAIL](#) in 1977 we knew of three mobile robots operating in the world. Recently a company that I founded manufactured its 3,000,000th mobile robot, and the pace is increasing. Other aspects of robots have had similarly spectacular advances, although it is harder to provide such crisp numeric characterizations. In recent years we have gone from robots being too unaware of their surroundings that it was unsafe for people to share their workspace to robots that people can work with in close contact, and from robots that were totally unaware of people to robots that pick up on natural social cues from facial expressions to prosody in people’s voices. Recently robotics has crossed the divide between flesh and machines so that now we are seeing neuro-robotics ranging from prosthetic robotic extensions to rehabilitative robots for the disabled. And very recently robotics has become a respected contributor to research in cognitive science and neuroscience.

The research results chronicled in this volume give the key ideas that have enabled these spectacular advances. The editors, the part editors, and all the contributors have done a stellar job in bring this knowledge together in one place. Their efforts have produced a work that will provide a basis for much further research and development. Thank you, and congratulations to all who have labored on this pivotal book.

Some of the future robotics research will be incremental in nature, taking the state of the art and improving upon it. Other parts of future research will be more revolutionary, based on ideas that are antithetical to some of the ideas and current state of the art presented in this book.

As you study this volume and look for places to contribute to research through your own talents and hard work I want to alert you to capabilities or aspirations that I believe will make robots even more useful, more productive, and more accepted. I describe these capabilities in terms of the age at which a child has equivalent capabilities:

- the object-recognition capabilities of a 2-year-old child
- the language capabilities of a 4-year-old child

-
- the manual dexterity of a 6-year-old child
 - the social understanding of an 8-year-old child

Each of these is a very difficult goal. However even small amounts of progress towards any one of these goals

will have immediate applications to robots out in the world. Good reading and best wishes as you contribute further to robotkind.

Cambridge, October 2007

Rodney Brooks

Preface

Reaching for the human frontier, robotics is vigorously engaged in the growing challenges of new emerging domains. Interacting, exploring, and working with humans, the new generation of robots will increasingly touch people and their lives. The credible prospect of practical robots among humans is the result of the scientific endeavor of a half a century of robotic developments that established robotics as a modern scientific discipline.

The undertaking of the *Springer Handbook of Robotics* was motivated by the rapid growth of the field. With the ever increasing amount of publications in journals, conference proceedings and monographs, it is difficult for those involved in robotics, particularly those who are just entering the field, to stay abreast of its wide range of developments. This task is made even more arduous by the very multidisciplinary nature of robotics.

The handbook follows preceding efforts in the 1980s and 1990s, which have brought valuable references to the robotics community: Robot Motion: Planning and Control (Brady, Hollerbach, Johnson, Lozano-Pérez, and Mason, MIT Press 1982), Robotics Science (Brady, MIT Press 1989), The Robotics Review 1 and 2 (Khatib, Craig, and Lozano-Pérez, MIT Press 1989 and 1992). With the greater expansion of the robotics field and its increased outreach towards other scientific disciplines, the need for a comprehensive reference source combining basic and advanced developments has naturally become yet more urgent.

The volume is the result of the effort by a number of contributors who themselves are actively involved in robotics research in countries around the world. It has been a gigantic task to insightfully provide coverage of all the areas of robotics by such a motivated and versatile group of individuals committed to this endeavour.

The project started in May 2002 during a meeting the two of us had with Springer Director Engineering Europe Dieter Merkle and STAR Senior Editor Thomas Ditzinger. A year earlier, together with Frans Groen, we had launched the Springer Tracts in Advanced Robotics (STAR) series, which was rapidly establishing itself as an important medium for the timely dissemination of robotics research.

It was in this context that we took on this challenging task and enthusiastically began the planning to develop the technical structure and build the group of contributors. To capture the multiple dimensions of the field in its well-established academic core, ongoing research developments, and emerging applications, we conceived the handbook in a three-layer structure for a total of seven parts.

The first layer and part is devoted to the robotics foundations. The consolidated methodologies and technologies are grouped in the four parts of the second layer, covering robot structures, sensing and perception, manipulation and interfaces, mobile and distributed robotics. The third layer includes the advanced applications in the two parts on field and service robotics, and human-centered and life-like robotics, respectively.

To develop each of these parts, we envisioned the establishment of an editorial team which could coordinate the authors' contributions to the various chapters. A year later our seven-member editorial team was formed: David Orin, Frank Park, Henrik Christensen, Makoto Kaneko, Raja Chatila, Alex Zelinsky and Daniela Rus. With the commitment of such a group of distinguished scholars, the handbook was granted quality, span, and balance in the scientific areas.

By early 2005, we assembled an authorship of more than one-hundred-and-fifty contributors. An internal web site was created to facilitate inter-part and chapter cross-references, and to pace the schedule for the development of the project. The contents were carefully tuned over the following year, and especially during the two full-day workshops held in the spring of 2005 and 2006, well attended by most of the authors.

Each chapter was peer reviewed by at least three independent reviewers, typically involving the part editor, and two authors of related chapters; and in some cases, included external experts in the field. Two review cycles were necessary, and even three in some cases. During the process, a few more authors were recruited whenever it was deemed necessary. Most chapters were finalized by the end of the summer of 2007, and the project was completed by the early spring of 2008 – generating, by that time, a record of over 10 000 emails in our folders. The result is an impressive collection of 64 chapters

over the 7 parts, contributed by 165 authors, with more than 1650 pages, 950 illustrations and 5500 references.

We are deeply thankful to the authors for their intellectual contributions, as well as to the reviewers and part editors for their conscientious work. We are indebted to Werner Skolaut, the Senior Manager of Springer Handbooks in Science and Engineering, who soon became a devoted member of our team with his painstaking support to technically editing the authors' typescripts and linking the editors' work with the copy editing and production of the handbook. We also wish to acknowledge the highly professional work by the Le-Tex staff, which re-typeset all the text, redrew and improved the many

illustrations, while timely interacting with the authors during the proof-reading of the material.

Six years after its conception the handbook comes to light. Beyond its tutorial value for our community, it is our hope that it will serve as a useful source to attract new researchers to robotics and inspire decades of vibrant progress in this fascinating field. The completion of every endeavor also brings new exciting challenges; at such times, our fellows are always reminded to ... keep the gradient ;-)

Napoli and Stanford
April 2008

Bruno Siciliano
Oussama Khatib

About the Editors

Bruno Siciliano received his Doctorate degree in Electronic Engineering from the University of Naples in 1987. He is Professor of Control and Robotics, and Director of the PRISMA Lab in the Department of Computer and Systems Engineering at University of Naples. His current research is in force control, visual servoing, dual-arm/hand manipulation, lightweight flexible arms, human-robot interaction and service robotics. Professor Siciliano has co-authored 6 books and 5 edited volumes, 65 journal papers, 165 conference papers and book chapters, and has delivered 85 invited lectures and seminars at institutions around the world. He is Co-Editor of the Springer Tracts in Advanced Robotics (STAR) series, the Springer Handbook of Robotics, and has served on the Editorial Boards of prestigious journals, as well as Chair or Co-Chair for numerous international conferences. He is a Fellow of both IEEE and ASME. Professor Siciliano is the President of the IEEE Robotics and Automation Society (RAS), after serving as Vice President for Technical Activities and Vice President for Publications, as a Distinguished Lecturer, as a member of the Administrative Committee and of several other society committees.

Oussama Khatib received his Doctorate degree in Electrical Engineering from Sup'Aero, Toulouse, France, in 1980. He is Professor of Computer Science at Stanford University. His current research, which focuses on human-centered robotics, is concerned with human motion synthesis, humanoid robotics, haptic teleoperation, medical robotics, and human-friendly robot design. His research in these areas builds on a large body of studies he pursued over the past 25 years and published in over 200 contributions. Professor Khatib has delivered over 50 keynote presentations and several hundreds of colloquia and seminars at institutions around the world. He is Co-Editor of the STAR series, the Springer Handbook of Robotics, and has served on the Advisory and Editorial Boards of prestigious institutions and journals, as well as Chair or Co-Chair for numerous international conferences. He is a Fellow of IEEE and has served RAS as a Distinguished Lecturer and as a member of the Administrative Committee. Professor Khatib is the President of the International Foundation of Robotics Research (IFRR) and a recipient of the Japan Robot Association (JARA) Award in Research and Development.

About the Part Editors

David E. Orin

The Ohio State University
Department of Electrical Engineering
Columbus, OH, USA
orin.1@osu.edu

Part A

David E. Orin received his PhD degree in Electrical Engineering from The Ohio State University in 1976. From 1976 to 1980 he taught at Case Western Reserve University. Since 1981, he has been at The Ohio State University, where he is currently a Professor of Electrical and Computer Engineering. His current work focuses on dynamic movement in biped locomotion. He has made many contributions to robot dynamics and legged locomotion, and he has over 125 publications. He has received a number of educational awards from his institution. He is an IEEE Fellow and has served on the program committee for several international conferences. He has received the Distinguished Service Award in recognition of his service for the IEEE Robotics and Automation Society, such as Vice President for Finance, Secretary, member of the Administrative Committee, and co-chair of the Fellow Evaluation Committee.

Frank C. Park

Seoul National University
Mechanical and Aerospace Engineering
Seoul, Korea
fcp@snu.ac.kr

Part B

Frank C. Park received the PhD degree in Applied Mathematics from Harvard University in 1991. From 1991 to 1995 he was an Assistant Professor of Mechanical and Aerospace Engineering at the University of California, Irvine. Since 1995 he has been at the School of Mechanical and Aerospace Engineering at Seoul National University, where he is currently full professor. His primary research interests in robotics include robot mechanics, planning, and control, robot design and structures, and industrial robotics. His other research interests include nonlinear systems theory, differential geometry and its applications, and related areas of applied mathematics. He has served the IEEE Robotics and Automation Society as a Secretary and as a Senior Editor of the IEEE Transactions on Robotics.

Henrik I. Christensen

Georgia Institute of Technology
Robotics and Intelligent Machines @ GT
Atlanta, GA, USA
hic@cc.gatech.edu

Part C

Henrik I. Christensen is the KUKA Chair of Robotics and Director of Robotics at Georgia Institute of Technology, Atlanta, GA. He received the MS and PhD degrees from Aalborg University in 1987 and 1990, respectively. He has held positions in Denmark, Sweden, and USA. He has published more than 250 contributions across vision, robotics, and AI. Results from his research have been commercialized through a number of major companies and 4 spin-offs. He served as the founding coordinator of the European Robotics Research Network (EURON). He has participated as a senior organizer in more than 50 different conferences and workshops. He is a Fellow of the International Foundation of Robotics Research, an Editorial Board member of the STAR series, and has served on the editorial board of several leading journals in the field. He has been a Distinguished Lecturer of the IEEE Robotics and Automation Society.

Makoto Kaneko

Osaka University
Department of Mechanical Engineering
Graduate School of Engineering
Suita, Japan
mk@mech.eng.osaka-u.ac.jp

Part D

Makoto Kaneko received the MS and PhD degrees in Mechanical Engineering from Tokyo University in 1978 and 1981, respectively. From 1981 to 1990 he was Researcher at the Mechanical Engineering Laboratory, from 1990 to 1993 an Associate Professor at Kyushu Institute of Technology, from 1993 to 2006 Professor at Hiroshima University, and in 2006 became a Professor at Osaka University. His research interests include tactile-based active sensing, grasping strategy, hyper human technology and its application to medical diagnosis, and his work has received 17 awards. He is an Editorial Board member of the STAR series and has served as chair or co-chair for several international conferences. He is an IEEE Fellow. He has served the IEEE Robotics and Automation Society as a Vice-President for Member Activities and as a Technical Editor of the IEEE Transactions on Robotics and Automation.

Raja Chatila

LAAS-CNRS
Toulouse, France
raja.chatila@laas.fr

Part E

Raja Chatila received his PhD degree from the University of Toulouse in 1981. He is currently Director of LAAS-CNRS (Laboratory of Systems Analysis and Architecture), Toulouse, France where he is since 1983. He was an invited professor at Tsukuba University in 1997. His research work encompasses several aspects in field, planetary, aerial and service robotics, cognitive robotics, learning, human-robot interaction, and networked robotics. He is author of over 150 international publications on these topics. He is a Fellow of the International Foundation of Robotics Research. He has served on the editorial boards of several leading publications, including the STAR series, and as chair or co-chair for several international conferences. He has served the IEEE Robotics and Automation Society as a member of the Administrative Committee, as an Associate Editor of the IEEE Transactions on Robotics and Automation and as a Distinguished Lecturer. He is a member of IEEE, ACM and AAAI, and a member of various national and international boards and evaluation committees.

Alexander Zelinsky

Commonwealth Scientific and Industrial Research Organisation (CSIRO)
ICT Centre
Epping, NSW, Australia
alex.zelinsky@csiro.au

Part F

Alexander Zelinsky is the Director of the Information and Communication Technologies Centre at the CSIRO. Before joining CSIRO, he was CEO and Founder of Seeing Machines Pty Limited and a Professor at the Australian National University, in the Research School of Information Sciences and Engineering. He is a well-known scientist specializing in robotics and computer vision, he is widely recognized as an innovator in human-machine interaction, and he has over 100 publications in the field. His work has received both national and international awards. He has served on the editorial boards of two leading publications, and on the program committees of several international conferences. He is an IEEE Fellow and has served the IEEE Robotics and Automation Society as a member of the Administrative Committee and as Vice-President for Industrial Activities.

Daniela Rus

Massachusetts Institute of Technology
CSAIL Center for Robotics
Cambridge, MA, USA
rus@csail.mit.edu

Part G

Daniela Rus received her PhD degree in Computer Science from Cornell University in 1992. From 1994 to 2003 she taught at Dartmouth, Hanover. Since 2004 she has been at MIT, where she is currently a Professor of Electrical Engineering and Computer Science. She co-directs the CSAIL Center for robotics and is an Associate Director of CSAIL. Her research interests center on distributed robotics and mobile computing, and she has published extensively in the field. Her work in robotics aims to develop self-organizing systems and spans the spectrum from novel mechanical design and experimental platforms to developing and analyzing algorithms for locomotion, manipulation, and group control. She has received a number of awards, including the MacArthur Fellow. She has been on the program committees of several international conferences, and has served the IEEE Robotics and Automation Society as Education Co-Chair.

Contents

| | |
|------------------------------------|------|
| List of Abbreviations | LIII |
|------------------------------------|------|

Introduction

| | |
|---------------------------------------------|---|
| <i>Bruno Siciliano, Oussama Khatib.....</i> | 1 |
|---------------------------------------------|---|

Part A Robotics Foundations

1 Kinematics

| | |
|---------------------------------------------------|----|
| <i>Kenneth Waldron, James Schmiedeler.....</i> | 9 |
| 1.1 Overview..... | 9 |
| 1.2 Position and Orientation Representation | 10 |
| 1.3 Joint Kinematics..... | 18 |
| 1.4 Geometric Representation | 23 |
| 1.5 Workspace | 25 |
| 1.6 Forward Kinematics..... | 26 |
| 1.7 Inverse Kinematics | 27 |
| 1.8 Forward Instantaneous Kinematics | 29 |
| 1.9 Inverse Instantaneous Kinematics | 30 |
| 1.10 Static Wrench Transmission..... | 30 |
| 1.11 Conclusions and Further Reading | 31 |
| References | 31 |

2 Dynamics

| | |
|-----------------------------------------------|----|
| <i>Roy Featherstone, David E. Orin.....</i> | 35 |
| 2.1 Overview..... | 36 |
| 2.2 Spatial Vector Notation | 37 |
| 2.3 Canonical Equations | 43 |
| 2.4 Dynamic Models of Rigid-Body Systems..... | 45 |
| 2.5 Kinematic Trees..... | 50 |
| 2.6 Kinematic Loops..... | 57 |
| 2.7 Conclusions and Further Reading | 60 |
| References | 62 |

3 Mechanisms and Actuation

| | |
|---------------------------------------------------|----|
| <i>Victor Scheinman, J. Michael McCarthy.....</i> | 67 |
| 3.1 Overview..... | 67 |
| 3.2 System Features | 68 |
| 3.3 Kinematics and Kinetics..... | 69 |
| 3.4 Serial Robots | 72 |
| 3.5 Parallel Robots | 73 |
| 3.6 Mechanical Structure | 75 |

| | | |
|----------|----------------------------------------------------------------|------------|
| 3.7 | Joint Mechanisms..... | 76 |
| 3.8 | Robot Performance..... | 82 |
| 3.9 | Conclusions and Further Reading | 84 |
| | References | 84 |
| 4 | Sensing and Estimation | |
| | <i>Henrik I. Christensen, Gregory D. Hager</i> | <i>87</i> |
| 4.1 | The Perception Process | 88 |
| 4.2 | Sensors | 90 |
| 4.3 | Estimation Processes | 93 |
| 4.4 | Representations | 104 |
| 4.5 | Conclusions and Further Readings..... | 106 |
| | References | 106 |
| 5 | Motion Planning | |
| | <i>Lydia E. Kavraki, Steven M. LaValle</i> | <i>109</i> |
| 5.1 | Motion Planning Concepts | 110 |
| 5.2 | Sampling-Based Planning | 111 |
| 5.3 | Alternative Approaches..... | 115 |
| 5.4 | Differential Constraints | 118 |
| 5.5 | Extensions and Variations..... | 121 |
| 5.6 | Advanced Issues..... | 124 |
| 5.7 | Conclusions and Further Reading | 127 |
| | References | 128 |
| 6 | Motion Control | |
| | <i>Wankyun Chung, Li-Chen Fu, Su-Hau Hsu[†]</i> | <i>133</i> |
| 6.1 | Introduction to Motion Control..... | 134 |
| 6.2 | Joint Space Versus Operational Space Control | 135 |
| 6.3 | Independent-Joint Control | 137 |
| 6.4 | PID Control | 139 |
| 6.5 | Tracking Control | 141 |
| 6.6 | Computed-Torque Control..... | 143 |
| 6.7 | Adaptive Control | 147 |
| 6.8 | Optimal and Robust Control | 150 |
| 6.9 | Digital Implementation | 153 |
| 6.10 | Learning Control..... | 155 |
| | References | 157 |
| 7 | Force Control | |
| | <i>Luigi Villani, Joris De Schutter.....</i> | <i>161</i> |
| 7.1 | Background | 161 |
| 7.2 | Indirect Force Control | 164 |
| 7.3 | Interaction Tasks | 171 |
| 7.4 | Hybrid Force/Motion Control..... | 177 |

| | | |
|-------------------------|------------------------------------------------------|-----|
| 7.5 | Conclusions and Further Reading | 181 |
| References | 183 | |
| 8 | Robotic Systems Architectures and Programming | |
| | <i>David Kortenkamp, Reid Simmons</i> | 187 |
| 8.1 | Overview..... | 187 |
| 8.2 | History..... | 189 |
| 8.3 | Architectural Components..... | 193 |
| 8.4 | Case Study – GRACE | 200 |
| 8.5 | The Art of Robot Architectures | 202 |
| 8.6 | Conclusions and Further Reading | 203 |
| References | 204 | |

|---------------------------------------------------------------------|-------------|
| <i>Erwin Prassler, Kazuhiro Kosuge</i> | 1253 |
| 54.1 Cleaning Robots | 1254 |
| 54.2 Lawn-Mowing Robots | 1271 |
| 54.3 Smart Appliances | 1273 |
| 54.4 Smart Homes | 1275 |
| 54.5 Domestic Robotics: It Is the Business Case Which Matters | 1279 |
| 54.6 Conclusions and Further Reading | 1280 |
| References | 1280 |

55 Robots for Education

| | |
|--------------------------------------------------------------------|------|
| <i>David P. Miller, Illah R. Nourbakhsh, Roland Siegwart</i> | 1283 |
| 55.1 The Role of Robots in Education | 1284 |
| 55.2 Educational Robot Tournaments..... | 1285 |
| 55.3 Education Robot Platforms..... | 1287 |
| 55.4 Education Robot Controllers and Programming Environments..... | 1290 |
| 55.5 Robots and Informal Learning Venues (Museums) | 1292 |
| 55.6 Educational Evaluation of Robot Programs | 1296 |
| 55.7 Conclusions and Further Reading | 1298 |
| References | 1298 |

Part G Human-Centered and Life-Like Robotics**56 Humanoids**

| | |
|---------------------------------------------------------------------------------------------------------------------|------|
| <i>Charles C. Kemp, Paul Fitzpatrick, Hirohisa Hirukawa, Kazuhito Yokoi, Kensuke Harada, Yoshio Matsumoto</i> | 1307 |
| 56.1 Why Humanoids? | 1307 |
| 56.2 History and Overview..... | 1310 |
| 56.3 Locomotion | 1312 |
| 56.4 Manipulation | 1315 |
| 56.5 Whole-Body Activities | 1318 |
| 56.6 Communication..... | 1325 |
| 56.7 Conclusions and Further Reading | 1329 |
| References | 1329 |

57 Safety for Physical Human–Robot Interaction

| | |
|--------------------------------------------------------------------|------|
| <i>Antonio Bicchi, Michael A. Peshkin, J. Edward Colgate</i> | 1335 |
| 57.1 Motivations for Safe pHRI..... | 1336 |
| 57.2 Safety for Hands-Off pHRI | 1337 |
| 57.3 Design of Intrinsically Safe Robots | 1338 |
| 57.4 Safety for Hands-On pHRI | 1341 |
| 57.5 Safety Standards for pHRI | 1345 |
| 57.6 Conclusions | 1346 |
| References | 1346 |

58 Social Robots that Interact with People

| | |
|---------------------------------------------------------------------|------|
| <i>Cynthia Breazeal, Atsuo Takanishi, Tetsunori Kobayashi</i> | 1349 |
| 58.1 Social Robot Embodiment | 1350 |
| 58.2 Multimodal Communication | 1352 |
| 58.3 Expressive Emotion-Based Interaction | 1356 |
| 58.4 Socio-cognitive Skills..... | 1360 |
| 58.5 Conclusion and Further Reading | 1365 |
| References | 1366 |

59 Robot Programming by Demonstration

| | |
|-----------------------------------------------------------------------------|------|
| <i>Aude Billard, Sylvain Calinon, Rüdiger Dillmann, Stefan Schaal</i> | 1371 |
| 59.1 History | 1372 |

| | | |
|------|-------------------------------------------------|-------------|
| 59.2 | Engineering-Oriented Approaches..... | 1374 |
| 59.3 | Biologically-Oriented Learning Approaches | 1386 |
| 59.4 | Conclusions and Open Issues in Robot PbD | 1389 |
| | References | 1389 |

60 Biologically Inspired Robots

| | | |
|----------------------------------------------|------------------------------------------|-------------|
| <i>Jean-Arcady Meyer, Agnès Guillot.....</i> | 1395 | |
| 60.1 | General Background | 1395 |
| 60.2 | Bio-inspired Morphologies | 1396 |
| 60.3 | Bio-inspired Sensors | 1398 |
| 60.4 | Bio-inspired Actuators | 1402 |
| 60.5 | Bio-inspired Control Architectures | 1408 |
| 60.6 | Energetic Autonomy | 1412 |
| 60.7 | Collective Robotics..... | 1413 |
| 60.8 | Biohybrid Robots..... | 1415 |
| 60.9 | Discussion | 1417 |
| 60.10 | Conclusion | 1418 |
| | References | 1418 |

61 Evolutionary Robotics

| | | |
|----------------------------------------------------------|---------------------------------------------|-------------|
| <i>Dario Floreano, Phil Husbands, Stefano Nolfi.....</i> | 1423 | |
| 61.1 | Method..... | 1423 |
| 61.2 | First Steps | 1424 |
| 61.3 | Simulation and Reality | 1428 |
| 61.4 | Simple Controllers, Complex Behaviors | 1429 |
| 61.5 | Seeing the Light | 1431 |
| 61.6 | Computational Neuroethology | 1434 |
| 61.7 | Evolution and Learning | 1439 |
| 61.8 | Competition and Cooperation | 1442 |
| 61.9 | Evolutionary Hardware | 1444 |
| 61.10 | Closing Remarks | 1447 |
| | References | 1447 |

62 Neurorobotics: From Vision to Action

| | | |
|--------------------------------------------------------------------|------------------------------------|-------------|
| <i>Michael A. Arbib, Giorgio Metta, Patrick van der Smagt.....</i> | 1453 | |
| 62.1 | Definitions | 1453 |
| 62.2 | Neuroethological Inspiration | 1454 |
| 62.3 | The Role of the Cerebellum | 1462 |
| 62.4 | The Role of Mirror Systems | 1467 |
| 62.5 | Extroduction | 1474 |
| 62.6 | Further Reading | 1475 |
| | References | 1475 |

63 Perceptual Robotics

| | | |
|-------------------------------------------------------------------------|-------------------------------------------|------|
| <i>Heinrich H. Bühlhoff, Christian Wallraven, Martin A. Giese</i> | 1481 | |
| 63.1 | Overview..... | 1481 |
| 63.2 | Example-Based Object Representations..... | 1483 |

| | | |
|-----------|----------------------------------------------------------------|-------------|
| 63.3 | Example-Based Movement Representations | 1490 |
| 63.4 | Example-Based Synthesis Models: From Faces to Movements | 1492 |
| 63.5 | Conclusions and Further Reading | 1494 |
| | References | 1495 |
| 64 | Roboethics: Social and Ethical Implications of Robotics | |
| | <i>Gianmarco Veruggio, Fiorella Operto</i> | 1499 |
| 64.1 | A Methodological Note..... | 1501 |
| 64.2 | Specificity of Robotics | 1502 |
| 64.3 | What Is a Robot? | 1502 |
| 64.4 | Cultural Differences in Robot's Acceptance..... | 1503 |
| 64.5 | From Literature to Today's Debate | 1503 |
| 64.6 | Roboethics | 1504 |
| 64.7 | Ethics and Morality..... | 1505 |
| 64.8 | Moral Theories | 1505 |
| 64.9 | Ethics in Science and Technology | 1506 |
| 64.10 | Conditions for Implementation | 1507 |
| 64.11 | Operativeness of the Principles | 1507 |
| 64.12 | Ethical Issues in an ICT Society | 1507 |
| 64.13 | Harmonization of Principles..... | 1509 |
| 64.14 | Ethics and Professional Responsibility | 1510 |
| 64.15 | Roboethics Taxonomy..... | 1511 |
| 64.16 | Conclusions and Further Reading | 1519 |
| | References | 1522 |

List of Abbreviations

A

| | |
|--------|--------------------------------------------------------------------|
| AAAI | American Association for Artificial Intelligence |
| ABA | articulated-body algorithm |
| ABRT | automated bus rapid transit |
| ACAS | airborne collision avoidance systems |
| ACC | adaptive cruise control |
| ACM | active cord mechanism |
| ACM | Association of Computing Machinery |
| ADAS | advanced driver assistance systems |
| ADL | activities of daily living |
| ADSL | asymmetric digital subscriber line |
| AGV | automated guided vehicles |
| AHS | advanced highway systems |
| AI | artificial intelligence |
| AIP | anterior interparietal area |
| AIS | artificial intelligence (AI) system |
| AISB | artificial intelligence and simulation o behavior |
| AIT | anterior inferotemporal cortex |
| AM | actuators for manipulation |
| AMA | artificial moral agents |
| AMD | autonomous mental development |
| ANSI | American National Standards Institute |
| AP | antipersonnel |
| APG | adjustable pattern generator |
| AR | augmented reality |
| ARAMIS | Space Application of Automation, Robotics and Machine Intelligence |
| ASCL | adaptive seek control logic |
| ASD | autism spectrum disorder |
| ASIC | application-specific integrated circuit |
| ASKA | receptionist robot |
| ASM | advanced servomanipulator |
| ASN | active sensor network |
| ASTRO | autonomous space transport robotic operations |
| ASV | adaptive suspension vehicle |
| AT | antitank |
| ATLSS | advanced technology for large structural systems |
| ATR | Advanced Telecommunications Research Institute International |
| AuRA | autonomous robot architecture |
| AUV | autonomous underwater vehicles |
| AV | antivehicle |

B

| | |
|---------|--------------------------------------------------------------------|
| BIOROB | biomimetic robotics |
| BLDC | brushless direct current |
| BLE | broadcast of local eligibility |
| BLEEX | Berkeley lower-extremity exoskeleton |
| BLUE | best linear unbiased estimator |
| BN | Bayes network |
| BRT | bus rapid transit |
| C/A | coarse-acquisition |
| CAM | computer-aided manufacturing |
| CAD | computer-aided design |
| CAE | computer-aided engineering |
| CALM | continuous air interface long and medium range |
| CAN | controller area network |
| CARD | computer-aided remote driving |
| CASPER | continuous activity scheduling, planning, execution and replanning |
| CAT | computer-aided tomography |
| CB | cluster bombs |
| CCD | charge-coupled devices |
| CCI | control command interpreter |
| CCP | coverage configuration protocol |
| CCT | conservative congruence transformation |
| CCW | counterclockwise |
| CE | computer ethics |
| CEA | Commission de Energie Atomique |
| CEBOT | cellular robot |
| CF | climbing fibers |
| CF | contact formation |
| CG | center of gravity |
| CGA | clinical gait analysis |
| CGI | common gateway interface |
| CIE | International Commission on Illumination |
| CIRCA | cooperative intelligent real-time control architecture |
| CIS | computer-integrated surgery |
| CLARAty | coupled layered architecture for robot autonomy |
| CLEaR | closed-loop execution and recovery |
| CLIK | closed-loop inverse kinematics |
| CMAC | cerebellar model articulation controller |
| CML | concurrent mapping and localization |
| CNC | computer numerical control |
| CNP | contract net protocol |

| | | | |
|----------|--------------------------------------------------------------|----------|------------------------------------------------------------|
| CNT | carbon nanotubes | DVL | Doppler velocity log |
| COG | center of gravity | DWA | dynamic window approach |
| CONE | Collaborative Observatory for Nature Environments | E | |
| CONRO | configurable robot | EBA | extrastriate body part area |
| COR | center of rotation | EBID | electron-beam-induced deposition |
| CORBA | common object request broker architecture | ECU | electronics controller unit |
| COV | characteristic output vector | EDM | electrical discharge machining |
| CP | closest point | EDM | electronic distance measuring |
| CP | complementarity problem | EEG | electroencephalogram |
| CP | cerebral palsy | EGNOS | Euro Geostationary Navigation Overlay Service |
| CPG | central pattern generators | EKF | extended Kalman filter |
| CPSR | computer professional for social responsibility | EM | expectation maximization |
| CRBA | composite-rigid-body algorithm | EMG | electromyography |
| CRLB | Cramer–Rao lower bound | EMS | electrical master–slave manipulators |
| CSIRO | Commonwealth Scientific and Industrial Research Organization | ENSICA | Ecole Nationale Supérieure des Constructions Aeronautiques |
| CSMA | carrier sense multiple access | EO | elementary operators |
| CT | computed tomography | EOD | explosive ordnance disposal |
| CTFM | continuous-transmission frequency-modulated | EP | exploratory procedures |
| CTL | cut-to-length | EPFL | Ecole Polytechnique Fédérale de Lausanne |
| CU | control unit | EPP | extended physiological proprioception |
| CVIS | cooperative vehicle infrastructure systems | ERA | European robotic arm |
| CW | clockwise | ES | electrical stimulation |
| D | | ESA | European Space Agency |
| DARPA | Defense Advanced Research Projects Agency | ESL | execution support language |
| DARS | distributed autonomous robotics systems | ETS | engineering test satellite |
| DBNs | dynamic Bayesian networks | EVA | extravehicular activity |
| DD | differentially driven | F | |
| DDF | decentralized data fusion | FARS | Fagg-Arbib-Rizzolatti-Sakata |
| DeVAR | desktop vocational assistant robot | FE | finite element |
| DFRA | distributed field robot architecture | FESEM | field-emission SEM |
| DFT | discrete Fourier transform | FIFO | first-in first-out |
| DGA | Delegation Générale pour L’Armement | fMRI | functional magnetic resonance imaging |
| DH | Denavit–Hartenberg | FMS | flexible manufacturing systems |
| DIO | digital input-output | FNS | functional neural stimulation |
| DIRA | distributed robot architecture | FOPL | first-order predicate logic |
| DL | description logics | FPGAs | field programmable gate array |
| DLR | Deutsches Zentrum für Luft- und Raumfahrt | FRI | foot rotating indicator |
| DM2 | distributed macro-mini actuation | FSA | finite-state acceptors |
| DoD | Department of Defense | FSM | finite-state machine |
| DOF | degree of freedom | FSR | force sensing resistor |
| DOG | difference of Gaussian | FST | finite-state transducer |
| DOP | dilution of precision | FSW | feasible solution of wrench |
| DPN | dip-pen nanolithography | FTTH | fiber to the home |
| DRIE | deep reactive ion etching | G | |
| DSM | dynamic state machine | GAS | global asymptotic stability |
| DSO | Defense Sciences Office | GBAS | ground-based augmentation systems |
| DSRC | dedicated short-range communications | GCR | goal-contact relaxation |

| | | | |
|-------|-------------------------------------------------------|------|-----------------------------------------------------|
| GDP | gross domestic product | IA | instantaneous allocation |
| GenoM | generator of modules | IAD | intelligent assist device |
| GEO | geostationary Earth orbit | ICA | independent component analysis |
| GI | gastrointestinal | ICBL | International Campaign to Ban Landmines |
| GICHD | Geneva International Center for Humanitarian Demining | ICE | internet communications engine |
| GJM | generalized Jacobian matrix | ICP | iterative closest-point algorithm |
| GLS | Global Navigation Satellite System | ICR | instantaneous center of rotation |
| | Landing System | ICRA | International Conference on Robotics and Automation |
| GMM | Gaussian mixture model | ICT | information and communication technology |
| GMR | Gaussian mixture regression | IDL | interface definition language |
| GNS | global navigation systems | IE | information ethics |
| GNSS | global navigation satellite system | IED | improvised explosive device |
| GP | Gaussian processes | IEEE | Institute of Electrical and Electronics Engineers |
| GPR | ground-penetrating radar | IETF | Internet engineering task force |
| GPRS | general packet radio service | IFRR | International Foundation of Robotics Research |
| GPS | global positioning system | iGPS | indoor GPS |
| GRACE | graduate robot attending conference | IHIP | intermediate haptic interaction points |
| GSD | geon structural description | IK | inverse kinematics |
| GSI | Gadd's severity index | ILP | inductive logic programming |
| GUI | graphical user interface | ILS | instrument landing system |
| GZMP | generalized ZMP | IMTS | intelligent multimode transit system |

H

| | | | |
|----------|----------------------------------------------------------------------|--------|------------------------------------------------------|
| HAL | hybrid assisted limb | IMU | inertial measurement units |
| HAMMER | hierarchical attentive multiple models for execution and recognition | IOSS | input-output-to-state stability |
| HCI | human computer interaction | IP | internet protocol |
| HD | haptic device | IPC | interprocess communication |
| HDSL | high data rate digital subscriber line | ISO | International Organization for Standardization |
| HEPA | semi-high efficiency-particulate airfilter | ISP | internet service provider |
| HF | hard-finger | ISS | input-to-state stability |
| HIC | head injury criterion | IST | Information Society Technologies |
| HIP | haptic interaction point | IST | Instituto Superior Técnico |
| HJB | Hamilton–Jacobi–Bellman | IT | intrinsic tactile |
| HJI | Hamilton–Jacobi–Isaac | IT | inferotemporal |
| HMD | head-mounted display | ITD | interaural time difference |
| HMM | hidden Markov model | IxTeT | indexed time table |
| HMX | high melting point explosives | | |
| HO | human operator | | |
| HRI | human–robot interaction | | |
| HRTEM | high-resolution transmission electron microscopes | | |
| HST | Hubble space telescope | JAUS | joint architecture for unmanned systems |
| HSTAMIDS | handheld standoff mine detection system | JAXA | Japan space exploration agency |
| HTML | hypertext markup language | JDL | joint directors of the laboratories |
| HTN | hierarchical task network | JEMRMS | Japanese experiment module remote manipulator system |

I

| | | | |
|-------|-------------------------------------------------------|-----|----------------------------|
| I/O | input/output | JHU | Johns Hopkins University |
| I3CON | industrialized, integrated, intelligent, construction | JND | just noticeable difference |

J

| | |
|--------|------------------------------------------------------|
| JADS | joint architecture for unmanned systems |
| JAXA | Japan space exploration agency |
| JDL | joint directors of the laboratories |
| JEMRMS | Japanese experiment module remote manipulator system |
| JHU | Johns Hopkins University |
| JND | just noticeable difference |
| JPL | Jet Propulsion Laboratory |
| JSIM | joint-space inertia matrix |
| JSP | Java Server Pages |

| | |
|----------|-----------------------------------------------------------------|
| K | |
| KR | knowledge representation |
| L | |
| LAAS | Laboratoire d'Analyse et d'Architecture des Systèmes |
| LADAR | laser radar or laser detection and ranging |
| LAN | local-area network |
| LARC | Lie algebra rank condition |
| LBL | long-baseline system |
| LCSP | linear constraint satisfaction program |
| LGN | lateral geniculate nucleus |
| LIDAR | light detection and ranging |
| LOS | line of sight |
| LP | linear program |
| LQG | linear quadratic Gaussian |
| LSS | logical sensor system |
| LVDT | linear variable differential transformer |
| LWR | locally weighted regression |
| M | |
| MACA | Afghanistan Mine Action Center |
| MANET | mobile ad hoc network |
| MAP | maximum a posteriori probability |
| MBARI | Monterey Bay Aquarium Research Institute |
| MBE | molecular-beam epitaxy |
| MBS | mobile base system |
| MC | Monte Carlo |
| MCS | mission control system |
| MDP | Markovian decision process |
| MST | microsystem technology |
| MEMS | microelectromechanical systems |
| MER | Mars exploration rovers |
| MESUR | Mars environmental survey |
| MF | Mossy fibers |
| MIA | mechanical impedance adjuster |
| MIG | metal inert gas |
| MIMO | multi-input multi-output |
| MIR | mode identification and recovery |
| MIS | minimally invasive surgery |
| MITI | Ministry of International Trade and Industry |
| ML | maximum likelihood |
| ML | machine learning |
| MLE | maximum-likelihood estimation |
| MLS | multilevel surface map |
| MNS | mirror neuron system |
| MOCVD | metallo-organic chemical vapor deposition |
| MOMR | multiple operator multiple robot |
| MOSR | multiple operator single robot |
| MPC | model predictive control |
| MPFIM | multiple paired forward-inverse models |
| MPM | manipulator positioning mechanism |
| MR | multirobot tasks |
| MR | multiple reflection |
| MR | magnetorheological |
| MRAC | model reference adaptive control |
| MRI | magnetic resonance imaging |
| MRL | manipulator retention latch |
| MRSR | Mars rover sample return |
| MRTA | multirobot task allocation |
| MSAS | Multifunctional Satellite Augmentation System |
| MSER | maximally stable extremal regions |
| MSM | master-slave manipulator |
| N | |
| MT | multitask |
| MT | medial temporal |
| MTBF | mean time between failure |
| MTRAN | modular transformer |
| NAP | nonaccidental properties |
| NASA | National Aeronautics and Space Agency |
| NASDA | National Space Development Agency of Japan |
| NASREM | NASA/NBS standard reference model |
| NBS | National Bureau of Standards |
| NCEA | National Center for Engineering in Agriculture |
| NCER | National Conference on Educational Robotics |
| ND | nearness diagram navigation |
| NDDS | network data distribution service |
| NEMO | network mobility |
| NEMS | nanoelectromechanical systems |
| NICT | National Institute of Information and Communications Technology |
| NIDRR | National Institute on Disability and Rehabilitation Research |
| NIMS | networked infomechanical systems |
| NIOSH | National Institute for Occupational Health and Safety |
| NMEA | National Marine Electronics Association |
| NN | neural networks |
| NPS | Naval Postgraduate School |
| NRM | nanorobotic manipulators |
| NURBS | non-uniform rational B-spline |
| O | |
| OASIS | onboard autonomous science investigation system |
| OBSS | orbiter boom sensor system |
| OCU | operator control units |
| ODE | ordinary differential equation |

| | | | |
|----------|-----------------------------------------------------------------------------|----------|-----------------------------------------------------------------------|
| OH&S | occupation health and safety | PTU | pan–tilt unit |
| OLP | offline programming | PVDF | polyvinylidene fluoride |
| OM | optical microscope | PwoF | point-contact-without-friction |
| ORB | object request brokers | PZT | lead zirconate titanate |
| ORCCAD | open robot controller computer aided design | Q | |
| ORM | obstacle restriction method | QD | quantum dot |
| ORU | orbital replacement unit | QRO | quest for curiosity |
| OSIM | operational-space inertia matrix | QT | quasistatic telerobotics |
| P | | | |
| P&O | prosthetics and orthotics | R.U.R. | Rossum's Universal Robots |
| PAPA | privacy, accuracy, intellectual property, and access | RAIM | receiver autonomous integrity monitoring |
| PAS | pseudo-amplitude scan | RALPH | rapidly adapting lane position handler |
| PB | parametric bias | RAM | random-access (volatile) memory |
| PbD | programming by demonstration | RANSAC | random sample consensus |
| PC | principal contact | RAP | reactive action packages |
| PC | Purkinje cells | RAS | Robotics and Automation Society |
| PCA | principle components analysis | RBC | recognition-by-components |
| PD | proportional-derivative | RBF | radial basis function |
| PDDL | planning domain description language | RC | radio-controlled |
| PDGF | power data grapple fixtures | RCC | remote center of compliance |
| PEAS | probing environment and adaptive sleeping protocol | RCM | remote center of motion |
| PET | positron emission tomography | RCR | responsible conduct of research |
| PF | parallel fibers | RCS | real-time control system |
| PFC | prefrontal cortex | RERC | Rehabilitation Engineering Research Center on Rehabilitation Robotics |
| PFM | potential field method | RF | radiofrequency |
| pHRI | physical human–robot interaction | RFID | radiofrequency identification |
| PI | policy iteration | RFWR | receptive field weighted regression |
| PIC | programmable interrupt controller | RG | rate gyros |
| PIC | programmable intelligent computer | RGB | red, green, blue |
| PID | proportional–integral–derivative | RIG | rate-integrating gyros |
| PIT | posterior inferotemporal cortex | RL | reinforcement learning |
| PKM | parallel kinematic machine | RLG | random loop generator |
| PLC | programmable logic controller | RMMS | reconfigurable modular manipulator system |
| PLD | programmable logic device | RNEA | recursive Newton–Euler algorithm |
| PLEXIL | plan execution interchange language | RNNPB | recurrent neural network with parametric bias |
| PMD | photonic mixer device | RNS | reaction null space |
| PMMA | polymethyl methacrylate | ROC | receiver operating curve |
| PNT | Petri net transducers | ROKVISS | robotic components verification on the ISS |
| POMDP | partially observable MDP | ROM | read-only memory |
| PPRK | palm pilot robot kit | ROTEX | robot technology experiment |
| PPS | precise positioning system | ROV | remotely operated vehicle |
| PR | photoresist | RPC | remote procedure call |
| PRISMA | Projects of Robotics for Industry and Services, Mechatronics and Automation | RPI | Rensselaer Polytechnic Institute |
| PRM | probabilistic roadmap method | RPV | remotely piloted vehicle |
| PRN | pseudorandom noise | RRT | rapid random tree |
| PRS | procedural reasoning system | RSS | realistic robot simulation |
| PS | power source | | |
| PTP | point-to-point | | |

| | | | |
|------|--------------------------------------------|-------|-----------------------------------------|
| RT | reaction time | SPDM | special-purpose dexterous manipulator |
| RT | room-temperature | SPS | standard position system |
| RTCA | Radio Technical Commission for Aeronautics | SR | single-robot |
| RTD | resistance temperature device | SRMS | shuttle remote manipulator system |
| RTI | real-time innovations | SSRMS | Space shuttle remote manipulator system |
| RTK | real-time kinematics | ST | single-task |
| RTS | real-time system | STM | scanning tunneling microscopes |
| RWI | real-world interface | STS | superior temporal sulcus |
| RWS | robotic work station | SVD | singular value decomposition |
| | | SWNT | single-walled carbon nanotubes |

S

| | |
|--------|----------------------------------------------------------|
| SA | selective availability |
| SAIC | Science Applications International, Inc. |
| SAIL | Stanford Artificial Intelligence Laboratory |
| SAN | semiautonomous navigation |
| SBAS | satellite-based augmentation systems |
| SBL | short-baseline system |
| SCARA | selective compliance assembly robot arm |
| SCI | spinal cord injury |
| SDK | standard development kit |
| SDR | software for distributed robotics |
| SDV | spatial dynamic voting |
| SEA | series elastic actuator |
| SEE | standard end-effector |
| SELF | sensorized environment for life |
| SEM | scanning electron microscopes |
| SET | single-electron transistors |
| SF | soft-finger |
| SfM | structure from motion |
| SFX | sensor fusion effects |
| SGAS | semiglobal asymptotic stability |
| SGUUB | semiglobal uniform ultimate boundedness |
| SHOP | simple hierarchical ordered planner |
| SIFT | scale-invariant feature transformation |
| SIGMOD | Special Interest Group on Management of Data |
| SIPE | system for interactive planning and execution monitoring |
| SIR | sampling importance resampling |
| SISO | single-input single-output |
| SKM | serial kinematic machines |
| SLAM | simultaneous localization and mapping |
| SLAMP | sheep loading animal manipulation platform |
| SLICE | specification language for ICE |
| SLRV | surveyor lunar rover vehicle |
| SMA | shape-memory alloy |
| SMC | sequential Monte Carlo |
| SNOM | scanning near-field OM |
| SOI | silicon-on-insulator |
| SOMR | single operator multiple robot |
| SOSR | single operator single robot |
| SPA | sense–plan–act |

T

| | |
|--------|-----------------------------------------------------------|
| TA | time-extended assignment |
| TAP | test action pairs |
| TC | technical committee |
| TCP | transmission control protocol |
| TDL | task description language |
| TDT | tension differential type |
| TEM | transmission electron microscopes |
| tEODor | telerob explosive ordnance disposal and observation robot |
| TF-IDF | term-frequency inverse document frequency |
| TMS | transcranial magnetic stimulation |
| TOF | time of flight |
| TPBVP | two-point boundary value problem |
| TSEE | teleoperated small emplacement excavator |
| TSP | telesensor programming |
| TTI | thoracic trauma index |
| TTS | text-to-speech |

U

| | |
|------|---------------------------------------|
| UAS | unmanned aerial systems |
| UAV | unmanned aerial vehicles |
| UDP | user data protocol |
| UGV | unmanned ground vehicle |
| UML | unified modeling language |
| URL | uniform resource locator |
| US | ultrasound |
| USBL | ultrashort-baseline system |
| USV | unmanned surface vehicle |
| UUB | uniform ultimate boundedness |
| UVU | unmanned underwater vehicles |
| UVMS | underwater vehicle manipulator system |
| UWB | ultra-wideband |
| UXO | unexploded ordnance |

V

| | |
|-------|--------------------------|
| VANET | vehicular ad-hoc network |
| VC | viscous injury response |
| VCR | videocassette recorder |

| | | | |
|------|-----------------------------------|------|----------------------------------------|
| vdW | van der Waals | WAN | wide-area network |
| VFH | vector field histogram | WG | world graph |
| VI | value iteration | WMR | wheeled mobile robot |
| VIA | variable-impedance actuation | WMSD | work-related musculoskeletal disorders |
| VLSI | very-large-scale integrated | WTA | winner-take-all |
| VM | virtual manipulator | WWW | world wide web |
| VO | velocity obstacles | | |
| VOR | vestibular-ocular reflex | | |
| VOR | VHF omnidirectional range | | |

Introduction

Introduction

Bruno Siciliano, Oussama Khatib

Robots! Robots on Mars and in oceans, in hospitals and homes, in factories and schools; robots fighting fires, making goods and products, saving time and lives ... Robots today are making a considerable impact on many aspects of modern life, from industrial manufacturing to healthcare, transportation, and exploration of the deep space and sea. Tomorrow, robots will be as pervasive and personal as today's personal computers. The dream to create machines that are skilled and intelligent has been part of humanity from the beginning of time. This dream is now becoming part of our world's striking reality.

Since the early civilizations, one of man's greatest ambitions has been to create artifacts in their image. The legend of the Titan Prometheus, who molded humankind from clay, or that of the giant Talus, the bronze slave forged by Hephaestus (3500 BC), testify to this quest in Greek mythology. The Egyptians' oracle statues hiding priests inside (2500 BC) were perhaps the precursor of our modern thinking machines. The clepsydra water clock introduced by the Babylonians (1400 BC) was one of the first automated mechanical artifacts. In the following centuries, human creativity has given rise to a host of devices such as the automaton theatre of Hero of Alexandria (100 AD), the hydro-powered water-raising and humanoid machines of Al-Jazari (1200), and Leonardo da Vinci's numerous ingenious designs (1500). The development of automata continued to flourish in the eighteen century both in Europe and Asia, with creations such as Jacquet-Droz's family of androids (drawer, musician and writer) and the "karakuri-ningyo" mechanical dolls (tea server and archer).

The robot "concept" was clearly established by those many creative historical realizations. Nonetheless, the emergence of the "physical" robot had to await the advent of its underlying technologies during the course of the twentieth century. In 1920, the term *robot* – derived from "robota" which means subordinate labour in Slav languages – was first introduced by the Czech playwright Karel Čapek in his play "Rossum's Universal Robots (R.U.R.)". In 1940, the ethics of the interaction

between robots and humans was envisioned to be governed by the well-known three fundamental laws of Isaac Asimov, the Russian science-fiction writer in his novel "Runaround".

The middle of the twentieth century brought the first explorations of the connection between human intelligence and machines, marking the beginning of an era of fertile research in the field of artificial intelligence (AI). Around that time, the first robots were realized. They benefited from advances in the different technologies of mechanics, controls, computers and electronics. As always, new designs motivate new research and discoveries, which, in turn, lead to enhanced solutions and thus to novel concepts. This virtuous circle over time produced that knowledge and understanding which gave birth to the field of *robotics*, properly referred to as: the science and technology of robots.

The early robots built in the 1960s stemmed from the confluence of two technologies: numerical control machines for precise manufacturing, and teleoperators for remote radioactive material handling. These master-slave arms were designed to duplicate one-to-one the mechanics of the human arm, and had rudimentary control and little perception about the environment. Then, during the mid-to-late twentieth century, the development of integrated circuits, digital computers and miniaturized components enabled computer-controlled robots to be designed and programmed. These robots, termed industrial robots, became essential components in the automation of flexible manufacturing systems in the late 1970s. Further to their wide application in the automotive industry, industrial robots were successfully employed in general industry, such as the metal products, the chemical, the electronics and the food industries. More recently, robots have found new applications outside the factories, in areas such as cleaning, search and rescue, underwater, space, and medical applications.

In the 1980s robotics was defined as the science which studies the *intelligent connection between perception and action*. With reference to this definition, the action of a robotic system is entrusted to a *locomotion*

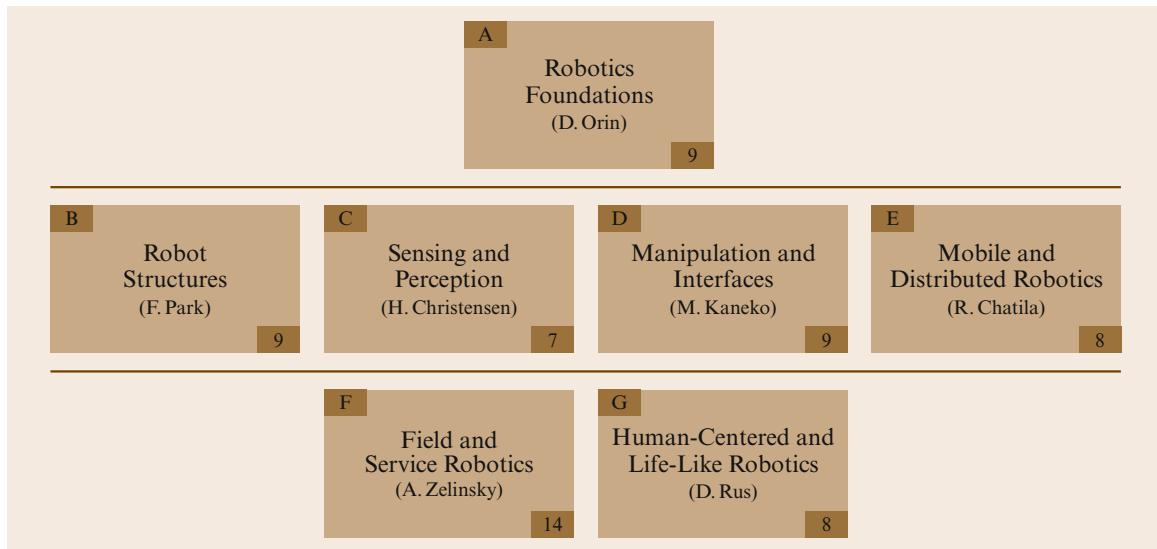

Fig. 1 Organization of the handbook

apparatus to move in the environment (wheels, crawlers, legs, propellers) and/or to a *manipulation* apparatus to operate on objects present in the environment (arms, end effectors, artificial hands), where suitable *actuators* animate the mechanical components of the robot. The perception is extracted from the *sensors* providing information on state of the robot (position and speed) and its surrounding environment (force and tactile, range and vision). The intelligent connection is entrusted to a *programming, planning and control* architecture which relies on the perception and available *models* of the robot and environment and exploits learning and skill acquisition.

In the 1990s research was boosted by the need to resort to robots to address human safety in hazardous environments (*field robotics*), or to enhance the human operator ability and reduce his/her fatigue (*human augmentation*), or else by the desire to develop products with wide potential markets aimed at improving the quality of life (*service robotics*). A common denominator of such application scenarios was the need to operate in a scarcely structured environment which ultimately requires increased abilities and a higher degree of *autonomy*.

By the dawn of the new millennium, robotics has undergone a major transformation in scope and dimensions. This expansion has been brought about by the maturity of the field and the advances in its related technologies. From a largely dominant industrial focus, robotics has been rapidly expanding into the

challenges of the human world (*human-centered and life-like robotics*). The new generation of robots is expected to safely and dependably co-habitat with humans in homes, workplaces, and communities, providing support in services, entertainment, education, healthcare, manufacturing, and assistance.

Beyond its impact on physical robots, the body of knowledge robotics has produced is revealing a much wider range of applications reaching across diverse research areas and scientific disciplines, such as: biomechanics, haptics, neurosciences, virtual simulation, animation, surgery, and sensor networks among others. In return, the challenges of the new emerging areas are proving an abundant source of stimulation and insights for the field of robotics. It is indeed at the intersection of disciplines that the most striking advances happen.

Today, new communities of users and developers are forming, with growing connections to the core of robotics research. A strategic goal for the robotics community is one of outreach and scientific cooperation with these communities. Future developments and expected growth of the field will largely depend on the research community's abilities to achieve this objective.

The dissemination of research results and findings in archival publications and conference presentations has played an important role in the advancement of robotics in the past decades. The extent of scientific activities in robotics has led to the establishment of professional societies and research networks devoted to the field.

The introduction of graduate programs in robotics in many academic institutions around the world is a clear illustration of the level of maturity reached by robotics as a scientific field.

The intensive stream of robotics research documented in the literature culminates into this unique reference, which aims at collecting in one self-contained volume the most significant achievements of our international robotics community. The *Springer Handbook of Robotics* presents a full coverage of the field from its foundations, through the research areas, up to the new emerging applications of robotics. Accordingly, the material is organized in three logical layers reflecting the historical development of the field, as illustrated in Fig. 1.

The foundations of robotics science, laid down in the first layer (Part A with its 9 chapters), address the theory of robot mechanics, sensing, planning, and control. The consolidated methodologies and technologies of robot structures (Part B with its 9 chapters), sensing and perception (Part C with its 7 chapters), manipulation and interfaces (Part D with its 8 chapters) and mobile and distributed robotics (Part E with its 8 chapters) are presented in the second layer. The third layer is devoted to advanced applications, such as in field and service robotics (Part F with its 14 chapters) and human-centered and life-like robotics (Part G with its 9 chapters).

Part A presents the fundamental principles and methods that are used to model, design, and control a robotic system. All of the foundational topics are included in this part: kinematics, dynamics, mechanical design and actuation, sensing and estimation, motion planning, motion control, force control, robotic systems architectures and programming, and **AI** reasoning methods for task planning and learning. A chapter is devoted to each of these topics. The topics are expanded and applied to specific robotic structures and systems in subsequent parts.

Part B is concerned with the design, modeling, motion planning, and control of the actual physical realizations of a robot. Some of the more obvious mechanical structures that come to mind are arms, legs, and hands; to this list can be added wheeled vehicles and platforms, and robot structures at the micro and nano scales. With separate chapters devoted to performance criteria and model identification, the chapters in this part successively examine serial redundant mechanisms, parallel

mechanisms, flexible robots, robot hands, robot legs, wheeled robots, and micro and nano-scale robots.

Part C covers different sensory modalities and integration of sensor data across space and time to generate models of robots and the external environment. Robotics is the intelligent coupling of perception and action and as such Part C complements Part B to build systems. This part of the handbook covers sensing across contact, proprioception to exteroception. The main sensor types such as tactile, odometry, **GPS**, ranging and visual perception are presented. Both basic sensor models, sensor data processing and associated representations are covered. Finally, a chapter on sensor fusion introduces the mathematical tools needed for integration of sensor information across space and time.

Part D is concerned with interaction between robots and objects, or between humans and robots. Manipulation is supposed to handle an object through direct contact by arms or fingers or just a pusher, while interfaces are supposed to make either direct or indirect interaction between humans and robots. For enhancing dexterity in robot manipulation, motion for manipulation tasks, contact modeling and manipulation, grasping, and cooperative manipulators are addressed in the first half of this part. For achieving a skillful manipulation or power increase in a human/robot system, haptics, tererobotics, networked telerobotics, and exoskeletons for human performance augmentation are discussed in the second half of part D.

Part E covers a wide span of topics. This part addresses motion planning and control of wheeled robots with kinematic constraints, perception and world modeling, simultaneous localization and mapping, and the integration of those capacities in a control architecture, as a mobile robot is actually the paradigm of a complex integrated system. This part completes Part A on foundations in the context of mobile robotics, and given the role of perception, is closely related to Part C on sensing. In addition, multi-robot interaction and systems are also discussed, including modular and reconfigurable robots as well as networked robotics.

Part F covers topics related to creating field and service application-based robots that operate in all types of environments. This includes applications ranging from industrial robots, through a diverse array of air, land, sea and space applications to educational robotics. This part

of the handbook, which draws on Parts A, B, C, D and E, describes how robots can be put to work.

Part G covers topics related to creating robots that operate in human-centered environments. This includes the design of robots with humanoid and other biologically inspired morphologies, sensors, actuators, and control architectures. User interfaces, such as programming by demonstration and programming for safety, are also included in this part, and it concludes with the socio-ethical implications of robots.

The handbook was conceived to provide a valuable resource not only for robotics experts, but also for newcomers to this expanding field (engineers, medical doctors, computer scientists, and designers). In particular, it is important to underline the tutorial value of Part A to graduate students and post-docs, the research value of Parts B to E for a wider coverage of research in robotics, and the added value of Parts F and G to engineers and scientists interested in new applications.

The contents of the various chapters have been inspired by a classic cut, i. e. avoiding the inclusion of on-going or not well-established methods. An objective perspective has been taken, while covering multiple approaches, with the goal of ensuring a high archival value to the handbook. Each chapter is preceded by a short summary, and an introductory section providing the state of the art in the area. The core sections are developed at a tutorial level. Lengthy mathematical derivations have been avoided whenever possible, while the equations, tables, and algorithms are illustrated in ready-to-use form. The final section of the chapter provides conclusions and topics for further reading.

From the foundations to the social and ethical implications of robotics, the sixty-four chapters of the handbook provide a comprehensive collection of five decades of progress in robotics. This sum is a testimony to the level of accomplishments in our field, and a premise of further advances towards new frontiers of robotics.

The chapters contained in **Part A**, Robotics Foundations, present the fundamental principles and methods that are used to develop a robotic system. In order to perform the tasks that are envisioned for robots, many challenging problems have been uncovered in kinematics, dynamics, design, actuation, sensing, motion planning, control, programming, and task planning. The chapters in this part address the basic issues in each of these areas. Some of the basic problems in robotics are outlined as follows. Robots often consist of a large number of degrees of freedom so that they can provide the rich set of three-dimensional (3-D) motions that may be required for a range of tasks. The kinematic and dynamic relationships between the joint actuators' motion and torques, and the desired motion and force for a task can be very complex. The design of the link and joint structures, as well as the actuation, to achieve the desired performance is also challenging. The robot is a nonlinear, coupled system which is difficult to control because of its complex dynamics. This is exacerbated when the environment is unstructured, and often sophisticated sensing and estimation techniques are required.

In addition to control of the motion, control of the interaction forces between the robot and environment is needed when manipulating objects or interacting with humans. A fundamental robotics task is to plan collision-free motion for complex bodies from a start to a goal position among a collection of obstacles, and this can become an intractable computational problem. In order to achieve some of the intelligence ascribed to humans, robots need to be equipped with sophisticated task planners that employ symbolic reasoning to move in dynamic, partially known environments. Robot software architectures also have special needs because of these requirements.

While the basic issues outlined in the previous paragraphs are addressed in this part, more depth can be found in other parts of the Handbook. The kinematics, dynamics, mechanical design, and control principles and methods introduced in this part can be applied to robotic structures made up of arms, hands, and legs (Part B) as well as to manipulators (Part D), wheeled mobile robots (Part E), and field and service robots (Part F). Force control is especially important for manipulators and their interfaces (Part D). The basic sensing and estimation techniques presented here are expanded and applied to specific sensing modalities in Part C. Motion planning is an important aspect of manipulation (Part D) and mobile and distributed robotic systems (Part E). Robotic systems architectures and **AI** reasoning methods are particularly important in mobile and

distributed robotics (Part E) and human-centered and lifelike robotics (Part G).

With this overview of Part A, we now provide a brief synopsis of each chapter.

Chapter 1, Kinematics, provides a number of representations and conventions to describe the motion of the bodies in a robotic mechanism. These include rotation matrices, Euler angles, quaternions, homogeneous transformations, screw transformations, matrix exponential parameterization, and Plücker coordinates. Representations of the kinematics of all common joint types are provided, along with a modified form of the Denavit–Hartenberg convention. These representational tools are applied to compute the workspace, the forward and inverse kinematics, the forward and inverse instantaneous kinematics, the Jacobian, and the static wrench transmission.

Chapter 2, Dynamics, presents the dynamic equations of motion which provide the relationships between actuation and contact forces acting on robot mechanisms, and the acceleration and motion trajectories that result. Efficient algorithms are provided for important dynamics computations which include inverse dynamics, forward dynamics, the joint-space inertia matrix, and the operational-space inertia matrix. The algorithms may be applied to fixed-base robots, mobile robots, and parallel robot mechanisms. Compact formulation of the algorithms results from using six-dimensional (6-D) spatial notation to describe rigid-body velocity, acceleration, inertia, etc.

Chapter 3, Mechanisms and Actuation, focuses on the principles that guide the design and construction of robotic systems. The kinematic equations and Jacobian are used to characterize the work envelope and mechanical advantage, and guide the selection of the robot's size and joint arrangement. The design of both serial and parallel robots is addressed. Practical consideration is given to the design of the link and joint structures along with selection of the actuators and transmission drives to power the movement. Robot performance in terms of speed, acceleration, repeatability, and other measures is also addressed.

Chapter 4, Sensing and Estimation, provides a brief overview of common sensing methods and estimation techniques that have found broad applicability in robotics. These provide information about the state of the environment and robot system. The presentation is structured according to a perception process model that includes sensing, feature extraction, data association, parameter estimation, and model integration. Several common sensing modalities are introduced and charac-

terized. Methods for estimation in linear and nonlinear systems are discussed, including statistical estimation, the Kalman filter, and sample-based methods. The several common representations for estimation are also introduced.

Chapter 5, Motion Planning, addresses the fundamental robotics task to plan collision-free motion for complex bodies from a start to a goal position among a collection of obstacles. The basic geometric path planning problem (the piano mover's problem) is introduced, but the focus of the chapter is on sampling-based planning methods because of their generally wider applicability. Planning with differential constraints is considered and is important for wheeled mobile robots. Extensions and variations to the basic motion planning problem, as well as advanced issues, are discussed at the end of the chapter.

Chapter 6, Motion Control, focuses on the motion control of a rigid manipulator. The main challenges addressed are the complexity of the nonlinear, coupled dynamics and the structured and unstructured uncertainties. The chapter discusses topics ranging from independent-joint control and **PID** control to computed-torque control to manage the complex dynamics. Adaptive and robust control are presented to address the problems related to the uncertainties in the system. The chapter concludes with some practical considerations of digital implementation and learning control for repetitive motions.

Chapter 7, Force Control, focuses on the control of the interaction forces between a robotic system and its

environment. The chapter groups interaction control into two categories: indirect and direct force control, which achieve the control without (indirect) or with (direct) explicit closure of a force feedback loop. Impedance control and hybrid force/motion control are examples of each, respectively. The fundamental problem of interaction tasks modeling is presented to provide the basis for the force control schemes.

Chapter 8, Robotic Systems Architectures, and Programming, presents the software architectures and supporting programming tools and environments that have been developed for robotic systems. Robot architectures have special needs because of the requirements of the robot to interact asynchronously, in real time, with an uncertain, often dynamic, environment. The chapter discusses the major types of architectural components for a layered robot control architecture – behavioral control, executives, and task planners – along with the commonly used techniques for interconnecting these components.

Chapter 9, AI Reasoning Methods for Robotics, sketches the state of the art in artificial intelligence for the symbol-based reasoning methods and applications considered most relevant for robotics. Reasoning on a mobile robot is especially challenging because of its dynamic, partially known environment. The chapter describes knowledge representation and inference, covering both logics- and probability-based approaches. Besides reasoning methods, the chapter considers generic reasoning applications, namely, action planning and robot learning.

Kinematics

1. Kinematics

Kenneth Waldron, James Schmiedeler

Kinematics pertains to the motion of bodies in a robotic mechanism without regard to the forces/torques that cause the motion. Since robotic mechanisms are by their very essence designed for motion, kinematics is the most fundamental aspect of robot design, analysis, control, and simulation. The robotics community has focused on efficiently applying different representations of position and orientation and their derivatives with respect to time to solve foundational kinematics problems.

This chapter will present the most useful representations of the position and orientation of a body in space, the kinematics of the joints most commonly found in robotic mechanisms, and a convenient convention for representing the geometry of robotic mechanisms. These representational tools will be applied to compute the *workspace*, the *forward* and *inverse kinematics*, the *forward* and *inverse instantaneous kinematics*, and the *static wrench transmission* of a robotic mechanism. For brevity, the focus will be on algorithms applicable to open-chain mechanisms.

The goal of this chapter is to provide the reader with general tools in tabulated form and a broader overview of algorithms that can be applied together to solve kinematics problems pertaining to a particular robotic mechanism.

1.1 Overview

Unless explicitly stated otherwise, robotic mechanisms are systems of rigid bodies connected by joints. The position and orientation of a rigid body in space are collectively termed the *pose*. Therefore, robot kinemat-

ics describes the pose, velocity, acceleration, and all higher-order derivatives of the pose of the bodies that comprise a mechanism. Since kinematics does not address the forces/torques that induce motion, this chapter

focuses on describing pose and velocity. These descriptions are foundational elements of dynamics (Chap. 2), motion planning (Chap. 5), and motion control (Chap. 6) algorithms.

Among the many possible topologies in which systems of bodies can be connected, two are of particular importance in robotics: serial chains and fully parallel mechanisms. A serial chain is a system of rigid bodies in

which each member is connected to two others, except for the first and last members that are each connected to only one other member. A fully parallel mechanism is one in which there are two members that are connected together by multiple joints. In practice, each *joint* is often itself a serial chain. This chapter focuses almost exclusively on algorithms applicable to serial chains. Parallel mechanisms are dealt with in more detail in Chap. 12.

1.2 Position and Orientation Representation

Spatial, rigid-body kinematics can be viewed as a comparative study of different ways of representing the pose of a body. Translations and rotations, referred to in combination as rigid-body displacements, are also expressed with these representations. No one approach is optimal for all purposes, but the advantages of each can be leveraged appropriately to facilitate the solution of different problems.

The minimum number of coordinates required to locate a body in Euclidean space is six. Many representations of spatial pose employ sets with superabundant coordinates in which auxiliary relationships exist among the coordinates. The number of independent auxiliary relationships is the difference between the number of coordinates in the set and six.

This chapter and those that follow it make frequent use of *coordinate reference frames* or simply *frames*. A coordinate reference frame i consists of an origin, denoted O_i , and a triad of mutually orthogonal basis vectors, denoted $(\hat{x}_i \ \hat{y}_i \ \hat{z}_i)$, that are all fixed within a particular body. The pose of a body will always be expressed relative to some other body, so it can be expressed as the pose of one coordinate frame relative to another. Similarly, rigid-body displacements can be expressed as displacements between two coordinate frames, one of which may be referred to as *moving*, while the other may be referred to as *fixed*. This indicates that the observer is located in a stationary position within the fixed reference frame, not that there exists any absolutely fixed frame.

1.2.1 Position and Displacement

The position of the origin of coordinate frame i relative to coordinate frame j can be denoted by the 3×1 vector

$${}^j p_i = \begin{pmatrix} {}^j p_i^x \\ {}^j p_i^y \\ {}^j p_i^z \end{pmatrix}.$$

The components of this vector are the Cartesian coordinates of O_i in the j frame, which are the projections of the vector ${}^j p_i$ onto the corresponding axes. The vector components could also be expressed as the spherical or cylindrical coordinates of O_i in the j frame. Such representations have advantages for analysis of robotic mechanisms including spherical and cylindrical joints.

A translation is a displacement in which no point in the rigid body remains in its initial position and all straight lines in the rigid body remain parallel to their initial orientations. (The points and lines are not necessarily contained within the boundaries of the finite rigid body, but rather, any point or line in space can be taken to be rigidly fixed in a body.) The translation of a body in space can be represented by the combination of its positions prior to and following the translation. Conversely, the position of a body can be represented as a translation that takes the body from a position in which the coordinate frame fixed to the body coincides with the fixed coordinate frame to the current position in which the two frames are not coincident. Thus, any representation of position can be used to create a representation of displacement, and vice versa.

1.2.2 Orientation and Rotation

There is significantly greater breadth in the representation of orientation than in that of position. This section does not include an exhaustive summary, but focuses on the representations most commonly applied to robotic mechanisms.

A rotation is a displacement in which at least one point of the rigid body remains in its initial position and not all lines in the body remain parallel to their initial orientations. For example, a body in a circular orbit rotates about an axis through the center of its circular path, and every point on the axis of rotation is a point

in the body that remains in its initial position. As in the case of position and translation, any representation of orientation can be used to create a representation of rotation, and vice versa.

Rotation Matrices

The orientation of coordinate frame i relative to coordinate frame j can be denoted by expressing the basis vectors $(\hat{\mathbf{x}}_i \ \hat{\mathbf{y}}_i \ \hat{\mathbf{z}}_i)$ in terms of the basis vectors $(\hat{\mathbf{x}}_j \ \hat{\mathbf{y}}_j \ \hat{\mathbf{z}}_j)$. This yields $({}^j\hat{\mathbf{x}}_i \ {}^j\hat{\mathbf{y}}_i \ {}^j\hat{\mathbf{z}}_i)$, which when written together as a 3×3 matrix is known as the rotation matrix. The components of ${}^j\mathbf{R}_i$ are the dot products of basis vectors of the two coordinate frames.

$${}^j\mathbf{R}_i = \begin{pmatrix} \hat{\mathbf{x}}_i \cdot \hat{\mathbf{x}}_j & \hat{\mathbf{y}}_i \cdot \hat{\mathbf{x}}_j & \hat{\mathbf{z}}_i \cdot \hat{\mathbf{x}}_j \\ \hat{\mathbf{x}}_i \cdot \hat{\mathbf{y}}_j & \hat{\mathbf{y}}_i \cdot \hat{\mathbf{y}}_j & \hat{\mathbf{z}}_i \cdot \hat{\mathbf{y}}_j \\ \hat{\mathbf{x}}_i \cdot \hat{\mathbf{z}}_j & \hat{\mathbf{y}}_i \cdot \hat{\mathbf{z}}_j & \hat{\mathbf{z}}_i \cdot \hat{\mathbf{z}}_j \end{pmatrix}. \quad (1.1)$$

Because the basis vectors are unit vectors and the dot product of any two unit vectors is the cosine of the angle between them, the components are commonly referred to as direction cosines.

An elementary rotation of frame i about the $\hat{\mathbf{z}}_j$ axis through an angle θ is

$$\mathbf{R}_Z(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (1.2)$$

while the same rotation about the $\hat{\mathbf{y}}_j$ axis is

$$\mathbf{R}_Y(\theta) = \begin{pmatrix} \cos \theta & 0 & \sin \theta \\ 0 & 1 & 0 \\ -\sin \theta & 0 & \cos \theta \end{pmatrix}, \quad (1.3)$$

and about the $\hat{\mathbf{x}}_j$ axis is

$$\mathbf{R}_X(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}. \quad (1.4)$$

The rotation matrix ${}^j\mathbf{R}_i$ contains nine elements, while only three parameters are required to define the orientation of a body in space. Therefore, six auxiliary relationships exist between the elements of the matrix. Because the basis vectors of coordinate frame i are mutually orthonormal, as are the basis vectors of coordinate frame j , the columns of ${}^j\mathbf{R}_i$ formed from the dot products of these vectors are also mutually orthonormal. A matrix composed of mutually orthonormal vectors is known as an orthogonal matrix and has the property that its inverse is simply its transpose. This property provides the six auxiliary relationships. Three require the

column vectors to have unit length, and three require the column vectors to be mutually orthogonal. Alternatively, the orthogonality of the rotation matrix can be seen by considering the frames in reverse order. The orientation of coordinate frame j relative to coordinate frame i is the rotation matrix ${}^i\mathbf{R}_j$ whose rows are clearly the columns of the matrix ${}^j\mathbf{R}_i$. Rotation matrices are combined through simple matrix multiplication such that the orientation of frame i relative to frame k can be expressed as

$${}^k\mathbf{R}_i = {}^k\mathbf{R}_j \ {}^j\mathbf{R}_i.$$

In summary, ${}^j\mathbf{R}_i$ is the rotation matrix that transforms a vector expressed in coordinate frame i to a vector expressed in coordinate frame j . It provides a representation of the orientation of frame i relative to j and thus, can be a representation of rotation from frame i to frame j . Table 1.1 lists the equivalent rotation matrices for the other representations of orientation listed in this section. Table 1.2 contains the conversions from a known rotation matrix to these other representations.

Euler Angles

For a minimal representation, the orientation of coordinate frame i relative to coordinate frame j can be denoted as a vector of three angles (α, β, γ) . These angles are known as Euler angles when each represents a rotation about an axis of a moving coordinate frame. In this way, the location of the axis of each successive rotation depends upon the preceding rotation(s), so the order of the

Table 1.2 Conversions from a rotation matrix to various representations of orientation

Rotation matrix:

$${}^j\mathbf{R}_i = \begin{pmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{pmatrix}$$

Z-Y-X Euler angles (α, β, γ):

$$\beta = \text{Atan2}(-r_{31}, \sqrt{r_{11}^2 + r_{21}^2})$$

$$\alpha = \text{Atan2}\left(\frac{r_{21}}{\cos \beta}, \frac{r_{11}}{\cos \beta}\right)$$

$$\gamma = \text{Atan2}\left(\frac{r_{32}}{\cos \beta}, \frac{r_{33}}{\cos \beta}\right)$$

X-Y-Z fixed angles (ψ, θ, ϕ):

$$\theta = \text{Atan2}(-r_{31}, \sqrt{r_{11}^2 + r_{21}^2})$$

$$\psi = \text{Atan2}\left(\frac{r_{21}}{\cos \theta}, \frac{r_{11}}{\cos \theta}\right)$$

$$\phi = \text{Atan2}\left(\frac{r_{32}}{\cos \theta}, \frac{r_{33}}{\cos \theta}\right)$$

Angle axis $\theta \hat{\mathbf{w}}$:

$$\theta = \cos^{-1}\left(\frac{r_{11} + r_{22} + r_{33} - 1}{2}\right)$$

$$\hat{\mathbf{w}} = \frac{1}{2\sin\theta} \begin{pmatrix} r_{32} - r_{23} \\ r_{13} - r_{31} \\ r_{21} - r_{12} \end{pmatrix}$$

Unit quaternions $(\epsilon_0 \ \epsilon_1 \ \epsilon_2 \ \epsilon_3)^\top$:

$$\epsilon_0 = \frac{1}{2}\sqrt{1 + r_{11} + r_{22} + r_{33}}$$

$$\epsilon_1 = \frac{r_{32} - r_{23}}{4\epsilon_0}$$

$$\epsilon_2 = \frac{r_{13} - r_{31}}{4\epsilon_0}$$

$$\epsilon_3 = \frac{r_{21} - r_{12}}{4\epsilon_0}$$

rotations must accompany the three angles to define the orientation. For example, the symbols (α, β, γ) are used throughout this handbook to indicate Z-Y-X Euler angles. Taking the moving frame i and the fixed frame j to be initially coincident, α is the rotation about the \hat{z} axis of frame i , β is the rotation about the rotated \hat{y} axis of frame i , and finally, γ is the rotation about the twice rotated \hat{x} axis of frame i . The equivalent rotation matrix ${}^j\mathbf{R}_i$ is given in Table 1.1. Z-Y-Z and Z-X-Z Euler angles are other commonly used conventions from among the 12 different possible orders of rotations.

Regardless of the order of rotations, an Euler angle representation of orientation always exhibits a singularity when the first and last rotations both occur about the same axis. This can be readily seen in Table 1.2 wherein the angles α and γ are undefined when $\beta = \pm 90^\circ$. (For Z-Y-Z and Z-X-Z Euler angles, the singularity occurs when the second rotation is 0° or 180° .) This creates a problem in relating the angular velocity vector of a body to the time derivatives of Euler angles, which somewhat lim-

its their usefulness in modeling robotic systems. This velocity relationship for Z-Y-X Euler angles is

$$\begin{pmatrix} \dot{\alpha} \\ \dot{\beta} \\ \dot{\gamma} \end{pmatrix} = \begin{pmatrix} -\sin \beta & 0 & 1 \\ \cos \beta \sin \gamma & \cos \gamma & 0 \\ \cos \beta \cos \gamma & -\sin \beta & 0 \end{pmatrix} \begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix}. \quad (1.5)$$

Fixed Angles

A vector of three angles can also denote the orientation of coordinate frame i relative to coordinate frame j when each angle represents a rotation about an axis of a fixed reference frame. Appropriately, such angles are referred to as fixed angles, and the order of the rotations must again accompany the angles to define the orientation. X-Y-Z fixed angles, denoted here as (ψ, θ, ϕ) , are a common convention from among the, again, 12 different possible orders of rotations. Taking the moving frame i and the fixed frame j to be initially coincident, ψ is the yaw rotation about the fixed \hat{x}_j axis, θ is the pitch rotation about the fixed \hat{y}_j axis, and ϕ is the roll rotation about the fixed \hat{z}_j axis. As can be seen by comparing the respective equivalent rotation matrices in Table 1.1 and the respective conversions in Table 1.2, a set of X-Y-Z fixed angles is exactly equivalent to the same set of Z-Y-X Euler angles ($\alpha = \phi$, $\beta = \theta$, and $\gamma = \psi$). This result holds in general such that three rotations about the three axes of a fixed frame define the same orientation as the same three rotations taken in the opposite order about the three axes of a moving frame. Likewise, all fixed-angle representations of orientations suffer from the singularity discussed for Euler angles. Also, the relationship between the time derivatives of fixed angles and the angular velocity vector is similar to the relationship for Euler angles.

Angle-Axis

A single angle θ in combination with a unit vector $\hat{\mathbf{w}}$ can also denote the orientation of coordinate frame i relative to coordinate frame j . In this case, frame i is rotated through the angle θ about an axis defined by the vector $\hat{\mathbf{w}} = (w_x \ w_y \ w_z)^\top$ relative to frame j . The vector $\hat{\mathbf{w}}$ is sometimes referred to as the equivalent axis of a finite rotation. The angle-axis representation, typically written as either $\theta \hat{\mathbf{w}}$ or $(\theta w_x \ \theta w_y \ \theta w_z)^\top$, is superabundant by one because it contains four parameters. The auxiliary relationship that resolves this is the unit magnitude of vector $\hat{\mathbf{w}}$. Even with this auxiliary relationship, the angle-axis representation is not unique because rotation through an angle of $-\theta$ about $-\hat{\mathbf{w}}$ is equivalent to a rotation through θ about $\hat{\mathbf{w}}$. Table 1.3 contains

Table 1.3 Conversions from angle-axis to unit quaternion representations of orientation and vice versa

Angle-axis $\theta \hat{w}$ to unit quaternion $(\epsilon_0 \epsilon_1 \epsilon_2 \epsilon_3)^\top$:

$$\begin{aligned}\epsilon_0 &= \cos \frac{\theta}{2} \\ \epsilon_1 &= w_x \sin \frac{\theta}{2} \\ \epsilon_2 &= w_y \sin \frac{\theta}{2} \\ \epsilon_3 &= w_z \sin \frac{\theta}{2}\end{aligned}$$

Unit quaternion $(\epsilon_0 \epsilon_1 \epsilon_2 \epsilon_3)^\top$ to angle-axis $\theta \hat{w}$:

$$\begin{aligned}\theta &= 2 \cos^{-1} \epsilon_0 \\ w_x &= \frac{\epsilon_1}{\sin \frac{\theta}{2}} \\ w_y &= \frac{\epsilon_2}{\sin \frac{\theta}{2}} \\ w_z &= \frac{\epsilon_3}{\sin \frac{\theta}{2}}\end{aligned}$$

the conversions from angle-axis representation to unit quaternions and vice versa. The conversions from these two representations to Euler angles or fixed angles can be easily found by using the conversions in Table 1.2 in conjunction with the equivalent rotation matrices in Table 1.1. Velocity relationships are more easily dealt with using the closely related quaternion representation.

Quaternions

The quaternion representation of orientation due to *Hamilton* [1.1], while largely superseded by the simpler vector representations of *Gibbs* [1.2] and *Grassmann* [1.3], is extremely useful for problems in robotics that result in representational singularities in the vector/matrix notation [1.4]. Quaternions do not suffer from singularities as Euler angles do.

A quaternion ϵ is defined to have the form

$$\epsilon = \epsilon_0 + \epsilon_1 i + \epsilon_2 j + \epsilon_3 k,$$

where the components ϵ_0 , ϵ_1 , ϵ_2 , and ϵ_3 are scalars, sometimes referred to as Euler parameters, and i , j , and k are operators. The operators are defined to satisfy the following combinatory rules:

$$ii = jj = kk = -1,$$

$$ij = k, \quad jk = i, \quad ki = j,$$

$$ji = -k, \quad kj = -i, \quad ik = -j.$$

Two quaternions are added by adding the respective components separately, so the operators act as separators. The null element for addition is the quaternion $\mathbf{0} = 0 + 0i + 0j + 0k$, and quaternion sums are associative, commutative, and distributive. The null element for multiplication is $\mathbf{I} = 1 + 0i + 0j + 0k$, as can be seen

using $I\epsilon = \epsilon$ for any quaternion ϵ . Quaternion products are associative and distributive, but not commutative, and following the conventions of the operators and addition, have the form

$$\begin{aligned}\mathbf{ab} &= a_0 b_0 - a_1 b_1 - a_2 b_2 - a_3 b_3 \\ &\quad + (a_0 b_1 + a_1 b_0 + a_2 b_3 - a_3 b_2)i \\ &\quad + (a_0 b_2 + a_2 b_0 + a_3 b_1 - a_1 b_3)j \\ &\quad + (a_0 b_3 + a_3 b_0 + a_1 b_2 - a_2 b_1)k.\end{aligned}\quad (1.6)$$

It is convenient to define the conjugate of a quaternion

$$\tilde{\epsilon} = \epsilon_0 - \epsilon_1 i - \epsilon_2 j - \epsilon_3 k,$$

so that

$$\epsilon \tilde{\epsilon} = \tilde{\epsilon} \epsilon = \epsilon_0^2 + \epsilon_1^2 + \epsilon_2^2 + \epsilon_3^2.$$

A unit quaternion can then be defined such that $\epsilon \tilde{\epsilon} = 1$. Often, ϵ_0 is referred to as the scalar part of the quaternion, and $(\epsilon_1 \epsilon_2 \epsilon_3)^\top$ is referred to as the vector part.

Unit quaternions are used to describe orientation, and the unit magnitude provides the auxiliary relationship to resolve the use of superabundant (four) coordinates. A vector is defined in quaternion notation as a quaternion with $\epsilon_0 = 0$. Thus, a vector $\mathbf{p} = (p_x \ p_y \ p_z)^\top$ can be expressed as a quaternion $\mathbf{p} = p_x i + p_y j + p_z k$. For any unit quaternion ϵ , the operation $\epsilon \mathbf{p} \tilde{\epsilon}$ performs a rotation of the vector \mathbf{p} about the direction $(\epsilon_1 \epsilon_2 \epsilon_3)^\top$. This is clearly seen by expanding the operation $\epsilon \mathbf{p} \tilde{\epsilon}$ and comparing the results with the equivalent rotation matrix listed in Table 1.1. Also, as shown in Table 1.3, unit quaternions are closely related to the angle-axis representation of orientation. ϵ_0 corresponds to the angle of rotation, while ϵ_1 , ϵ_2 , and ϵ_3 define the axis of rotation.

For velocity analysis, the time derivative of the quaternion can be related to the angular velocity vector as

$$\begin{pmatrix} \dot{\epsilon}_0 \\ \dot{\epsilon}_1 \\ \dot{\epsilon}_2 \\ \dot{\epsilon}_3 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} -\epsilon_1 & -\epsilon_2 & -\epsilon_3 \\ \epsilon_0 & \epsilon_3 & -\epsilon_2 \\ -\epsilon_3 & \epsilon_0 & \epsilon_1 \\ \epsilon_2 & -\epsilon_1 & \epsilon_0 \end{pmatrix} \begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix}. \quad (1.7)$$

While a unit quaternion represents only the orientation of a body, quaternions may be dualized [1.5–7] to create an algebra that provides a description of the position and orientation of a body in space. Other combined representations are discussed in the following sections.

1.2.3 Homogeneous Transformations

The preceding sections have addressed representations of position and orientation separately. With homogeneous transformations, position vectors and rotation

matrices are combined together in a compact notation. Any vector ${}^i\mathbf{r}$ expressed relative to the i coordinate frame can be expressed relative to the j coordinate frame if the position and orientation of the i frame are known relative to the j frame. Using the notation of Sect. 1.2.1, the position of the origin of coordinate frame i relative to coordinate frame j can be denoted by the vector ${}^j\mathbf{p}_i = ({}^j p_i^x \ {}^j p_i^y \ {}^j p_i^z)^\top$. Using the notation of Sect. 1.2.2, the orientation of frame i relative to frame j can be denoted by the rotation matrix ${}^j\mathbf{R}_i$. Thus,

$${}^j\mathbf{r} = {}^j\mathbf{R}_i {}^i\mathbf{r} + {}^j\mathbf{p}_i. \quad (1.8)$$

This equation can be written

$$\begin{pmatrix} {}^j\mathbf{r} \\ 1 \end{pmatrix} = \begin{pmatrix} {}^j\mathbf{R}_i & {}^j\mathbf{p}_i \\ \mathbf{0}^\top & 1 \end{pmatrix} \begin{pmatrix} {}^i\mathbf{r} \\ 1 \end{pmatrix}, \quad (1.9)$$

where

$${}^j\mathbf{T}_i = \begin{pmatrix} {}^j\mathbf{R}_i & {}^j\mathbf{p}_i \\ \mathbf{0}^\top & 1 \end{pmatrix} \quad (1.10)$$

is the 4×4 homogeneous transformation matrix and $({}^j\mathbf{r} 1)^\top$ and $({}^i\mathbf{r} 1)^\top$ are the homogeneous representations of the position vectors ${}^j\mathbf{r}$ and ${}^i\mathbf{r}$. The matrix ${}^j\mathbf{T}_i$ transforms vectors from coordinate frame i to coordinate frame j . Its inverse ${}^j\mathbf{T}_i^{-1}$ transforms vectors from coordinate frame j to coordinate frame i .

$${}^j\mathbf{T}_i^{-1} = {}^i\mathbf{T}_j = \begin{pmatrix} {}^j\mathbf{R}_i^\top & -{}^j\mathbf{R}_i^\top {}^j\mathbf{p}_i \\ \mathbf{0}^\top & 1 \end{pmatrix}. \quad (1.11)$$

Composition of 4×4 homogeneous transformation matrices is accomplished through simple matrix multiplication, just as in the case of 3×3 rotation matrices. Therefore, ${}^k\mathbf{T}_i = {}^k\mathbf{T}_j {}^j\mathbf{T}_i$. Since matrix multiplications do not commute, the order or sequence is important.

The homogeneous transformation of a simple rotation about an axis is sometimes denoted **Rot** such that a rotation of θ about an axis $\hat{\mathbf{z}}$ is

$$\mathbf{Rot}(\hat{\mathbf{z}}, \theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 & 0 \\ \sin \theta & \cos \theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (1.12)$$

Similarly, the homogeneous transformation of a simple translation along an axis is sometimes denoted **Trans** such that a translation of d along an axis $\hat{\mathbf{x}}$ is

$$\mathbf{Trans}(\hat{\mathbf{x}}, d) = \begin{pmatrix} 1 & 0 & 0 & d \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (1.13)$$

Homogeneous transformations are particularly attractive when compact notation is desired and/or when ease of programming is the most important consideration. This is not, however, a computationally efficient representation since it introduces a large number of additional multiplications by ones and zeros. Although homogeneous transformation matrices technically contain 16 elements, four are defined to be zero or one, and the remaining elements are composed of a rotation matrix and a position vector. Therefore, the only truly superabundant coordinates come from the rotation matrix component, so the relevant auxiliary relationships are those associated with the rotation matrix.

1.2.4 Screw Transformations

The transformation in (1.8) can be viewed as composed of a rotation between coordinate frames i and j and a separate displacement between those frames. To get from frame i to frame j , one could perform the rotation first, followed by the displacement, or vice versa. Alternatively, the spatial displacement between the frames can be expressed, except in the case of a pure translation, as a rotation about a unique line combined with a translation parallel to that line.

Chasles' Theorem

Chasles' theorem, in the form stated by Chirikjian and Kyatkin [1.8], has two parts. The first states that:

Any displacement of a body in space can be accomplished by means of a translation of a designated point from its initial to its final position, followed by a rotation of the whole body about that point to bring it into its final orientation.

The second part states that:

Any displacement of a body in space can be accomplished by means of a rotation of the body about a unique line in space accompanied by a translation of the body parallel to that line.

Such a line is called a screw axis, and it is this second result that is usually thought of as Chasles' theorem.

The first part of the theorem is almost axiomatic. A designated point in a body anywhere in Euclidean space can be displaced from a given initial position to a given final position. By further requiring that all points in the body traverse the same displacement, the body translates so that the designated point moves from its initial position to its final position. The body can then be rotated about that point into any given final orientation.

The second part of the theorem depends on this representation of a spatial displacement and requires a more complex argument. A preliminary theorem due to Euler allows greater specificity about the rotation of the body: *Any displacement of a body in which one point remains fixed is equivalent to a rotation of that body about a unique axis passing through that point.* Geometrically, embedding three points in the moving body and letting one be the fixed point about which rotation occurs, each of the other two will have initial and final positions. The right bisector planes of the lines joining the initial and final positions in each case necessarily contain the fixed point. Any line in the bisector plane can be the axis of a rotation that carries the corresponding point from its initial to its final position. Therefore, the unique line common to the two bisector planes is such that rotation about it will carry any point in the body from its initial to its final position. The rigidity condition requires that all planes in the body that contain that line rotate through the same angle.

For any rotation of a rigid body described by a rotation matrix ${}^j\mathbf{R}_i$, Euler's theorem states that there is a unique eigenvector $\hat{\mathbf{w}}$ such that

$${}^j\mathbf{R}_i \hat{\mathbf{w}} = \hat{\mathbf{w}}, \quad (1.14)$$

where $\hat{\mathbf{w}}$ is a unit vector parallel to the axis of rotation. This expression requires a unit eigenvalue of ${}^j\mathbf{R}_i$ corresponding to the eigenvector $\hat{\mathbf{w}}$. The remaining two eigenvalues are $\cos \theta \pm i \sin \theta$, where i is the complex operator and θ is the angle of rotation of the body about the axis.

Combining the first part of Chasles' theorem with Euler's theorem, a general spatial displacement can be expressed as a translation taking a point from its initial to its final position, followed by a unique rotation about a unique axis through that point that carries the body from its initial to its final orientation. Resolving the translation into components in the direction of and orthogonal to the rotation axis, every point in the body has the same displacement component in the direction of the axis because rotation about it does not affect that component. Projected into a plane normal to the rotation axis, the kinematic geometry of the displacement is identical to that of planar motion. Just as there is a unique point in the plane about which a body could be rotated between two given positions, there is a unique point in the projection plane. If the rotation axis is moved to pass through that point, the spatial displacement can be accomplished by a rotation about that axis combined with a translation along it, as stated by the theorem.

The line about which rotation takes place is called the screw axis of the displacement. The ratio of the linear displacement d to the rotation θ is referred to as the pitch h of the screw axis [1.4]. Thus,

$$d = h\theta. \quad (1.15)$$

The screw axis of a pure translation is not unique. Any line parallel to the translation can be regarded as the screw axis, and since the rotation θ is zero, the axis of a translation is said to have infinite pitch.

A screw axis is most conveniently represented in any reference frame by means of a unit vector $\hat{\mathbf{w}}$ parallel to it and the position vector ρ of any point lying on it. Additional specification of the pitch h and the angle of rotation θ completely defines the location of a second coordinate frame relative to the reference frame. Thus, a total of eight coordinates define a screw transformation, which is superabundant by two. The unit magnitude of vector $\hat{\mathbf{w}}$ provides one auxiliary relationship, but in general, there is no second auxiliary relationship because the same screw axis is defined by all points lying on it, which is to say that the vector ρ contains one free coordinate.

Algebraically, a screw displacement is represented by

$${}^j\mathbf{r} = {}^j\mathbf{R}_i({}^i\mathbf{r} - \rho) + d\hat{\mathbf{w}} + \rho. \quad (1.16)$$

Comparing this expression to (1.8) yields

$${}^j\mathbf{p}_i = d\hat{\mathbf{w}} + (\mathbf{1}_{3\times 3} - {}^j\mathbf{R}_i)\rho. \quad (1.17)$$

$\mathbf{1}_{3\times 3}$ denotes the 3×3 identity matrix. An expression for d is easily obtained by taking the inner product of both sides of the equation with $\hat{\mathbf{w}}$.

$$d = \hat{\mathbf{w}}^\top {}^j\mathbf{p}_i. \quad (1.18)$$

The matrix $\mathbf{1}_{3\times 3} - {}^j\mathbf{R}_i$ is singular, so (1.17) cannot be solved to give a unique value of ρ , but since ρ can represent any point on the screw axis, this would not be appropriate. One component of ρ can be arbitrarily chosen, and any two of the component equations can then be solved to find the two other components of ρ . All other points on the screw axis are then given by $\rho + k\hat{\mathbf{w}}$, where k can take any value.

Table 1.4 contains the conversions between screw transformations and homogeneous transformations. Note that the equivalent rotation matrix for a screw transformation has the same form as the equivalent rotation matrix for an angle-axis representation of orientation in Table 1.1. Also, the auxiliary relationship that the vector ρ be orthogonal to the screw axis ($\hat{\mathbf{w}}^\top \rho = 0$) is used in Table 1.4 to provide a unique conversion to the

Table 1.4 Conversions from a screw transformation to a homogeneous transformation and vice versa, with abbreviations $c_\theta := \cos \theta$, $s_\theta := \sin \theta$, and $v_\theta := 1 - \cos \theta$

Screw transformation to homogeneous transformation:

$$\begin{aligned} {}^j R_i = & \begin{pmatrix} w_x^2 v_\theta + c_\theta & w_x w_y v_\theta - w_z s_\theta & w_x w_z v_\theta + w_y s_\theta \\ w_x w_y v_\theta + w_z s_\theta & w_y^2 v_\theta + c_\theta & w_y w_z v_\theta - w_x s_\theta \\ w_x w_z v_\theta - w_y s_\theta & w_y w_z v_\theta + w_x s_\theta & w_z^2 v_\theta + c_\theta \end{pmatrix} \\ {}^j p_i = & (1_{3 \times 3} - {}^j R_i) \rho + h\theta \hat{w} \end{aligned}$$

Homogeneous transformation to screw transformation:

$$l = \begin{pmatrix} r_{32} - r_{23} \\ r_{13} - r_{31} \\ r_{21} - r_{12} \end{pmatrix}^\top$$

$$\theta = \text{sign}(l^\top {}^j p_i) \left| \cos^{-1} \left(\frac{r_{11} + r_{22} + r_{33} - 1}{2} \right) \right|$$

$$h = \frac{l^\top {}^j p_i}{2\theta \sin \theta}$$

$$\rho = \frac{(1_{3 \times 3} - {}^j R_i^\top) {}^j p_i}{2(1 - \cos \theta)}$$

$$\hat{w} = \frac{l}{2 \sin \theta}$$

screw transformation. The inverse result, that of finding the rotation matrix ${}^j R_i$ and the translation ${}^j p_i$ corresponding to a given screw displacement, is found from Rodrigues' equation.

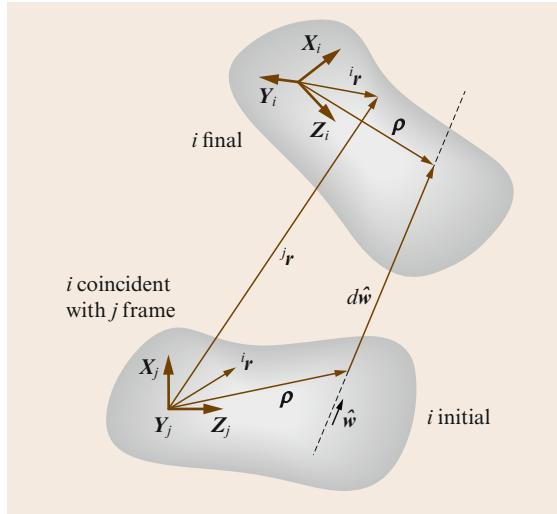

Fig. 1.1 Initial and final positions of an arbitrary point in a body undergoing a screw displacement; ${}^i r$ is the position of the point relative to the moving frame, which is coincident with the fixed reference frame j in its initial position; ${}^j r$ is the position of the point relative to the fixed frame after the screw displacement of the moving body

Rodrigues' Equation

Given a screw axis, the angular displacement of a body about it, and the translation of the body along it, the displacement of an arbitrary point in that body can be found. Viewing a matrix transformation as describing the displacement of the body, this is equivalent to finding the matrix transformation equivalent to a given screw displacement.

Referring to Fig. 1.1, the position vectors of a point before and after a screw displacement can be geometrically related as

$$\begin{aligned} {}^j r = & {}^i r + d \hat{w} + \sin \theta \hat{w} \times ({}^i r - \rho) \\ & - (1 - \cos \theta)({}^i r - \rho) - ({}^i r - \rho) \cdot \hat{w} \hat{w}, \end{aligned} \quad (1.19)$$

where ${}^i r$ and ${}^j r$ denote the initial and final positions of the point, \hat{w} and ρ specify the screw axis, and θ and d give the displacement about it. This result is usually referred to as Rodrigues' equation [1.9], which can be written as a matrix transformation [1.10],

$${}^j r = {}^j R_i {}^i r + {}^j p_i, \quad (1.20)$$

since, when expanded, it gives three linear equations for the components of ${}^j r$ in terms of those of ${}^i r$.

$${}^j R_i =$$

$$\begin{pmatrix} w_x^2 v_\theta + c_\theta & w_x w_y v_\theta - w_z s_\theta & w_x w_z v_\theta + w_y s_\theta \\ w_x w_y v_\theta + w_z s_\theta & w_y^2 v_\theta + c_\theta & w_y w_z v_\theta - w_x s_\theta \\ w_x w_z v_\theta - w_y s_\theta & w_y w_z v_\theta + w_x s_\theta & w_z^2 v_\theta + c_\theta \end{pmatrix}$$

$${}^j p_i = (1_{3 \times 3} - {}^j R_i) \rho + h\theta \hat{w},$$

where the abbreviations are $c_\theta := \cos \theta$, $s_\theta := \sin \theta$, and $v_\theta = 1 - \cos \theta$. The rotation matrix ${}^j R_i$ expressed in this form is also called the screw matrix, and these equations give the elements of ${}^j R_i$ and ${}^j p_i$ in terms of the screw parameters.

An exception arises in the case of a pure translation, for which $\theta = 0$ and Rodrigues' equation becomes

$${}^j r = {}^i r + d \hat{w}. \quad (1.21)$$

Substituting for this case, ${}^j R_i = 1_{3 \times 3}$ and ${}^j p_i = d \hat{w}$.

Additional information on screw theory can be found in [1.11–15].

1.2.5 Matrix Exponential Parameterization

The position and orientation of a body can also be expressed in a unified fashion with an exponential mapping. This approach is introduced first with its application to pure rotation and expanded to rigid-body

motion. More details on the approach can be found in [1.16] and [1.17].

Exponential Coordinates for Rotation

The set of all orthogonal matrices with determinant 1, which is the set of all rotation matrices \mathbf{R} , is a *group* under the operation of matrix multiplication denoted as $SO(3) \subset \mathbb{R}^{3 \times 3}$ [1.18]. This stands for *special orthogonal* wherein *special* alludes to the $\det \mathbf{R}$ being +1 instead of ± 1 . The set of rotation matrices satisfies the four axioms of a group:

- closure:* $\mathbf{R}_1 \mathbf{R}_2 \in SO(3) \quad \forall \mathbf{R}_1, \mathbf{R}_2 \in SO(3);$
- identity:* $\mathbf{1}_{3 \times 3} \mathbf{R} = \mathbf{R} \mathbf{1}_{3 \times 3} = \mathbf{R} \quad \forall \mathbf{R} \in SO(3);$
- inverse:* $\mathbf{R}^\top \in SO(3)$ is the unique inverse of \mathbf{R} $\forall \mathbf{R} \in SO(3);$
- associativity:* $(\mathbf{R}_1 \mathbf{R}_2) \mathbf{R}_3 = \mathbf{R}_1 (\mathbf{R}_2 \mathbf{R}_3) \quad \forall \mathbf{R}_1, \mathbf{R}_2, \mathbf{R}_3 \in SO(3).$

In the angle-axis representation presented in Sect. 1.2.2, orientation is expressed as an angle θ of rotation about an axis defined by the unit vector $\hat{\mathbf{w}}$. The equivalent rotation matrix found in Table 1.1 can be expressed as the exponential map

$$\mathbf{R} = e^{S(\hat{\mathbf{w}})\theta} = \mathbf{1}_{3 \times 3} + \theta S(\hat{\mathbf{w}}) + \frac{\theta^2}{2!} S(\hat{\mathbf{w}})^2 + \frac{\theta^3}{3!} S(\hat{\mathbf{w}})^3 + \dots, \quad (1.22)$$

where $S(\hat{\mathbf{w}})$ is the unit skew-symmetric matrix

$$S(\hat{\mathbf{w}}) = \begin{pmatrix} 0 & -w_z & w_y \\ w_z & 0 & -w_x \\ -w_y & w_x & 0 \end{pmatrix}. \quad (1.23)$$

Thus, the exponential map transforms a skew-symmetric matrix $S(\hat{\mathbf{w}})$ that corresponds to an axis of rotation $\hat{\mathbf{w}}$ into an orthogonal matrix \mathbf{R} that corresponds to a rotation about the axis $\hat{\mathbf{w}}$ through an angle of θ . It can be shown that the closed-form expression for $e^{S(\hat{\mathbf{w}})\theta}$, which can be efficiently computed, is

$$e^{S(\hat{\mathbf{w}})\theta} = \mathbf{1}_{3 \times 3} + S(\hat{\mathbf{w}}) \sin \theta + S(\hat{\mathbf{w}})^2 (1 - \cos \theta). \quad (1.24)$$

The components of $(\theta w_x \theta w_y \theta w_z)^\top$, which are related to the elements of the rotation matrix \mathbf{R} in Table 1.2, are referred to as the *exponential coordinates* for \mathbf{R} .

Exponential Coordinates for Rigid-Body Motion

As indicated in Sect. 1.2.3, the position and orientation of a body can be expressed by the combination of a position vector $\mathbf{p} \in \mathbb{R}^3$ and a rotation matrix $\mathbf{R} \in SO(3)$.

The product space of \mathbb{R}^3 with $SO(3)$ is the group known as $SE(3)$, which stands for *special Euclidean*.

$$SE(3) = \{(\mathbf{p}, \mathbf{R}) : \mathbf{p} \in \mathbb{R}^3, \mathbf{R} \in SO(3)\} = \mathbb{R}^3 \times SO(3).$$

The set of homogeneous transformations satisfies the four axioms of a group:

- *closure:* $\mathbf{T}_1 \mathbf{T}_2 \in SE(3) \quad \forall \mathbf{T}_1, \mathbf{T}_2 \in SE(3);$
- *identity:* $\mathbf{1}_{4 \times 4} \mathbf{T} = \mathbf{T} \mathbf{1}_{4 \times 4} = \mathbf{T} \quad \forall \mathbf{T} \in SE(3);$
- *inverse:* the unique inverse of $\mathbf{T} \quad \forall \mathbf{T} \in SE(3)$ is given in (1.11);
- *associativity:* $(\mathbf{T}_1 \mathbf{T}_2) \mathbf{T}_3 = \mathbf{T}_1 (\mathbf{T}_2 \mathbf{T}_3) \quad \forall \mathbf{T}_1, \mathbf{T}_2, \mathbf{T}_3 \in SE(3).$

In the screw transformation representation in Sect. 1.2.4, position and orientation are expressed by the angle θ of rotation about a screw axis defined by the unit vector $\hat{\mathbf{w}}$, the point ρ on the axis such that $\hat{\mathbf{w}}^\top \rho = 0$, and the pitch h of the screw axis. The equivalent homogeneous transformation found in Table 1.4 can be expressed as the exponential map

$$\mathbf{T} = e^{\hat{\xi}\theta} = \mathbf{1}_{4 \times 4} + \hat{\xi}\theta + \frac{(\hat{\xi}\theta)^2}{2!} + \frac{(\hat{\xi}\theta)^3}{3!} + \dots, \quad (1.25)$$

where

$$\hat{\xi} = \begin{pmatrix} S(\hat{\mathbf{w}}) & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix} \quad (1.26)$$

is the generalization of the unit skew-symmetric matrix $S(\hat{\mathbf{w}})$ known as a *twist*. The twist coordinates of $\hat{\xi}$ are given by $\xi := (\hat{\mathbf{w}}^\top \mathbf{v}^\top)^\top$. It can be shown that the closed-form expression for $e^{\hat{\xi}\theta}$ is

$$e^{\hat{\xi}\theta} = \begin{pmatrix} e^{S(\hat{\mathbf{w}})\theta} & (\mathbf{1}_{3 \times 3} - e^{S(\hat{\mathbf{w}})\theta})(\hat{\mathbf{w}} \times \mathbf{v}) + \hat{\mathbf{w}}^\top \mathbf{v} \theta \hat{\mathbf{w}} \\ \mathbf{0}^\top & 1 \end{pmatrix}. \quad (1.27)$$

Comparison of this result with the conversion between homogeneous and screw transformations in Table 1.4 yields

$$\mathbf{v} = \rho \times \hat{\mathbf{w}} \quad (1.28)$$

and

$$h = \hat{\mathbf{w}}^\top \mathbf{v}. \quad (1.29)$$

Thus, the exponential map for a twist transforms the initial pose of a body into its final pose. It gives the relative rigid-body motion. The vector $\xi\theta$ contains the *exponential coordinates* for the rigid-body transformation.

As for screw transformations, the case of pure translation is unique. In this case, $\hat{\mathbf{w}} = \mathbf{0}$, so

$$\mathrm{e}^{\hat{\mathbf{x}}\theta} = \begin{pmatrix} \mathbf{1}_{3 \times 3} & \theta \mathbf{v} \\ \mathbf{0}^\top & 1 \end{pmatrix}. \quad (1.30)$$

1.2.6 Plücker Coordinates

A minimum of four coordinates are needed to define a line in space. The Plücker coordinates of a line form a six-dimensional vector, so they are superabundant by two. They can be viewed as a pair of three-dimensional vectors; one is parallel to the line, and the other is the *moment* of that vector about the origin. Thus, if \mathbf{u} is any vector parallel to the line and ρ is the position of any point on the line relative to the origin, the Plücker coordinates (L, M, N, P, Q , and R) are given by

$$(L, M, N) = \mathbf{u}^\top; \quad (P, Q, R) = (\rho \times \mathbf{u})^\top. \quad (1.31)$$

For simply defining a line, the magnitude of \mathbf{u} is not unique, nor is the component of ρ parallel to \mathbf{u} . Two auxiliary relationships are imposed to reduce the set to just four independent coordinates. One is that the scalar product of the two three-dimensional vectors is identically zero.

$$\mathbf{L}\mathbf{P} + \mathbf{M}\mathbf{Q} + \mathbf{N}\mathbf{R} \equiv 0. \quad (1.32)$$

The other is the invariance of the line designated when the coordinates are all multiplied by the same scaling factor.

$$(L, M, N, P, Q, R) \equiv (kL, kM, kN, kP, kQ, kR). \quad (1.33)$$

This relationship may take the form of constraining \mathbf{u} to have unit magnitude so that L, M , and N are the direction cosines.

In this handbook, it is often useful to express velocities in Plücker coordinates, wherein unlike the definition of lines, the magnitudes of the two three-dimensional vectors are not arbitrary. This leads to the motor notation of *von Mises* [1.9, 19] and *Everett* [1.20]. For instantaneously coincident coordinate frames, one fixed and the

other embedded in the moving body, $\boldsymbol{\omega}$ is the angular velocity of the body and \mathbf{v}_O is the velocity of the origin O of the body-fixed frame when both are expressed relative to the fixed frame. This provides a Plücker coordinate system for the spatial velocity \mathbf{v} of the body. The Plücker coordinates of \mathbf{v} are simply the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O ,

$$\mathbf{v} = \begin{pmatrix} \boldsymbol{\omega} \\ \mathbf{v} \end{pmatrix}. \quad (1.34)$$

The transformation from Plücker coordinate system i to Plücker coordinate system j for spatial velocities is achieved with the spatial transform jX_i . If \mathbf{v}_i and \mathbf{v}_j denote the spatial velocities of a body relative to the i and j frames, respectively, and ${}^j\mathbf{p}_i$ and ${}^j\mathbf{R}_i$ denote the position and orientation of frame i relative to frame j ,

$${}^j\mathbf{v}_j = {}^jX_i \mathbf{v}_i, \quad (1.35)$$

where

$${}^jX_i = \begin{pmatrix} {}^j\mathbf{R}_i & \mathbf{0}_{3 \times 3} \\ S({}^j\mathbf{p}_i) {}^j\mathbf{R}_i & {}^j\mathbf{R}_i \end{pmatrix}, \quad (1.36)$$

such that

$${}^jX_i^{-1} = {}^iX_j = \begin{pmatrix} {}^i\mathbf{R}_j & \mathbf{0}_{3 \times 3} \\ -{}^i\mathbf{R}_j S({}^j\mathbf{p}_i) & {}^i\mathbf{R}_j \end{pmatrix} \quad (1.37)$$

and

$${}^kX_i = {}^kX_j {}^jX_i, \quad (1.38)$$

and $S({}^j\mathbf{p}_i)$ is the skew-symmetric matrix

$$\begin{pmatrix} 0 & -{}^j\mathbf{p}_i^z & {}^j\mathbf{p}_i^y \\ {}^j\mathbf{p}_i^z & 0 & -{}^j\mathbf{p}_i^x \\ -{}^j\mathbf{p}_i^y & {}^j\mathbf{p}_i^x & 0 \end{pmatrix}. \quad (1.39)$$

Spatial vector notation, which includes the spatial velocities and transforms briefly mentioned here, is treated in greater depth in Sect. 2.2. Specifically, Table 2.1 gives a computationally efficient algorithm for applying a spatial transform.

1.3 Joint Kinematics

Unless explicitly stated otherwise, the kinematic description of robotic mechanisms typically employs a number of idealizations. The links that compose the robotic mechanism are assumed to be perfectly rigid

bodies having surfaces that are geometrically perfect in both position and shape. Accordingly, these rigid bodies are connected together at joints where their idealized surfaces are in ideal contact without any

clearance between them. The respective geometries of these surfaces in contact determine the freedom of motion between the two links, or the *joint kinematics*.

A kinematic joint is a connection between two bodies that constrains their relative motion. Two bodies that are in contact with one another create a simple kinematic joint. The surfaces of the two bodies that are in contact are able to move over one another, thereby permitting relative motion of the two bodies. Simple kinematic joints are classified as lower pair joints if contact occurs over surfaces [1.22] and as higher pair joints if contact occurs only at points or along lines.

A joint model describes the motion of a frame fixed in one body of a joint relative to a frame fixed in the other body. The motion is expressed as a function of the joint's motion variables, and other elements of a joint model include the rotation matrix, position vector, free modes, and constrained modes. The free modes of a joint define the directions in which motion is allowed. They are represented by the $6 \times n_i$ matrix Φ_i whose columns are the Plücker coordinates of the allowable motion. This

matrix relates the spatial velocity vector across the joint v_{rel} to the joint velocity vector \dot{q} ,

$$v_{\text{rel}} = \Phi_i \dot{q}. \quad (1.40)$$

In contrast, the constrained modes of a joint define the directions in which motion is not allowed. They are represented by the $6 \times (6 - n_i)$ matrix Φ_i^c that is complementary to Φ_i . Tables 1.5 and 1.6 contain the formulas of the joint models for all of the joints described in this section. They are used extensively for the dynamic analysis presented in Chap. 2. Additional information on joints can be found in Chap. 3.

1.3.1 Lower Pair Joints

Lower pair joints are mechanically attractive since wear is spread over the whole surface and lubricant is trapped in the small clearance space (in nonidealized systems) between the surfaces, resulting in relatively good lubrication. As can be proved [1.23] from the requirement for surface contact, there are only six possible forms of lower pair: revolute, prismatic, helical, cylindrical, spherical, and planar joints.

Table 1.5 Joint model formulas for one-degree-of-freedom lower pair joints, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$. (Adapted in part from Table 4.1 in [1.21])

| Joint type | Joint rotation matrix $j\mathbf{R}_i$ | Position vector $j\mathbf{p}_i$ | Free modes Φ_i | Constrained modes Φ_i^c | Pose state vars. θ_i | \dot{q}_i |
|------------------------------|------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------|------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------|------------------|
| Revolute R | $\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$ | θ_i | $\dot{\theta}_i$ |
| Prismatic P | $1_{3 \times 3}$ | $\begin{pmatrix} 0 \\ 0 \\ d_i \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}$ | d_i | \dot{d}_i |
| Helical H (pitch h) | $\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ h\theta_i \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ h \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -h \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$ | θ_i | $\dot{\theta}_i$ |

Table 1.6 Joint model formulas for higher-degree-of-freedom lower pair joints, universal joint, rolling contact joint, and 6-DOF joint, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$. (Adapted in part from Table 4.1 in [1.21]) *The Euler angles α_i , β_i , and γ_i could be used in place of the unit quaternion ϵ_i to represent orientation

| Joint type | Joint rotation matrix \mathbf{R}_i | Position vector \mathbf{p}_i | Free modes Φ_i | Constrained modes Φ_i^c | Pose Variables | Velocity Variables $\dot{\mathbf{q}}_i$ |
|-------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------|--------------------------------------------------------------------------------|
| Cylindrical C | $\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ d_i \end{pmatrix}$ | $\begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}$ | θ_i d_i | $\begin{pmatrix} \dot{\theta}_i \\ \dot{d}_i \end{pmatrix}$ |
| Spherical* S | (see Table 1.1) | $\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ | $\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | ϵ_i | ω_i rel |
| Planar | $\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} c_{\theta_i} d_{xi} - s_{\theta_i} d_{yi} \\ s_{\theta_i} d_{xi} + c_{\theta_i} d_{yi} \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | θ_i d_{xi} d_{yi} | $\begin{pmatrix} \dot{\theta}_i \\ \dot{d}_{xi} \\ \dot{d}_{yi} \end{pmatrix}$ |
| Flat planar rolling contact (fixed radius r) | $\begin{pmatrix} c_{\theta_i} & -s_{\theta_i} & 0 \\ s_{\theta_i} & c_{\theta_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} r\theta_i c_{\theta_i} - rs_{\theta_i} \\ -r\theta_i s_{\theta_i} - rc_{\theta_i} \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 1 \\ r \\ 0 \\ 0 \end{pmatrix}$ | $\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & -r & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$ | θ_i | $\dot{\theta}_i$ |
| Universal U | $\begin{pmatrix} c_{\alpha_i} c_{\beta_i} & -s_{\alpha_i} & c_{\alpha_i} s_{\beta_i} \\ s_{\alpha_i} c_{\beta_i} & c_{\alpha_i} & s_{\alpha_i} s_{\beta_i} \\ -s_{\beta_i} & 0 & c_{\beta_i} \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$ | $\begin{pmatrix} -s_{\beta_i} & 0 \\ 0 & 1 \\ c_{\beta_i} & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}$ | $\begin{pmatrix} c_{\beta_i} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ s_{\beta_i} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$ | α_i β_i | $\begin{pmatrix} \dot{\alpha}_i \\ \dot{\beta}_i \end{pmatrix}$ |
| 6-DOF* | (see Table 1.1) | $0\mathbf{p}_i$ | $1_{6 \times 6}$ | ϵ_i $0\mathbf{p}_i$ | ω_i v_i | |

Revolute

The most general form of a revolute joint, often abbreviated as “R” and sometimes referred to colloquially as a hinge or pin joint, is a lower pair composed of two congruent surfaces of revolution. The surfaces are the same except one of them is an external surface, convex in any plane normal to the axis of revolution, and one is an internal surface, concave in any plane normal to

the axis. The surfaces may not be solely in the form of right circular cylinders, since surfaces of that form do not provide any constraint on axial sliding. A revolute joint permits only rotation of one of the bodies joined relative to the other. The position of one body relative to the other may be expressed as the angle between two lines normal to the joint axis, one fixed in each body. Thus, the joint has one *degree of freedom* (DOF). When

the \hat{z} axis of coordinate frame i is aligned with a revolute joint axis, the formulas in Table 1.5 define the revolute joint model.

Prismatic

The most general form of a prismatic joint, often abbreviated as “P” and sometimes referred to colloquially as a sliding joint, is a lower pair formed from two congruent general cylindrical surfaces. These may not be right circular cylindrical surfaces. A general cylindrical surface is obtained by extruding any curve in a constant direction. Again, one surface is internal and the other is an external surface. A prismatic joint permits only sliding of one of the members joined relative to the other along the direction of extrusion. The position of one body relative to the other is determined by the distance between two points on a line parallel to the direction of sliding, with one point fixed in each body. Thus, this joint also has one degree of freedom. When the \hat{z} axis of coordinate frame i is aligned with a prismatic joint axis, the formulas in Table 1.5 define the prismatic joint model.

Helical

The most general form of a helical joint, often abbreviated as “H” and sometimes referred to colloquially as a screw joint, is a lower pair formed from two helicoidal surfaces formed by extruding any curve along a helical path. The simple example is a screw and nut wherein the basic generating curve is a pair of straight lines. The angle of rotation about the axis of the screw joint θ is directly related to the distance of displacement of one body relative to the other along that axis d by the expression $d = h\theta$, where the constant h is called the pitch of the screw. When the \hat{z} axis of coordinate frame i is aligned with a helical joint axis, the formulas in Table 1.5 define the helical joint model.

Cylindrical

A cylindrical joint, often abbreviated as “C”, is a lower pair formed by contact of two congruent right circular cylinders, one an internal surface and the other an external surface. It permits both rotation about the cylinder axis and sliding parallel to it. Therefore, it is a joint with two degrees of freedom. Lower pair joints with more than one degree of freedom are easily replaced by kinematically equivalent compound joints (see Sect. 1.3.3) that are serial chains of one-degree-of-freedom lower pairs. In the present case, the cylindrical joint can be replaced by a revolute in series with a prismatic joint whose direction of sliding is parallel to the revolute

axis. While simpler to implement using the geometric representation discussed in Sect. 1.4, this approach has disadvantages for dynamic simulation. Modeling a single cylindrical joint as a combination of a prismatic and revolute joint requires the addition of a virtual link between the two with zero mass and zero length. The massless link can create computational problems. When the \hat{z} axis of coordinate frame i is aligned with a cylindrical joint axis, the formulas in Table 1.6 define the cylindrical joint model.

Spherical

A spherical joint, often abbreviated as “S”, is a lower pair formed by contact of two congruent spherical surfaces. Once again, one is an internal surface, and the other is an external surface. A spherical joint permits rotation about any line through the center of the sphere. Thus, it permits independent rotation about axes in up to three different directions and has three degrees of freedom. A spherical joint is easily replaced by a kinematically equivalent compound joint consisting of three revolutes that have concurrent axes. They do not need to be successively orthogonal, but often they are implemented that way. The arrangement is, in general, kinematically equivalent to a spherical joint, but it does exhibit a singularity when the revolute joint axes become coplanar. This is as compared to the native spherical joint that never has such a singularity. Likewise, if a spherical joint is modeled in simulation as three revolutes, computational difficulties again can arise from the necessary inclusion of massless virtual links having zero length. The joint model formulas of a spherical joint are given in Table 1.6.

Planar

A planar joint is formed by planar contacting surfaces. Like the spherical joint, it is a lower pair joint with three degrees of freedom. A kinematically equivalent compound joint consisting of a serial chain of three revolutes with parallel axes can replace a planar joint. As was the case with the spherical joint, the compound joint exhibits a singularity when the revolute axes become coplanar. When the \hat{z} axis of coordinate frame i is aligned with the normal to the plane of contact, the formulas in Table 1.6 define the planar joint model.

1.3.2 Higher Pair Joints

Some higher pair joints also have attractive properties, particularly rolling pairs in which one body rolls without slipping over the surface of the other. This is mechan-

ically attractive since the absence of sliding means the absence of abrasive wear. However, since ideal contact occurs at a point, or along a line, application of a load across the joint may lead to very high local stresses resulting in other forms of material failure and, hence, wear. Higher pair joints can be used to create kinematic joints with special geometric properties, as in the case of a gear pair, or a cam and follower pair.

Rolling Contact

Rolling contact actually encompasses several different geometries. Rolling contact in planar motion permits one degree of freedom of relative motion as in the case of a roller bearing, for example. As noted above, rolling contact has desirable wear properties since the absence of sliding means the absence of abrasive wear. Planar rolling contact can take place along a line, thereby spreading the load and wear somewhat. Three-dimensional rolling contact allows rotation about any axis through the point of contact that is, in principle, unique. Hence, a three-dimensional rolling contact pair permits relative motion with three degrees of freedom. When the \hat{z} axis of coordinate frame i is aligned with the axis of rotation and passes through the center of the roller of fixed radius r , the formulas in Table 1.6 define the planar rolling contact joint model for a roller on a flat surface.

Regardless of whether the joint is planar or three-dimensional, the *no-slip* condition associated with a rolling contact joint requires that the instantaneous relative velocity between the points on the two bodies in contact be zero. If P is the point of rolling contact between bodies i and j ,

$$\mathbf{v}_{P_i/P_j} = 0. \quad (1.41)$$

Likewise, relative acceleration is in the direction of the common normal to the two surfaces at the point of contact. Because the constraint associated with the joint is expressed in terms of velocity, it is nonholonomic, as discussed in Sect. 1.3.6. A more detailed discussion of the kinematic constraints for rolling contact is found in Sect. 17.2.2 of Chap. 17.

1.3.3 Compound Joints

Compound kinematic joints are connections between two bodies formed by chains of other members and simple kinematic joints. A compound joint may constrain the relative motion of the two bodies joined in the same way as a simple joint. In such a case, the two joints are said to be kinematically equivalent.

Universal

A universal joint, often abbreviated as “U” and referred to as a Cardan or Hooke joint, is a compound joint with two degrees of freedom. It consists of a serial chain of two revolutes whose axes intersect orthogonally. The joint model for a universal joint, in which, from Euler angle notation, α_i is the first rotation about the Z -axis and then β_i is the rotation about the Y -axis, is given in Table 1.6. This is a joint for which the matrices Φ_i and Φ_i^c are not constant, so in general, $\dot{\Phi}_i \neq 0$ and $\dot{\Phi}_i^c \neq 0$. In this case, the orientation of the outboard reference frame varies with α_i .

1.3.4 6-DOF Joint

The motion of two bodies not jointed together can be modeled as a six-degree-of-freedom *joint* that introduces no constraints. This is particularly useful for mobile robots, such as aircraft, that make at most intermittent contact with the ground, and thus, a body in free motion relative to the fixed frame is termed a *floating base*. Such a free motion joint model enables the position and orientation of a floating base in space to be expressed with six joint variables. The 6-DOF joint model is included in Table 1.6.

1.3.5 Physical Realization

In an actual robotic mechanism, the joints may have physical limits beyond which motion is prohibited. The workspace (see Sect. 1.5) of a robotic manipulator is determined by considering the combined limits and freedom of motion of all of the joints within the mechanism. Revolute joints are easily actuated by rotating motors and are, therefore, extremely common in robotic systems. They may also be present as passive, unactuated joints. Also common, although less so than revolutes, prismatic joints are relatively easily actuated by means of linear actuators such as hydraulic or pneumatic cylinders, ball screws, or screw jacks. They always have motion limits since unidirectional sliding can, in principle, produce infinite displacements. Screw joints are most often found in robotic mechanisms as constituents of linear actuators such as screw jacks and ball screws and are seldom used as primary kinematic joints. Joints with more than one degree of freedom are generally used passively in robotic mechanisms because each degree of freedom of an active joint must be separately actuated. Passive spherical joints are quite often found in robotic mechanisms, while passive planar joints are only occasionally found. The effect of an actuated spherical joint

is achieved by employing the kinematically equivalent combination of three revolutes and actuating each. Universal joints are used in robotic mechanisms in both active and passive forms.

Serial chains are commonly denoted by the abbreviations for the joints they contain in the order in which they appear in the chain. For example, an RPR chain contains three links, the first jointed to the base with a revolute and to the second with a prismatic, while the second and third are jointed together with another revolute. If all of the joints are identical, the notation consists of the number of joints preceding the joint abbreviation, such as 6R for a six-axis serial-chain manipulator containing only revolute joints.

Joints are realized with hardware that is more complex than the idealizations presented in Sects. 1.3.1 and 1.3.2. For example, a revolute joint may be achieved with a ball bearing composed of a set of bearing balls trapped between two journals. The balls ideally roll without slipping on the journals, thereby taking advantage of the special properties of rolling contact joints. A prismatic joint may be realized by means of a roller-rail assembly.

1.3.6 Holonomic and Nonholonomic Constraints

With the exception of rolling contact, all of the constraints associated with the joints discussed in the preceding sections can be expressed mathematically by equations containing only the joint position variables.

These are called holonomic constraints. The number of equations, and hence the number of constraints, is $6 - n$, where n is the number of degrees of freedom of the joint. The constraints are intrinsically part of the axial joint model.

A nonholonomic constraint is one that cannot be expressed in terms of the position variables alone, but includes the time derivative of one or more of those variables. These constraint equations cannot be integrated to obtain relationships solely between the joint variables. The most common example in robotic systems arises from the use of a wheel or roller that rolls without slipping on another member. Nonholonomic constraints, particularly as they apply to wheeled robots, are discussed in more detail in Chap. 17.

1.3.7 Generalized Coordinates

In a robot manipulator consisting of N bodies, $6N$ coordinates are required to specify the position and orientation of all the bodies relative to a coordinate frame. Since some of those bodies are jointed together, a number of constraint equations will establish relationships between some of these coordinates. In this case, the $6N$ coordinates can be expressed as functions of a smaller set of coordinates \mathbf{q} that are all independent. The coordinates in this set are known as generalized coordinates, and motions associated with these coordinates are consistent with all of the constraints. The joint variables \mathbf{q} of a robot manipulator form a set of generalized coordinates [1.24, 25].

1.4 Geometric Representation

The geometry of a robotic manipulator is conveniently defined by attaching reference frames to each link. While these frames could be located arbitrarily, it is advantageous both for consistency and computational efficiency to adhere to a convention for locating the frames on the links. *Denavit and Hartenberg* [1.26] introduced the foundational convention that has been adapted in a number of different ways, one of which is the convention introduced by *Khalil and Dombre* [1.27] used throughout this handbook. In all of its forms, the convention requires only four rather than six parameters to locate one reference frame relative to another. The four parameters are the link length a_i , the link twist α_i , the joint offset d_i , and the joint angle θ_i . This parsimony is achieved through judicious placement of the reference

frame origins and axes such that the $\hat{\mathbf{x}}$ axis of one frame both intersects and is perpendicular to the $\hat{\mathbf{z}}$ axis of the preceding reference frame. The convention is applicable to manipulators consisting of revolute and prismatic joints, so when multiple-degree-of-freedom joints are present, they are modeled as combinations of revolute and prismatic joints, as discussed in Sect. 1.3.

There are essentially four different forms of the convention for locating reference frames in a robotic mechanism. Each exhibits its own advantages by managing trade-offs of intuitive presentation. In the original *Denavit and Hartenberg* [1.26] convention, joint i is located between links i and $i + 1$, so it is on the outboard side of link i . Also, the joint offset d_i and joint angle θ_i are measured along and about the $i - 1$ joint axis, so the

subscripts of the joint parameters do not match that of the joint axis. *Waldron* [1.28] and *Paul* [1.29] modified the labeling of axes in the original convention such that joint i is located between links $i - 1$ and i in order to make it consistent with the base member of a serial chain being member 0. This places joint i at the inboard side of link i and is the convention used in all of the other modified versions. Furthermore, Waldron and Paul addressed the mismatch between subscripts of the joint parameters and joint axes by placing the \hat{z}_i axis along the $i + 1$ joint axis. This, of course, relocates the subscript mismatch to the correspondence between the joint axis and the \hat{z} axis of the reference frame. *Craig* [1.30] eliminated all of the subscript mismatches by placing the \hat{z}_i axis along joint i , but at the expense of the homogeneous transformation $i^{-1}T_i$ being formed with a mixture of joint parameters with subscript i and link parameters with subscript $i - 1$. *Khalil* and *Dombre* [1.27] introduced another variation similar to Craig's except that it defines the link parameters a_i and α_i along and about the \hat{x}_{i-1} axis. In this case, the homogeneous transformation $i^{-1}T_i$ is formed only with parameters with subscript i , and the subscript mismatch is such that a_i and α_i indicate the length and twist of link $i - 1$ rather than link i . Thus, in summary, the advantages of the convention used throughout this handbook compared to the alternative conventions are

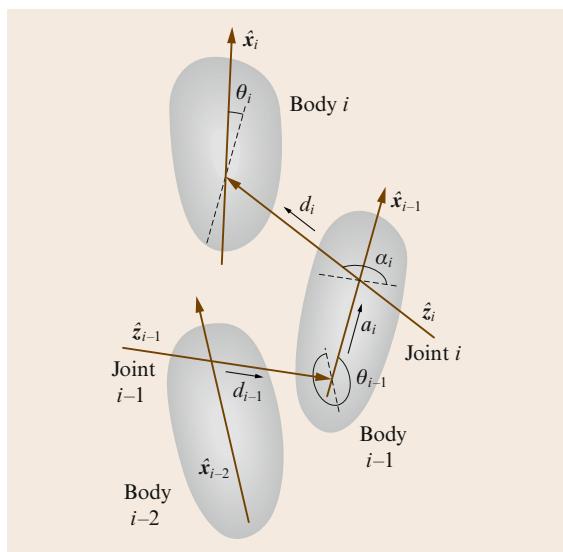

Fig. 1.2 Schematic of the numbering of bodies and joints in a robotic manipulator, the convention for attaching reference frames to the bodies, and the definitions of the four parameters, a_i , α_i , d_i , and θ_i , that locate one frame relative to another

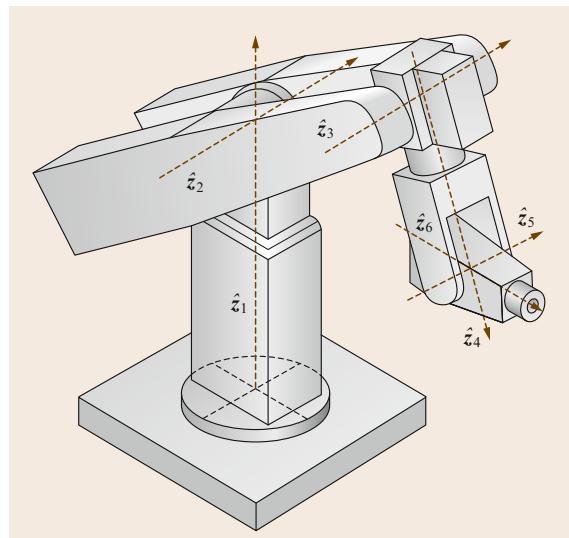

Fig. 1.3 Example six-degree-of-freedom serial chain manipulator composed of an articulated arm with no joint offsets and a spherical wrist

that the \hat{z} axes of the reference frames share the common subscript of the joint axes, and the four parameters that define the spatial transform from reference frame i to reference frame $i - 1$ all share the common subscript i .

In this handbook, the convention for serial chain manipulators is shown in Fig. 1.2 and summarized as follows. The numbering of bodies and joints follows the convention:

- the N moving bodies of the robotic mechanism are numbered from 1 to N . The number of the base is 0.
- the N joints of the robotic mechanism are numbered from 1 to N , with joint i located between members $i - 1$ and i .

With this numbering scheme, the attachment of reference frames follows the convention:

- the \hat{z}_i axis is located along the axis of joint i ,
- the \hat{x}_{i-1} axis is located along the common normal between the \hat{z}_{i-1} and \hat{z}_i axes.

Using the attached frames, the four parameters that locate one frame relative to another are defined as

- a_i is the distance from \hat{z}_{i-1} to \hat{z}_i along \hat{x}_{i-1} ,
- α_i is the angle from \hat{z}_{i-1} to \hat{z}_i about \hat{x}_{i-1} ,
- d_i is the distance from \hat{x}_{i-1} to \hat{x}_i along \hat{z}_i ,
- θ_i is the angle from \hat{x}_{i-1} to \hat{x}_i about \hat{z}_i .

Table 1.7 Geometric parameters of the example serial chain manipulator in Fig. 1.3

| i | α_i | a_i | d_i | θ_i |
|-----|------------------|-------|-------|------------|
| 1 | 0 | 0 | 0 | θ_1 |
| 2 | $-\frac{\pi}{2}$ | 0 | 0 | θ_2 |
| 3 | 0 | a_3 | 0 | θ_3 |
| 4 | $-\frac{\pi}{2}$ | 0 | d_4 | θ_4 |
| 5 | $\frac{\pi}{2}$ | 0 | 0 | θ_5 |
| 6 | $-\frac{\pi}{2}$ | 0 | 0 | θ_6 |

The geometric parameters for the example manipulator shown in Fig. 1.3 are listed in Table 1.7. All of the joints of this manipulator are revolutes, and joint 1 has a vertical orientation. Joint 2 is perpendicular to joint 1 and intersects it. Joint 3 is parallel to joint 2, and the length of link 2 is a_3 . Joint 4 is perpendicular to joint 3 and intersects it. Joint 5 likewise intersects joint 4 perpendicularly at an offset of d_4 from joint 3. Finally, joint 6 intersects joint 5 perpendicularly.

With this convention, reference frame i can be located relative to reference frame $i - 1$ by executing a rotation through an angle α_i about the \hat{x}_{i-1} axis, a translation of distance a_i along \hat{x}_{i-1} , a rotation through an angle θ_i about the \hat{z}_i axis, and a translation of distance d_i along \hat{z}_i . Through concatenation of these individual transformations,

$$\text{Rot}(\hat{x}_{i-1}, \alpha_i) \text{Trans}(\hat{x}_{i-1}, a_i) \text{Rot}(\hat{z}_i, \theta_i)$$

$$\text{Trans}(\hat{z}_i, d_i),$$

the equivalent homogeneous transformation is,

$${}^{i-1}\mathbf{T}_i = \begin{pmatrix} \cos \theta_i & -\sin \theta_i & 0 & a_i \\ \sin \theta_i \cos \alpha_i & \cos \theta_i \cos \alpha_i & -\sin \alpha_i & -\sin \alpha_i d_i \\ \sin \theta_i \sin \alpha_i & \cos \theta_i \sin \alpha_i & \cos \alpha_i & \cos \alpha_i d_i \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (1.42)$$

The identification of geometric parameters is addressed in Chap. 14.

1.5 Workspace

Most generally, the workspace of a robotic manipulator is the total volume swept out by the end-effector as the manipulator executes all possible motions. The workspace is determined by the geometry of the manipulator and the limits of the joint motions. It is more specific to define the reachable workspace as the total locus of points at which the end-effector can be placed and the dexterous workspace [1.31] as the subset of those points at which the end-effector can be placed while having an arbitrary orientation. Dexterous workspaces exist only for certain idealized geometries, so real industrial manipulators with joint motion limits almost never possess dexterous workspaces.

Many serial-chain robotic manipulators are designed such that their joints can be partitioned into a regional structure and an orientation structure. The joints in the regional structure accomplish the positioning of the end-effector in space, and the joints in the orientation structure accomplish the orientation of the end-effector. Typically, the inboard joints of a serial chain manipulator comprise the regional structure, while the outboard joints comprise the orientation structure. Also, since prismatic joints provide no capability for rotation, they are generally not employed within the orientation structure.

The regional workspace volume can be calculated from the known geometry of the serial-chain manipulator and motion limits of the joints. With three inboard joints comprising the regional structure, the area of workspace for the outer two (joints 2 and 3) is computed first, and then the volume is calculated by integrating over the joint variable of the remaining inboard joint (joint 1). In the case of a prismatic joint, this simply involves multiplying the area by the total length of travel of the prismatic joint. In the more common case of a revolute joint, it involves rotating the area about the joint axis through the full range of motion of the revolute [1.32]. By the theorem of Pappus, the associated volume V is

$$V = A\bar{r}\gamma, \quad (1.43)$$

where A is the area, \bar{r} is the distance from the area's centroid to the axis, and γ is the angle through which the area is rotated. The boundaries of the area are determined by tracing the motion of a reference point in the end-effector, typically the center of rotation of the wrist that serves as the orientation structure. Starting with each of the two joints at motion limits and with joint 2 locked, joint 3 is moved until its second motion limit is reached. Joint 3 is then locked, and joint 2 is freed to move to its second motion limit. Joint 2 is

again locked, while joint 3 is freed to move back to its original motion limit. Finally, joint 3 is locked, and joint 2 freed to move likewise to its original motion limit. In this way, the trace of the reference point is

a closed curve whose area and centroid can be calculated mathematically.

More details on manipulator workspace can be found in Chaps. 3 and 10.

1.6 Forward Kinematics

The forward kinematics problem for a serial-chain manipulator is to find the position and orientation of the end-effector relative to the base given the positions of all of the joints and the values of all of the geometric link parameters. Often, a frame fixed in the end-effector is referred to as the *tool frame*, and while fixed in the final link N , it in general has a constant offset in both position and orientation from frame N . Likewise, a *station frame* is often located in the base to establish the location of the task to be performed. This frame generally has a constant offset in its pose relative to frame 0, which is also fixed in the base.

A more general expression of the forward kinematics problem is to find the relative position and orientation of any two designated members given the geometric structure of the manipulator and the values of a number of joint positions equal to the number of degrees of freedom of the mechanism. The forward kinematics problem is critical for developing manipulator coordination algorithms because joint positions are typically measured by sensors mounted on the joints and it is necessary to calculate the positions of the joint axes relative to the fixed reference frame.

In practice, the forward kinematics problem is solved by calculating the transformation between a reference frame fixed in the end-effector and another reference frame fixed in the base, i.e., between the tool and station frames. This is straightforward for a serial chain since the transformation describing the position of the end-effector relative to the base is obtained by simply concatenating transformations between frames fixed in adjacent links of the chain. The convention for the geometric representation of a manipulator presented in Sect. 1.4 reduces this to finding an equivalent 4×4 homogeneous transformation matrix that relates the spatial displacement of the end-effector reference frame to the base reference frame.

For the example serial-chain manipulator shown in Fig. 1.3 and neglecting the addition of tool and station frames, the transformation is

$${}^0T_6 = {}^0T_1 {}^1T_2 {}^2T_3 {}^3T_4 {}^4T_5 {}^5T_6 . \quad (1.44)$$

Table 1.8 contains the elements of 0T_6 that are calculated using Table 1.7 and (1.42).

Once again, homogeneous transformations provide a compact notation, but are computationally inefficient for solving the forward kinematics problem. A reduction in computation can be achieved by separating the

Table 1.8 Forward kinematics of the example serial chain manipulator in Fig. 1.3, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$

| ${}^0T_6 = \begin{pmatrix} r_{11} & r_{12} & r_{13} & {}^0p_6^x \\ r_{21} & r_{22} & r_{23} & {}^0p_6^y \\ r_{31} & r_{32} & r_{33} & {}^0p_6^z \\ 0 & 0 & 0 & 1 \end{pmatrix},$ |
| $\begin{aligned} r_{11} = & c_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6}) \\ & - c_{\theta_1}s_{\theta_2}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) \\ & + s_{\theta_1}(s_{\theta_4}c_{\theta_5}c_{\theta_6} + c_{\theta_4}s_{\theta_6}), \end{aligned}$ |
| $\begin{aligned} r_{21} = & s_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6}) \\ & - s_{\theta_1}s_{\theta_2}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) \\ & - c_{\theta_1}(s_{\theta_4}c_{\theta_5}c_{\theta_6} + c_{\theta_4}s_{\theta_6}), \end{aligned}$ |
| $\begin{aligned} r_{31} = & (c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})(s_{\theta_4}s_{\theta_6} - c_{\theta_4}c_{\theta_5}c_{\theta_6}) \\ & + s_{\theta_2}s_{\theta_6}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}), \end{aligned}$ |
| $\begin{aligned} r_{12} = & c_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6}) \\ & + c_{\theta_1}s_{\theta_2}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) \\ & + s_{\theta_1}(c_{\theta_4}c_{\theta_6} - s_{\theta_4}c_{\theta_5}s_{\theta_6}), \end{aligned}$ |
| $\begin{aligned} r_{22} = & s_{\theta_1}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6}) \\ & + s_{\theta_1}s_{\theta_2}s_{\theta_6}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) \\ & - c_{\theta_1}(c_{\theta_4}c_{\theta_6} - s_{\theta_4}c_{\theta_5}s_{\theta_6}), \end{aligned}$ |
| $\begin{aligned} r_{32} = & (c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3})(c_{\theta_4}c_{\theta_5}s_{\theta_6} + s_{\theta_4}c_{\theta_6}) \\ & - s_{\theta_2}s_{\theta_6}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}), \end{aligned}$ |
| $\begin{aligned} r_{13} = & c_{\theta_1}c_{\theta_2}s_{\theta_5}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}) \\ & - c_{\theta_1}c_{\theta_5}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) \\ & - s_{\theta_1}s_{\theta_4}s_{\theta_5}, \end{aligned}$ |
| $\begin{aligned} r_{23} = & s_{\theta_1}c_{\theta_4}s_{\theta_5}(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}) \\ & - s_{\theta_1}c_{\theta_5}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}) + c_{\theta_1}s_{\theta_4}s_{\theta_5}, \end{aligned}$ |
| $\begin{aligned} {}^0p_6^x = & a_3c_{\theta_1}c_{\theta_2} - d_4c_{\theta_1}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}), \\ {}^0p_6^y = & a_3s_{\theta_1}c_{\theta_2} - d_4s_{\theta_1}(c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3}), \\ {}^0p_6^z = & -a_3s_{\theta_2} + d_4(s_{\theta_2}s_{\theta_3} - c_{\theta_2}c_{\theta_3}). \end{aligned}$ |

position and orientation portions of the transformation to eliminate all multiplications by the 0 and 1 elements of the matrices. In Chap. 2, calculations are made using the spatial vector notation briefly introduced here in Sect. 1.2.6 and explained in detail in Sect. 2.2. This approach does not employ homogeneous transformations, but rather separates out the rotation matrices and positions to achieve computation efficiency. Table 2.1 provides the detailed formulas, with the product of

spatial transforms particularly relevant to the forward kinematics problem.

Kinematic trees are the general structure of robot mechanisms that do not contain closed loops, and the forward kinematics of tree structures are addressed in Chap. 2. The forward kinematics problem for closed chains is much more complicated because of the additional constraints present. Solution methods for closed chains are included in Chap. 12.

1.7 Inverse Kinematics

The inverse kinematics problem for a serial-chain manipulator is to find the values of the joint positions given the position and orientation of the end-effector relative to the base and the values of all of the geometric link parameters. Once again, this is a simplified statement applying only to serial chains. A more general statement is: given the relative positions and orientations of two members of a mechanism, find the values of all of the joint positions. This amounts to finding all of the joint positions given the homogeneous transformation between the two members of interest.

In the common case of a six-degree-of-freedom serial chain manipulator, the known transformation is 0T_6 . Reviewing the formulation of this transformation in Sect. 1.6, it is clear that the inverse kinematics problem for serial-chain manipulators requires the solution of nonlinear sets of equations. In the case of a six-degree-of-freedom manipulator, three of these equations relate to the position vector within the homogeneous transformation, and the other three relate to the rotation matrix. In the latter case, these three equations cannot come from the same row or column because of the dependency within the rotation matrix. With these nonlinear equations, it is possible that no solutions exist or multiple solutions exist [1.33]. For a solution to exist, the desired position and orientation of the end-effector must lie in the workspace of the manipulator. In cases where solutions do exist, they often cannot be presented in closed form, so numerical methods are required.

1.7.1 Closed-Form Solutions

Closed-form solutions are desirable because they are faster than numerical solutions and readily identify all possible solutions. The disadvantage of closed-form solutions is that they are not general, but robot dependent. The most effective methods for finding closed-form so-

lutions are ad hoc techniques that take advantage of particular geometric features of specific mechanisms. In general, closed-form solutions can only be obtained for six-degree-of-freedom systems with special kinematic structure characterized by a large number of the geometric parameters defined in Sect. 1.4 being zero-valued. Most industrial manipulators have such structure because it permits more efficient coordination software. Sufficient conditions for a six-degree-of-freedom manipulator to have closed-form inverse kinematics solutions are [1.34–36]:

1. three consecutive revolute joint axes intersect at a common point, as in a spherical wrist;
2. three consecutive revolute joint axes are parallel.

Closed-form solution approaches are generally divided into algebraic and geometric methods.

Algebraic Methods

Algebraic methods involve identifying the significant equations containing the joint variables and manipulating them into a soluble form. A common strategy is reduction to a transcendental equation in a single variable such as,

$$C_1 \cos \theta_i + C_2 \sin \theta_i + C_3 = 0 , \quad (1.45)$$

where C_1 , C_2 , and C_3 are constants. The solution to such an equation is

$$\theta_i = 2 \tan^{-1} \left(\frac{C_2 \pm \sqrt{C_2^2 - C_3^2 + C_1^2}}{C_1 - C_3} \right) . \quad (1.46)$$

Special cases in which one or more of the constants are zero are also common.

Reduction to a pair of equations having the form,

$$\begin{aligned} C_1 \cos \theta_i + C_2 \sin \theta_i + C_3 &= 0 , \\ C_1 \sin \theta_i - C_2 \cos \theta_i + C_4 &= 0 , \end{aligned} \quad (1.47)$$

is another particularly useful strategy because only one solution results,

$$\theta_i = \text{Atan2}(-C_1 C_4 - C_2 C_3, C_2 C_4 - C_1 C_3). \quad (1.48)$$

Geometric Methods

Geometric methods involve identifying points on the manipulator relative to which position and/or orientation can be expressed as a function of a reduced set of the joint variables. This often amounts to decomposing the spatial problem into separate planar problems. The resulting equations are solved using algebraic manipulation. The two sufficient conditions for existence of a closed-form solution for a six-degree-of-freedom manipulator that are listed above enable the decomposition of the problem into inverse position kinematics and inverse orientation kinematics. This is the decomposition into regional and orientation structures discussed in Sect. 1.5, and the solution is found by rewriting (1.44),

$${}^0T_6 {}^6T_5 {}^5T_4 {}^4T_3 = {}^0T_1 {}^1T_2 {}^2T_3. \quad (1.49)$$

The example manipulator in Fig. 1.3 has this structure, and this regional structure is commonly known as an articulated or anthropomorphic arm or an elbow manipulator. The solution to the inverse position kinematics problem for such a structure is summarized in Table 1.9. Because there are two solutions for θ_1 and likewise two solutions for both θ_2 and θ_3 corresponding to each θ_1 solution, there are a total of four solutions to the inverse position kinematics problem of the articulated arm manipulator. The orientation structure is simply a spherical wrist, and the corresponding solution to the inverse orientation kinematics problem is summarized in Table 1.10. Two solutions for θ_5 are given in Table 1.10, but only one solution for both θ_4 and θ_6 corresponds to each. Thus, the inverse orientation kinematics problem of a spherical wrist has two solutions. Combining the regional

Table 1.9 Inverse position kinematics of the articulated arm within the example serial chain manipulator in Fig. 1.3

$$\begin{aligned}\theta_1 &= \text{Atan2}({}^0p_6^y, {}^0p_6^x) \\ &\text{or } \text{Atan2}(-{}^0p_6^y, -{}^0p_6^x), \\ \theta_3 &= -\text{Atan2}(D, \pm\sqrt{1-D^2}), \\ &\text{where } D := \frac{({}^0p_6^x)^2 + ({}^0p_6^y)^2 + ({}^0p_6^z)^2 - a_3^2 - d_4^2}{2a_3d_4}, \\ \theta_2 &= \text{Atan2}({}^0p_6^z, \sqrt{({}^0p_6^x)^2 + ({}^0p_6^y)^2}) \\ &\quad - \text{Atan2}(d_4 \sin \theta_3, a_3 + d_4 \cos \theta_3)\end{aligned}$$

Table 1.10 Inverse orientation kinematics of the spherical wrist within the example serial chain manipulator in Fig. 1.3, with abbreviations $c_{\theta_i} := \cos \theta_i$ and $s_{\theta_i} := \sin \theta_i$

$$\begin{aligned}\theta_5 &= \text{Atan2}(\pm\sqrt{1-(r_{13}s_{\theta_1}-r_{23}c_{\theta_1})^2}, r_{13}s_{\theta_1}-r_{23}c_{\theta_1}), \\ \theta_4 &= \text{Atan2}(\mp(r_{13}c_{\theta_1}+r_{23}s_{\theta_1})s_{(\theta_2+\theta_3)} \mp r_{33}c_{(\theta_2+\theta_3)}, \\ &\quad \pm(r_{13}c_{\theta_1}+r_{23}s_{\theta_1})c_{(\theta_2+\theta_3)} \mp r_{23}s_{(\theta_2+\theta_3)}), \\ \theta_6 &= \text{Atan2}(\pm(r_{12}s_{\theta_1}+r_{22}c_{\theta_1}), \pm(r_{11}s_{\theta_1}-r_{21}c_{\theta_1})),\end{aligned}$$

where the \pm choice for θ_5 dictates all of the subsequent \pm and \mp for θ_4 and θ_6 .

and orientation structures, the total number of inverse kinematics solutions for the manipulator in Fig. 1.3 is eight.

1.7.2 Numerical Methods

Unlike the algebraic and geometric methods used to find closed-form solutions, numerical methods are not robot dependent, so they can be applied to any kinematic structure. The disadvantages of numerical methods are that they can be slower and in some cases, they do not allow computation of all possible solutions. For a six-degree-of-freedom serial-chain manipulator with only revolute and prismatic joints, the translation and rotation equations can always be reduced to a polynomial in a single variable of degree not greater than 16 [1.37]. Thus, such a manipulator can have as many as 16 real solutions to the inverse kinematics problem [1.38]. Since closed-form solution of a polynomial equation is only possible if the polynomial is of degree four or less, it follows that many manipulator geometries are not soluble in closed form. In general, a greater number of nonzero geometric parameters corresponds to a polynomial of higher degree in the reduction. For such manipulator structures, the most common numerical methods can be divided into categories of symbolic elimination methods, continuation methods, and iterative methods.

Symbolic Elimination Methods

Symbolic elimination methods involve analytical manipulations to eliminate variables from the system of nonlinear equations to reduce it to a smaller set of equations. Raghavan and Roth [1.39] used dialytic elimination to reduce the inverse kinematics problem of a general six-revolute serial-chain manipulator to a polynomial of degree 16 and to find all possible solutions. The roots provide solutions for one of the joint variables, while the other variables are computed by solving lin-

ear systems. *Manocha* and *Canny* [1.40] improved the numerical properties of this technique by reformulating the problem as a generalized eigenvalue problem. An alternative approach to elimination makes use of Gröbner bases [1.41, 42].

Continuation Methods

Continuation methods involve tracking a solution path from a start system with known solutions to a target system whose solutions are sought as the start system is transformed into the target system. These techniques have been applied to inverse kinematics problems [1.43], and special properties of polynomial systems can be exploited to find all possible solutions [1.44].

Iterative Methods

A number of different iterative methods can be employed to solve the inverse kinematics problem. Most of them converge to a single solution based on an initial guess, so the quality of that guess greatly impacts

the solution time. Newton–Raphson methods provide a fundamental approach that uses a first-order approximation to the original equations. *Pieber* [1.34] was among the first to apply the method to inverse kinematics, and others have followed [1.45, 46]. Optimization approaches formulate the problem as a nonlinear optimization problem and employ search techniques to move from an initial guess to a solution [1.47, 48]. Resolved motion rate control converts the problem to a differential equation [1.49], and a modified predictor–corrector algorithm can be used to perform the joint velocity integration [1.50]. Control-theory-based methods cast the differential equation into a control problem [1.51]. Interval analysis [1.52] is perhaps one of the most promising iterative methods because it offers rapid convergence to a solution and can be used to find all possible solutions. For complex mechanisms, the damped least-squares approach [1.53] is particularly attractive, and more detail is provided in Chap. 11.

1.8 Forward Instantaneous Kinematics

The forward instantaneous kinematics problem for a serial-chain manipulator is: given the positions of all members of the chain and the rates of motion about all the joints, find the total velocity of the end-effector. Here the rate of motion about the joint is the angular velocity of rotation about a revolute joint or the translational velocity of sliding along a prismatic joint. The total velocity of a member is the velocity of the origin of the reference frame fixed to it combined with its angular velocity. That is, the total velocity has six independent components and therefore, completely represents the velocity field of the member. It is important to note that this definition includes an assumption that the pose of the mechanism is completely known. In most situations, this means that either the forward or inverse position kinematics problem must be solved before the forward instantaneous kinematics problem can be addressed. The same is true of the inverse instantaneous kinematics problem discussed in the following section. The forward instantaneous kinematics problem is important when doing acceleration analysis for the purpose of studying dynamics. The total velocities of the members are needed for the computation of Coriolis and centripetal acceleration components.

1.8.1 Jacobian

Differentiation with respect to time of the forward position kinematics equations yields a set of equations of the form,

$$\mathbf{v}_N = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}, \quad (1.50)$$

where \mathbf{v}_N is the spatial velocity of the end-effector, $\dot{\mathbf{q}}$ is an N -dimensional vector composed of the joint rates, and $\mathbf{J}(\mathbf{q})$ is a $6 \times N$ matrix whose elements are, in gen-

Table 1.11 Algorithm for computing the columns of the Jacobian from the free modes of the joints

| n_i | Number of degrees of freedom of joint i |
|------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------|
| \mathbf{J} | ${}^k\mathbf{v}_N = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}$, where k is any frame |
| \mathbf{J}_{n_i} | n_i column(s) of \mathbf{J} associated with $\dot{\mathbf{q}}_i$, |
| $\boldsymbol{\Phi}_{\omega}$ | first three rows of $\boldsymbol{\Phi}$, |
| $\boldsymbol{\Phi}_v$ | last three rows of $\boldsymbol{\Phi}$, |
| | $\mathbf{J}_{n_i} = {}^k\mathbf{X}_i \boldsymbol{\Phi}_i$, |
| Expression | Computed value |
| $\mathbf{X}_1 \mathbf{X}_2$ | $(\mathbf{R}_1 \mathbf{R}_2; \mathbf{p}_2 + \mathbf{R}_2^T \mathbf{p}_1)$ |
| $\mathbf{X}\boldsymbol{\Phi}$ | $(\mathbf{R}\boldsymbol{\Phi}_{\omega}; \mathbf{R}(\boldsymbol{\Phi}_v - \mathbf{p} \times \boldsymbol{\Phi}_{\omega}))$ |
| \mathbf{X}^{-1} | $(\mathbf{R}^T; -\mathbf{R}\mathbf{p})$ |
| $\mathbf{X}^{-1}\boldsymbol{\Phi}$ | $(\mathbf{R}^T \boldsymbol{\Phi}_{\omega}; \mathbf{R}^T \boldsymbol{\Phi}_v + \mathbf{p} \times \mathbf{R}^T \boldsymbol{\Phi}_{\omega})$ |

eral, nonlinear functions of q_1, \dots, q_N . $\mathbf{J}(q)$ is called the Jacobian matrix of this algebraic system and is expressed relative to the same reference frame as the spatial velocity v_N [1.54]. If the joint positions are known, (1.50) yields six linear algebraic equations in the joint rates. If the joint rates are given, a solution of (1.50) is a solution of the forward instantaneous kinematics problem. Note that $\mathbf{J}(q)$ can be regarded as a known matrix for this purpose provided all the joint positions are known.

Using the spatial vector notation briefly introduced in Sect. 1.2.6 and explained in detail in Sect. 2.2, the

Jacobian can be easily computed from the free modes Φ_i of the joints and the associated spatial transforms ${}^j X_i$. The column(s) of $\mathbf{J}(q)$ associated with joint rate(s) \dot{q}_i is (are)

$${}^k X_i \Phi_i ,$$

where k denotes any reference frame relative to which v_N is expressed. Table 1.11 contains an algorithm for efficiently computing the columns of the Jacobian in this manner. Additional information about Jacobians can be found in Chap. 11.

1.9 Inverse Instantaneous Kinematics

The important problem from the point of view of robotic coordination is the inverse instantaneous kinematics problem. More information on robot coordination can be found in Chaps. 5 and 6. The inverse instantaneous kinematics problem for a serial chain manipulator is: given the positions of all members of the chain and the total velocity of the end-effector, find the rates of motion of all joints. When controlling a movement of an industrial robot which operates in the point-to-point mode, it is not only necessary to compute the final joint positions needed to assume the desired final hand position. It is also necessary to generate a smooth trajectory for motion between the initial and final positions. There are, of course, an infinite number of possible trajectories for this purpose. However, the most straightforward and successful approach employs algorithms based on the solution of the inverse instantaneous kinematics problem. This technique originated in the work of Whitney [1.55] and of Pieper [1.34].

1.9.1 Inverse Jacobian

In order to solve the linear system of equations in the joint rates obtained by decomposing (1.50) into its com-

ponent equations when v_N is known, it is necessary to invert the Jacobian matrix. The equation becomes

$$\dot{\mathbf{q}} = \mathbf{J}^{-1}(q)v_N . \quad (1.51)$$

Since \mathbf{J} is a 6×6 matrix, numerical inversion is not very attractive in real-time software which must run at computation cycle rates on the order of 100 Hz or more. Worse, it is quite possible for \mathbf{J} to become singular ($|\mathbf{J}| = 0$). The inverse does not then exist. More information on singularities can be found in Chaps. 3 and 12. Even when the Jacobian matrix does not become singular, it may become ill-conditioned, leading to degraded performance in significant portions of the manipulator's workspace. Most industrial robot geometries are simple enough that the Jacobian matrix can be inverted analytically, leading to a set of explicit equations for the joint rates [1.56–58]. This greatly reduces the number of computation operations needed as compared to numerical inversion. For more complex manipulator geometries, though, numerical inversion is the only solution option. The Jacobian of a redundant manipulator is not square, so it cannot be inverted. Chapter 11 discusses how various pseudoinverses can be used in such cases.

1.10 Static Wrench Transmission

Static wrench analysis of a manipulator establishes the relationship between wrenches applied to the end-effector and forces/torques applied to the joints. This is essential for controlling a manipulator's interactions with its environment. Examples include tasks involving fixed or quasi-fixed workpieces such as inserting a component in place with a specified force and tightening a nut to a prescribed torque. More information can be

found in Chaps. 7 and 27. Through the principle of virtual work, the relationship between wrenches applied to the end-effector and forces/torques applied to the joints can be shown to be

$$\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{f} , \quad (1.52)$$

where $\boldsymbol{\tau}$ is the n -dimensional vector of applied joint forces/torques for an n -degree-of-freedom manipulator

and f is the spatial force vector

$$\mathbf{f} = \begin{pmatrix} \mathbf{n} \\ \mathbf{f} \end{pmatrix} \quad (1.53)$$

in which \mathbf{n} and \mathbf{f} are the vectors of torques and forces, respectively, applied to the end-effector, both expressed in the reference frame relative to which

the Jacobian is also expressed. Thus, in the same way the Jacobian maps the joint rates to the spatial velocity of the end-effector, its transpose maps the wrenches applied to the end-effector to the equivalent joint forces/torques. As in the velocity case, when the Jacobian is not square, the inverse relationship is not uniquely defined.

1.11 Conclusions and Further Reading

This chapter presents an overview of how the fundamentals of kinematics can be applied to robotic mechanisms. The topics include various representations of the position and orientation of a rigid body in space, the freedom of motion and accompanying mathematical models of joints, a geometric representation that describes the bodies and joints of a robotics mechanism, the workspace of a manipulator, the problems of forward and inverse kinematics, the problems of forward and inverse instantaneous kinematics including the definition of the Jacobian, and finally the transmission of static wrenches. This chapter is certainly not a comprehensive account of robot kinematics. Fortunately, a number of excellent texts provide a broad introduction to robotics with significant focus on kinematics [1.17, 27, 29, 30, 51, 59–63].

From a historical perspective, robotics fundamentally changed the nature of the field of mechanism kinematics. Before the first work on the generation of coordination equations for robots [1.34, 55], the focus of the field was almost entirely on single-degree-of-freedom mechanisms. This is why robotics, following on from the advent of digital computing, led to a renaissance of work in mechanism kinematics. More details can be found in Chap. 3. The evolution of the field has continued as it has broadened from the study of simple serial chains for industrial robots, the focus of the analysis in this chapter, to parallel machines (see Chap. 12), human-like grippers (Chap. 15), robotic vehicles (Chap. 16 and Chap. 17), and even small-scale robots (see Chap. 18).

Dynamics

2. Dynamics

Roy Featherstone, David E. Orin

Part A | 2

The dynamic equations of motion provide the relationships between actuation and contact forces acting on robot mechanisms, and the acceleration and motion trajectories that result. Dynamics is important for mechanical design, control, and simulation. A number of algorithms are important in these applications, and include computation of the following: *inverse dynamics*, *forward dynamics*, the *joint-space inertia matrix*, and the *operational-space inertia matrix*. This chapter provides efficient algorithms to perform each of these calculations on a rigid-body model of a robot mechanism. The algorithms are presented in their most general form and are applicable to robot mechanisms with general connectivity, geometry, and joint types. Such mechanisms include fixed-base robots, mobile robots, and parallel robot mechanisms.

In addition to the need for computational efficiency, algorithms should be formulated with a compact set of equations for ease of development and implementation. The use of spatial notation has been very effective in this regard, and is used in presenting the dynamics algorithms. Spatial vector algebra is a concise vector notation for describing rigid-body velocity, acceleration, inertia, etc., using six-dimensional (6-D) vectors and tensors.

The goal of this chapter is to introduce the reader to the subject of robot dynamics and to provide the reader with a rich set of algorithms, in a compact form, that they may apply to their particular robot mechanism. These algorithms are presented in tables for ready access.

2.1 Overview

Robot dynamics provides the relationships between actuation and contact forces, and the acceleration and motion trajectories that result. The dynamic equations of motion provide the basis for a number of computational algorithms that are useful in mechanical design, control, and simulation. A growing area of their use is in computer animation of mobile systems, especially using human and humanoid models. In this Chapter, the fundamental dynamic relationships for robot mechanisms are presented, along with efficient algorithms for the most common computations. Spatial vector notation, a concise representation which makes use of 6-D vectors and tensors, is used in the algorithms.

This chapter presents efficient low-order algorithms for four major computations:

1. inverse dynamics, in which the required joint actuator torques/forces are computed from a specification of the robot's trajectory (position, velocity, and acceleration),
2. forward dynamics in which the applied joint actuator torques/forces are specified and the joint accelerations are to be determined,
3. the joint-space inertia matrix, which maps the joint accelerations to the joint torques/forces, and
4. the operational-space inertia matrix, which maps task accelerations to task forces in operational or Cartesian space.

Inverse dynamics is used in feedforward control. Forward dynamics is required for simulation. The joint-space inertia (mass) matrix is used in analysis, in feedback control to linearize the dynamics, and is an integral part of many forward dynamics formulations. The operational-space inertia matrix is used in control at the task or end-effector level.

2.1.1 Spatial Vector Notation

Section 2.2 presents the spatial vector notation, which is used to express the algorithms in this chapter in a clear and concise manner. It was originally developed by *Featherstone* [2.1] to provide a concise vector no-

tation for describing rigid-body velocity, acceleration, inertia, etc., using 6-D vectors and tensors. Section 2.2 explains the meanings of spatial vectors and operators, and provides a detailed tabulation of the correspondence between spatial and standard three-dimensional (3-D) quantities and operators, so that the algorithms in the later sections can be understood. Formulae for efficient computer implementation of spatial arithmetic are also provided. Effort is taken in the discussion of spatial vectors to distinguish between the coordinate vectors and the quantities they represent. This illuminates some of the important characteristics of spatial vectors.

2.1.2 Canonical Equations

The dynamic equations of motion are provided in Sect. 2.3 in two fundamental forms: the joint-space formulation and the operational-space formulation. The terms in the joint-space formulation have traditionally been derived using a Lagrangian approach in which they are developed independently of any reference coordinate frame. The Lagrange formulation provides a description of the relationship between the joint actuator forces and the motion of the mechanism, and fundamentally operates on the kinetic and potential energy in the system. The resulting joint-space formulation has a number of notable properties that have proven useful for developing control algorithms. The equations to relate the terms in the joint-space and operational-space formulations, along with an impact model, are also provided in this section.

2.1.3 Dynamic Models of Rigid-Body Systems

The algorithms in this chapter are model-based and require a data structure describing a robot mechanism as one of their input arguments. Section 2.4 gives a description of the components of this model: a connectivity graph, link geometry parameters, link inertia parameters, and a set of joint models. The description of the connectivity is general so that it covers both kinematic

trees and closed-loop mechanisms. Kinematic trees and the spanning tree for a closed-loop mechanism share a common notation. In order to describe the link and joint geometry, two coordinate frames are associated with each joint, one each attached to the *predecessor* and *successor* links. The successor frame is defined to be compatible with the modified Denavit–Hartenberg convention of *Craig* [2.2] for single-degree-of-freedom (**DOF**) joints. The predecessor frame may be defined in a convenient manner to describe a general multi-**DOF** joint. The relationship between connected links is described using the general joint model of *Roberson* and *Schwertassek* [2.3]. A humanoid robot is given as an example to illustrate the link and joint numbering scheme, as well as the assignment of coordinate frames to describe the links and joints. The example includes a floating base, and revolute, universal, and spherical joints.

2.1.4 Kinematic Trees

The algorithms presented in Sect. 2.5 calculate the inverse dynamics, forward dynamics, joint-space inertia matrix, and operational-space inertia matrix for any robot mechanism that is a kinematic tree. An $O(n)$ algorithm for inverse dynamics is provided, where n is the number of degrees of freedom in the mechanism. It uses a Newton–Euler formulation of the problem, and is based on the very efficient recursive Newton–Euler algorithm (**RNEA**) of *Luh*, *Walker*, and *Paul* [2.4]. Two algorithms are provided for forward dynamics. The first is the $O(n)$ articulated-body algorithm (**ABA**) which was developed by *Featherstone* [2.1]. The second is the $O(n^2)$ composite-rigid-body algorithm (**CRBA**), developed by *Walker* and *Orin* [2.5], to compute the joint-space inertia matrix (**JSIM**). This matrix, together with a vector computed using the **RNEA**, provide the coefficients of the equation of motion, which can then be solved directly for the accelerations [2.5]. The

operational-space inertia matrix (**OSIM**) is a kind of articulated-body inertia, and two algorithms are given to calculate it. The first uses the basic definition of the **OSIM**, and the second is a straightforward $O(n)$ algorithm which is based on efficient solution of the forward dynamics problem. The inputs, outputs, model data, and pseudocode for each algorithm are summarized in tables for ready access.

2.1.5 Kinematic Loops

The above algorithms apply only to mechanisms having the connectivity of kinematic trees, including unbranched kinematic chains. A final algorithm is provided in Sect. 2.6 for the forward dynamics of closed-loop systems, including parallel robot mechanisms. The algorithm makes use of the dynamic equations of motion for a spanning tree of the closed-loop system, and supplements these with loop-closure constraint equations. Three different methods are outlined to solve the resulting linear system of equations. Method 2 is particularly useful if $n \gg n^c$, where n^c is the number of constraints due to the loop-closing joints. This method offers the opportunity to use $O(n)$ algorithms on the spanning tree [2.6]. The section ends with an efficient algorithm to compute the loop-closure constraints by transforming them to a single coordinate system. Since the loop-closure constraint equations are applied at the acceleration level, standard *Baumgarte* stabilization [2.7] is used to prevent the accumulation of position and velocity errors in the loop-closure constraints.

The final section in this chapter provides a conclusion and suggestions for further reading. The area of robot dynamics has been, and continues to be, a very rich area of investigation. This section outlines the major contributions that have been made in the area and the work most often cited. Unfortunately, space does not permit us to provide a comprehensive review of the extensive literature in the area.

2.2 Spatial Vector Notation

There is no single standard notation for robot dynamics. The notations currently in use include 3-D vectors, 4×4 matrices, and several types of 6-D vector: screws, motors, Lie algebra elements, and spatial vectors. Six-dimensional vector notations are generally the best, being more compact than 3-D vectors, and more powerful than 4×4 matrices. We therefore use 6-D vectors throughout this chapter. In particular, we shall use the

spatial vector algebra described in [2.8]. This section provides a brief summary of spatial vectors. Descriptions of 4×4 matrix notations can be found in [2.2, 9], and descriptions of other 6-D vector notations can be found in [2.10–12].

In this handbook, vectors are usually denoted by bold italic letters (e.g., f , v). However, to avoid a few name clashes, we shall use upright bold letters to denote spatial

vectors (e.g., \mathbf{f} , \mathbf{v}). Note that this applies only to vectors, not tensors. Also, *in this section only*, we will underline coordinate vectors to distinguish them from the vectors that they represent (e.g., $\underline{\mathbf{v}}$ and $\underline{\mathbf{y}}$, representing \mathbf{v} and \mathbf{v}).

2.2.1 Motion and Force

For mathematical reasons, it is useful to distinguish between those vectors that describe the motions of rigid bodies, and those that describe the forces acting upon them. We therefore place motion vectors in a vector space called M^6 , and force vectors in a space called F^6 . (The superscripts indicate the dimension.) Motion vectors describe quantities like velocity, acceleration, infinitesimal displacement, and directions of motion freedom; force vectors describe force, momentum, contact normals, and so on.

2.2.2 Basis Vectors

Suppose that \mathbf{v} is a 3-D vector, and that $\underline{\mathbf{v}} = (v_x, v_y, v_z)^T$ is the Cartesian coordinate vector that represents \mathbf{v} in the orthonormal basis $\{\hat{x}, \hat{y}, \hat{z}\}$. The relationship between \mathbf{v} and $\underline{\mathbf{v}}$ is then given by the formula

$$\mathbf{v} = \hat{x}v_x + \hat{y}v_y + \hat{z}v_z.$$

This same idea applies also to spatial vectors, except that we use Plücker coordinates instead of Cartesian coordinates, and a Plücker basis instead of an orthonormal basis.

Plücker coordinates were introduced in Sect. 1.2.6, but the basis vectors are shown in Fig. 2.1. There are 12 basis vectors in total: six for motion vectors and six for forces. Given a Cartesian coordinate frame, O_{xyz} , the Plücker basis vectors are defined as follows: three unit rotations about the directed lines Ox , Oy , and Oz , denoted by \mathbf{d}_{Ox} , \mathbf{d}_{Oy} , and \mathbf{d}_{Oz} , three unit translations in the directions x , y , and z , denoted by \mathbf{d}_x , \mathbf{d}_y , and \mathbf{d}_z , three unit couples about the x , y , and z directions,

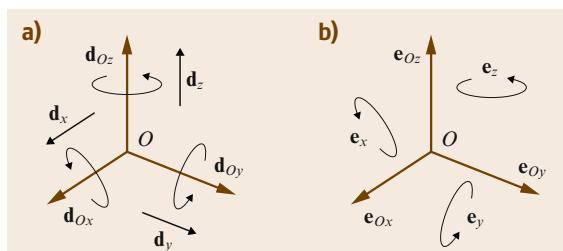

Fig. 2.1a,b Plücker basis vectors for motions (a) and forces (b)

denoted by \mathbf{e}_x , \mathbf{e}_y , and \mathbf{e}_z , and three unit forces along the lines Ox , Oy , and Oz , denoted by \mathbf{e}_{Ox} , \mathbf{e}_{Oy} , and \mathbf{e}_{Oz} .

2.2.3 Spatial Velocity and Force

Given any point O , the velocity of a rigid body can be described by a pair of 3-D vectors, $\boldsymbol{\omega}$ and \mathbf{v}_O , which specify the body's angular velocity and the linear velocity of the body-fixed point currently at O . Note that \mathbf{v}_O is not the velocity of O itself, but the velocity of the body-fixed point that happens to coincide with O at the current instant.

The velocity of this same rigid body can also be described by a single spatial motion vector, $\mathbf{v} \in M^6$. To obtain \mathbf{v} from $\boldsymbol{\omega}$ and \mathbf{v}_O , we first introduce a Cartesian frame, O_{xyz} , with its origin at O . This frame defines a Cartesian coordinate system for $\boldsymbol{\omega}$ and \mathbf{v}_O , and also a Plücker coordinate system for \mathbf{v} . Given these coordinate systems, it can be shown that

$$\mathbf{v} = \mathbf{d}_{Ox}\omega_x + \mathbf{d}_{Oy}\omega_y + \mathbf{d}_{Oz}\omega_z + \mathbf{d}_x v_{Ox} + \mathbf{d}_y v_{Oy} + \mathbf{d}_z v_{Oz}, \quad (2.1)$$

where ω_x, \dots, v_{Oz} are the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O in O_{xyz} . Thus, the Plücker coordinates of \mathbf{v} are the Cartesian coordinates of $\boldsymbol{\omega}$ and \mathbf{v}_O . The coordinate vector representing \mathbf{v} in O_{xyz} can be written

$$\underline{\mathbf{v}}_O = \begin{pmatrix} \omega_x \\ \vdots \\ v_{Oz} \end{pmatrix} = \begin{pmatrix} \boldsymbol{\omega} \\ \underline{\mathbf{v}}_O \end{pmatrix}. \quad (2.2)$$

The notation on the far right of this equation is simply a convenient abbreviation of the list of Plücker coordinates.

The definition of spatial force is very similar. Given any point O , any system of forces acting on a single rigid body is equivalent to a single force \mathbf{f} acting on a line passing through O , together with a pure couple, \mathbf{n}_O , which is the moment of the force system about O . Thus, the two vectors \mathbf{f} and \mathbf{n}_O describe the force acting on a rigid body in much the same way that $\boldsymbol{\omega}$ and \mathbf{v}_O describe its velocity. This same force can also be described by a single spatial force vector, $\mathbf{f} \in F^6$. Introducing the frame O_{xyz} , as before, it can be shown that

$$\mathbf{f} = \mathbf{e}_x n_{Ox} + \mathbf{e}_y n_{Oy} + \mathbf{e}_z n_{Oz} + \mathbf{e}_{Ox} f_x + \mathbf{e}_{Oy} f_y + \mathbf{e}_{Oz} f_z, \quad (2.3)$$

where n_{Ox}, \dots, f_z are the Cartesian coordinates of \mathbf{n}_O and \mathbf{f} in O_{xyz} . The coordinate vector representing \mathbf{f} in

O_{xyz} can then be written

$$\underline{\mathbf{f}}_O = \begin{pmatrix} n_{Ox} \\ \vdots \\ f_z \end{pmatrix} = \begin{pmatrix} \underline{n}_O \\ \underline{f} \end{pmatrix}. \quad (2.4)$$

Again, these are the Plücker coordinates of \mathbf{f} in O_{xyz} , and the notation on the far right is simply a convenient abbreviation of the list of Plücker coordinates.

2.2.4 Addition and Scalar Multiplication

Spatial vectors behave in the obvious way under addition and scalar multiplication. For example, if \mathbf{f}_1 and \mathbf{f}_2 both act on the same rigid body, then their resultant is $\mathbf{f}_1 + \mathbf{f}_2$; if two different bodies have velocities of \mathbf{v}_1 and \mathbf{v}_2 , then the velocity of the second body relative to the first is $\mathbf{v}_2 - \mathbf{v}_1$; and if \mathbf{f} denotes a force of 1 N acting along a particular line in space, then $\alpha \mathbf{f}$ denotes a force of α N acting along the same line.

2.2.5 Scalar Product

A scalar product is defined between any two spatial vectors, provided that one of them is a motion and the other a force. Given any $\mathbf{m} \in \mathbb{M}^6$ and $\mathbf{f} \in \mathbb{F}^6$, the scalar product can be written either $\mathbf{f} \cdot \mathbf{m}$ or $\mathbf{m} \cdot \mathbf{f}$, and expresses the work done by a force \mathbf{f} acting on a body with motion \mathbf{m} . Expressions like $\mathbf{f} \cdot \mathbf{f}$ and $\mathbf{m} \cdot \mathbf{m}$ are not defined. If $\underline{\mathbf{m}}$ and $\underline{\mathbf{f}}$ are coordinate vectors representing \mathbf{m} and \mathbf{f} in the same coordinate system, then

$$\mathbf{m} \cdot \mathbf{f} = \underline{\mathbf{m}}^T \underline{\mathbf{f}}. \quad (2.5)$$

2.2.6 Coordinate Transforms

Motion and force vectors obey different transformation rules. Let A and B be two coordinate frames, each defining a coordinate system of the same name; and let $\underline{\mathbf{m}}_A$, $\underline{\mathbf{m}}_B$, $\underline{\mathbf{f}}_A$, and $\underline{\mathbf{f}}_B$ be coordinate vectors representing the spatial vectors $\mathbf{m} \in \mathbb{M}^6$ and $\mathbf{f} \in \mathbb{F}^6$ in A and B coordinates, respectively. The transformation rules are then

$$\underline{\mathbf{m}}_B = {}^B\mathbf{X}_A \underline{\mathbf{m}}_A \quad (2.6)$$

and

$$\underline{\mathbf{f}}_B = {}^B\mathbf{X}_A^F \underline{\mathbf{f}}_A, \quad (2.7)$$

where ${}^B\mathbf{X}_A$ and ${}^B\mathbf{X}_A^F$ are the coordinate transformation matrices from A to B for motion and force vectors,

respectively. These matrices are related by the identity

$${}^B\mathbf{X}_A^F \equiv ({}^B\mathbf{X}_A)^{-T} \equiv ({}^A\mathbf{X}_B)^T. \quad (2.8)$$

Suppose that the position and orientation of frame A relative to frame B is described by a position vector ${}^B\mathbf{p}_A$ and a 3×3 rotation matrix ${}^B\mathbf{R}_A$, as described in Sect. 1.2. The formula for ${}^B\mathbf{X}_A$ is then

$$\begin{aligned} {}^B\mathbf{X}_A &= \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ S({}^B\mathbf{p}_A) & \mathbf{1} \end{pmatrix} \begin{pmatrix} {}^B\mathbf{R}_A & \mathbf{0} \\ \mathbf{0} & {}^B\mathbf{R}_A \end{pmatrix} \\ &= \begin{pmatrix} {}^B\mathbf{R}_A & \mathbf{0} \\ S({}^B\mathbf{p}_A) {}^B\mathbf{R}_A & {}^B\mathbf{R}_A \end{pmatrix}, \end{aligned} \quad (2.9)$$

and its inverse is

$${}^A\mathbf{X}_B = \begin{pmatrix} {}^A\mathbf{R}_B & \mathbf{0} \\ \mathbf{0} & {}^A\mathbf{R}_B \end{pmatrix} \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ -S({}^B\mathbf{p}_A) & \mathbf{1} \end{pmatrix}. \quad (2.10)$$

The quantity $S(\underline{\mathbf{p}})$ is the skew-symmetric matrix that satisfies $S(\underline{\mathbf{p}})\underline{\mathbf{v}} = \underline{\mathbf{p}} \times \underline{\mathbf{v}}$ for any 3-D vector $\underline{\mathbf{v}}$. It is defined by the equation

$$S(\underline{\mathbf{p}}) = \begin{pmatrix} 0 & -p_z & p_y \\ p_z & 0 & -p_x \\ -p_y & p_x & 0 \end{pmatrix}. \quad (2.11)$$

2.2.7 Vector Products

There are two vector (cross) products defined on spatial vectors. The first takes two motion-vector arguments, and produces a motion-vector result. It is defined by the formula

$$\begin{aligned} \underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_2 &= \begin{pmatrix} \underline{\mathbf{m}}_1 \\ \underline{\mathbf{m}}_{1O} \end{pmatrix} \times \begin{pmatrix} \underline{\mathbf{m}}_2 \\ \underline{\mathbf{m}}_{2O} \end{pmatrix} \\ &= \begin{pmatrix} \underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_2 \\ \underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_{2O} + \underline{\mathbf{m}}_{1O} \times \underline{\mathbf{m}}_2 \end{pmatrix}. \end{aligned} \quad (2.12)$$

The second takes a motion vector as left-hand argument and a force vector as right-hand argument, and produces a force-vector result. It is defined by the formula

$$\begin{aligned} \underline{\mathbf{m}} \times \underline{\mathbf{f}} &= \begin{pmatrix} \underline{\mathbf{m}} \\ \underline{\mathbf{m}}_O \end{pmatrix} \times \begin{pmatrix} \underline{\mathbf{f}}_O \\ \underline{\mathbf{f}} \end{pmatrix} \\ &= \begin{pmatrix} \underline{\mathbf{m}} \times \underline{\mathbf{f}}_O + \underline{\mathbf{m}}_O \times \underline{\mathbf{f}} \\ \underline{\mathbf{m}} \times \underline{\mathbf{f}} \end{pmatrix}. \end{aligned} \quad (2.13)$$

These products arise in differentiation formulae.

It is possible to define a spatial cross-product operator, in analogy with (2.11), as follows:

$$\underline{S}(\underline{\mathbf{m}}) = \begin{pmatrix} S(\underline{\mathbf{m}}) & \mathbf{0} \\ S(\underline{\mathbf{m}}_O) & S(\underline{\mathbf{m}}) \end{pmatrix}, \quad (2.14)$$

in which case

$$\underline{\mathbf{m}}_1 \times \underline{\mathbf{m}}_2 = \underline{S}(\underline{\mathbf{m}}_1) \underline{\mathbf{m}}_2, \quad (2.15)$$

but

$$\underline{\mathbf{m}} \times \underline{\mathbf{f}} = -\underline{S}(\underline{\mathbf{m}})^T \underline{\mathbf{f}}. \quad (2.16)$$

Observe that $\underline{S}(\underline{\mathbf{m}})$ maps motion vectors to motion vectors, but $\underline{S}(\underline{\mathbf{m}})^T$ maps force vectors to force vectors.

2.2.8 Differentiation

The derivative of a spatial vector is defined by

$$\frac{d}{dx} \mathbf{s}(x) = \lim_{\delta x \rightarrow 0} \frac{\mathbf{s}(x + \delta x) - \mathbf{s}(x)}{\delta x}, \quad (2.17)$$

where \mathbf{s} here stands for any spatial vector. The derivative is a spatial vector of the same kind (motion or force) as that being differentiated.

The formula for differentiating a spatial coordinate vector in a moving coordinate system is

$$\left(\frac{d}{dt} \mathbf{s} \right)_A = \frac{d}{dt} \underline{\mathbf{s}}_A + \underline{\mathbf{v}}_A \times \underline{\mathbf{s}}_A, \quad (2.18)$$

where \mathbf{s} is any spatial vector, $d\mathbf{s}/dt$ is the time derivative of \mathbf{s} , A is the moving coordinate system, $(d\mathbf{s}/dt)_A$ is the coordinate vector that represents $d\mathbf{s}/dt$ in A coordinates, $\underline{\mathbf{s}}_A$ is the coordinate vector that represents \mathbf{s} in A coordinates, $d\underline{\mathbf{s}}_A/dt$ is the time derivative of $\underline{\mathbf{s}}_A$ (which is the componentwise derivative, since $\underline{\mathbf{s}}_A$ is a coordinate vector), and $\underline{\mathbf{v}}_A$ is the velocity of the A coordinate frame, expressed in A coordinates.

The time derivative of a spatial vector that changes only because it is moving is given by

$$\frac{d}{dt} \mathbf{s} = \mathbf{v} \times \mathbf{s}, \quad (2.19)$$

where \mathbf{v} is the velocity of \mathbf{s} . This formula is useful for differentiating quantities that do not change in their own right, but are attached to moving rigid bodies (e.g., joint axis vectors).

2.2.9 Acceleration

Spatial acceleration is defined as the rate of change of spatial velocity. Unfortunately, this means that spatial

acceleration differs from the classical textbook definition of rigid-body acceleration, which we shall call *classical acceleration*. Essentially, the difference can be summarized as follows:

$$\underline{\mathbf{a}} = \begin{pmatrix} \dot{\underline{\omega}} \\ \dot{\underline{v}}_O \end{pmatrix} \quad \text{and} \quad \underline{\mathbf{a}}' = \begin{pmatrix} \dot{\underline{\omega}} \\ \dot{\underline{v}}'_O \end{pmatrix}, \quad (2.20)$$

where $\underline{\mathbf{a}}$ is the spatial acceleration, $\underline{\mathbf{a}}'$ is the classical acceleration, $\dot{\underline{v}}_O$ is the derivative of \underline{v}_O taking O to be fixed in space, and $\dot{\underline{v}}'_O$ is the derivative of \underline{v}_O taking O to be fixed in the body. The two accelerations are related by

$$\underline{\mathbf{a}}' = \underline{\mathbf{a}} + \begin{pmatrix} \mathbf{0} \\ \underline{\omega} \times \underline{v}_O \end{pmatrix}. \quad (2.21)$$

If \mathbf{r} is a position vector giving the position of the body-fixed point at O relative to any fixed point, then

$$\begin{aligned} \underline{v}_O &= \dot{\mathbf{r}}, \\ \dot{\underline{v}}'_O &= \ddot{\mathbf{r}}, \\ \dot{\underline{v}}_O &= \ddot{\mathbf{r}} - \underline{\omega} \times \underline{v}_O. \end{aligned} \quad (2.22)$$

The practical difference is that spatial accelerations are easier to use. For example, if the bodies B_1 and B_2 have velocities of \mathbf{v}_1 and \mathbf{v}_2 , respectively, and \mathbf{v}_{rel} is the relative velocity of B_2 with respect to B_1 , then

$$\mathbf{v}_2 = \mathbf{v}_1 + \mathbf{v}_{\text{rel}}.$$

The relationship between their spatial accelerations is obtained simply by differentiating the velocity formula:

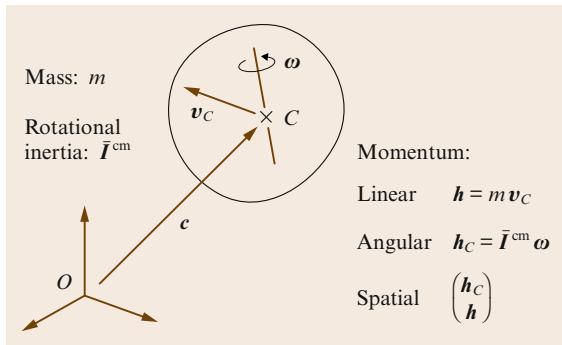

$$\frac{d}{dt} (\mathbf{v}_2 = \mathbf{v}_1 + \mathbf{v}_{\text{rel}}) \Rightarrow \underline{\mathbf{a}}_2 = \underline{\mathbf{a}}_1 + \underline{\mathbf{a}}_{\text{rel}}.$$

Observe that spatial accelerations are composed by addition, exactly like velocities. There are no Coriolis or centrifugal terms to worry about. This is a significant improvement on the formulae for composing classical accelerations, such as those in [2.2, 13, 14].

2.2.10 Spatial Momentum

Suppose that a rigid body has a mass of m , a center of mass at C , and a rotational inertia of \bar{I}^{cm} about C (Fig. 2.2). If this body is moving with a spatial velocity of $\underline{\mathbf{v}}_C = (\underline{\omega}^T \underline{v}_C^T)^T$, then its linear momentum is $\underline{\mathbf{h}} = m \underline{\mathbf{v}}_C$, and its intrinsic angular momentum is $\underline{\mathbf{h}}_C = \bar{I}^{\text{cm}} \underline{\omega}$. Its moment of momentum about a general point, O , is $\underline{\mathbf{h}}_O = \underline{\mathbf{h}}_C + \underline{\mathbf{c}} \times \underline{\mathbf{h}}$, where $\underline{\mathbf{c}} = \overrightarrow{OC}$. We can assemble these vectors into a spatial momentum vector as follows:

$$\underline{\mathbf{h}}_C = \begin{pmatrix} \underline{\mathbf{h}}_C \\ \underline{\mathbf{h}} \end{pmatrix} = \begin{pmatrix} \bar{I}^{\text{cm}} \underline{\omega} \\ m \underline{\mathbf{v}}_C \end{pmatrix} \quad (2.23)$$

**Fig. 2.2** Spatial momentum

and

$$\underline{h}_O = \begin{pmatrix} \underline{h}_O \\ \underline{h} \end{pmatrix} = \begin{pmatrix} 1 & S(\underline{c}) \\ \mathbf{0} & 1 \end{pmatrix} \underline{h}_C . \quad (2.24)$$

Spatial momentum is a force vector, and transforms accordingly.

2.2.11 Spatial Inertia

The spatial momentum of a rigid body is the product of its spatial inertia and velocity:

$$\mathbf{h} = \mathbf{I}\mathbf{v}, \quad (2.25)$$

where \mathbf{I} is the spatial inertia. Expressed in Plücker coordinates at C , we have

$$\underline{h}_C = \underline{I}_C \underline{v}_C , \quad (2.26)$$

which implies

$$\underline{I}_C = \begin{pmatrix} \bar{I}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} . \quad (2.27)$$

This is the general formula for the spatial inertia of a rigid body expressed at its center of mass. To express it at another point, O , we proceed as follows. From (2.24), (2.26), and (2.27)

$$\begin{aligned} \underline{h}_O &= \begin{pmatrix} 1 & S(\underline{c}) \\ \mathbf{0} & 1 \end{pmatrix} \begin{pmatrix} \bar{I}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \underline{v}_C \\ &= \begin{pmatrix} 1 & S(\underline{c}) \\ \mathbf{0} & 1 \end{pmatrix} \begin{pmatrix} \bar{I}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} 1 & \mathbf{0} \\ S(\underline{c})^T & 1 \end{pmatrix} \underline{v}_O \\ &= \begin{pmatrix} \bar{I}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix} \underline{v}_O ; \end{aligned}$$

but we also have that $\underline{h}_O = \underline{I}_O \underline{v}_O$, so

$$\underline{I}_O = \begin{pmatrix} \bar{I}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix} . \quad (2.28)$$

This equation can also be written

$$\underline{I}_O = \begin{pmatrix} \bar{I}_O & mS(\underline{c}) \\ mS(\underline{c})^T & m\mathbf{1} \end{pmatrix} , \quad (2.29)$$

where

$$\bar{I}_O = \bar{I}^{\text{cm}} + mS(\underline{c})S(\underline{c})^T \quad (2.30)$$

is the rotational inertia of the rigid body about O .

Spatial inertia matrices are symmetric and positive-definite. In the general case, 21 numbers are required to specify a spatial inertia (e.g., for an articulated-body or operational-space inertia); but a rigid-body inertia needs only 10 parameters: the mass, the coordinates of the center of mass, and the six independent elements of either \bar{I}^{cm} or \underline{I}_O .

The transformation rule for spatial inertias is

$$\underline{I}_B = {}^B X_A^F \underline{I}_A {}^A X_B , \quad (2.31)$$

where A and B are any two coordinate systems. In practice, we often need to calculate \underline{I}_A from \underline{I}_B , given only ${}^B X_A$. The formula for this transformation is

$$\underline{I}_A = ({}^B X_A)^T \underline{I}_B {}^B X_A . \quad (2.32)$$

If two bodies, having inertias \underline{I}_1 and \underline{I}_2 , are rigidly connected to form a single composite body, then the inertia of the composite, $\underline{I}_{\text{tot}}$, is the sum of the inertias of its parts:

$$\underline{I}_{\text{tot}} = \underline{I}_1 + \underline{I}_2 . \quad (2.33)$$

This single equation takes the place of three equations in the traditional 3-D vector approach: one to compute the composite mass, one to compute the composite center of mass, and one to compute the composite rotational inertia. If a rigid body with inertia \mathbf{I} is moving with a velocity of \mathbf{v} , then its kinetic energy is

$$T = \frac{1}{2} \mathbf{v} \cdot \mathbf{I} \mathbf{v} . \quad (2.34)$$

If a rigid body, B , is part of a larger system, then it is possible to define an apparent-inertia matrix for B , which describes the relationship between a force acting on B and its resulting acceleration, taking into account the effects of the other bodies in the system. Such quantities are called articulated-body inertias. If B happens to be the end-effector of a robot, then its apparent inertia is called an operational-space inertia.

2.2.12 Equation of Motion

The spatial equation of motion states that the net force acting on a rigid body equals its rate of change of momentum:

$$\mathbf{f} = \frac{d}{dt} (\mathbf{I}\mathbf{v}) = \mathbf{I}\mathbf{a} + \dot{\mathbf{I}}\mathbf{v} .$$

It can be shown that the expression $\dot{\mathbf{I}}\mathbf{v}$ evaluates to $(\mathbf{v} \times \mathbf{I}\mathbf{v})$ [2.8, 15], so the equation of motion can be written

$$\mathbf{f} = \mathbf{I}\mathbf{a} + \mathbf{v} \times \mathbf{I}\mathbf{v}. \quad (2.35)$$

This single equation incorporates both Newton's and Euler's equations of motion for a rigid body. To verify this, we can recover them as follows. Expressing (2.35) at the body's center of mass, and using (2.16), (2.14), and (2.22), we have

$$\begin{aligned} \begin{pmatrix} \underline{n}_C \\ \underline{f} \end{pmatrix} &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} \dot{\underline{\omega}} \\ \dot{\underline{v}}_C \end{pmatrix} \\ &\quad - \begin{pmatrix} \mathbf{S}(\underline{\omega})^T & \mathbf{S}(\underline{v}_C)^T \\ \mathbf{0} & \mathbf{S}(\underline{\omega})^T \end{pmatrix} \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} \underline{\omega} \\ m\underline{v}_C \end{pmatrix} \\ &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} & \mathbf{0} \\ \mathbf{0} & m\mathbf{1} \end{pmatrix} \begin{pmatrix} \dot{\underline{\omega}} \\ \ddot{\underline{c}} - \underline{\omega} \times \underline{v}_C \end{pmatrix} + \begin{pmatrix} \underline{\omega} \times \bar{\mathbf{I}}^{\text{cm}} \underline{\omega} \\ m\underline{\omega} \times \underline{v}_C \end{pmatrix} \\ &= \begin{pmatrix} \bar{\mathbf{I}}^{\text{cm}} \dot{\underline{\omega}} + \underline{\omega} \times \bar{\mathbf{I}}^{\text{cm}} \underline{\omega} \\ m\ddot{\underline{c}} \end{pmatrix}. \end{aligned} \quad (2.36)$$

2.2.13 Computer Implementation

The easiest way to implement spatial vector arithmetic on a computer is to start with an existing matrix arithmetic tool, like MATLAB® and write (or download from the Web) routines to do the following:

1. calculate $\mathbf{S}(\mathbf{m})$ from \mathbf{m} according to (2.14)
2. compose \mathbf{X} from \mathbf{R} and \mathbf{p} according to (2.9)
3. compose \mathbf{I} from m , \mathbf{c} , and $\bar{\mathbf{I}}^{\text{cm}}$ according to (2.28)

All other spatial arithmetic operations can be performed using standard matrix arithmetic routines. However, some additional routines could usefully be added to this list, such as:

- routines to calculate \mathbf{R} from various other representations of rotation
- routines to convert between spatial and 4×4 matrix quantities

This is the recommended approach whenever human productivity is more important than computational efficiency.

If greater efficiency is required, then a more elaborate spatial arithmetic library must be used, in which

1. a dedicated data structure is defined for each kind of spatial quantity, and
2. a suite of calculation routines are provided, each implementing a spatial arithmetic operation by means of an efficient formula.

Some examples of suitable data structures and efficient formulae are shown in Table 2.1. Observe that the suggested data structures for rigid-body inertias and Plücker transforms contain only a third as many numbers as the 6×6 matrices they represent. The efficient arithmetic formulae listed in this table offer cost savings ranging from a factor of 1.5 to a factor of 6 relative to the use of general 6×6 and 6×1 matrix arithmetic. Even more efficient formulae can be found in [2.16].

Table 2.1 Summary of spatial vector notation

| Spatial quantities: | |
|--------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| \mathbf{v} | velocity of a rigid body |
| \mathbf{a} | spatial acceleration of a rigid body ($\mathbf{a} = \dot{\mathbf{v}}$) |
| \mathbf{a}' | classical description of rigid-body acceleration expressed as a 6-D vector |
| \mathbf{f} | force acting on a rigid body |
| \mathbf{I} | inertia of a rigid body |
| \mathbf{X} | Plücker coordinate transform for motion vectors |
| \mathbf{X}^F | Plücker coordinate transform for force vectors ($\mathbf{X}^F = \mathbf{X}^{-T}$) |
| $B\mathbf{X}_A$ | Plücker transform from A coordinates to B coordinates |
| \mathbf{m} | a generic motion vector (any element of \mathbb{M}^6) |
| 3-D quantities: | |
| O | coordinate system origin |
| \mathbf{r} | position of the body-fixed point at O relative to any fixed point in space |
| $\underline{\omega}$ | angular velocity of a rigid body |
| \mathbf{v}_O | linear velocity of the body-fixed point at O ($\mathbf{v}_O = \dot{\mathbf{r}}$) |
| $\dot{\underline{\omega}}$ | angular acceleration of a rigid body |
| \mathbf{v}'_O | the derivative of \mathbf{v}_O taking O to be fixed in space |
| $\dot{\mathbf{v}}'_O$ | the derivative of \mathbf{v}_O taking O to be fixed in the body; the classical acceleration of the body-fixed point at O ($\dot{\mathbf{v}}'_O = \ddot{\mathbf{r}}$) |
| \mathbf{f} | linear force acting on a rigid body, or the resultant of a system of linear forces |
| n_O | moment about O of a linear force or system of linear forces |
| m | mass of a rigid body |
| \mathbf{c} | position of a rigid body's centre of mass, measured relative to O |
| \mathbf{h} | first moment of mass of a rigid body, $\mathbf{h} = m\mathbf{c}$; can also denote linear momentum |
| $\bar{\mathbf{I}}^{\text{cm}}$ | moment of inertia about a body's centre of mass |
| $\bar{\mathbf{I}}$ | moment of inertia about O |
| ${}^B\mathbf{R}_A$ | orthonormal rotation matrix transforming from A coordinates to B coordinates |
| ${}^A\mathbf{p}_B$ | location of the origin of B coordinates relative to the origin of A coordinates, expressed in A coordinates |

2.2.14 Summary

2.3 Canonical Equations

The equations of motion of a robot mechanism are usually presented in one of two canonical forms: the joint-space formulation,

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) = \boldsymbol{\tau}, \quad (2.37)$$

or the operational-space formulation,

$$\mathbf{A}(\mathbf{x})\ddot{\mathbf{x}} + \boldsymbol{\mu}(\mathbf{x}, \mathbf{v}) + \boldsymbol{\rho}(\mathbf{x}) = \mathbf{f}. \quad (2.38)$$

These equations show the functional dependencies explicitly: \mathbf{H} is a function of \mathbf{q} , \mathbf{A} is a function of \mathbf{x} ,

Table 2.1 (continued)

| Efficient spatial arithmetic formulae: | |
|----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Expression | Computed value |
| $X\mathbf{v}$ | $(\mathbf{R}\boldsymbol{\omega}; \mathbf{R}(\mathbf{v}_O - \mathbf{p} \times \boldsymbol{\omega}))$ |
| $X^F\mathbf{f}$ | $(\mathbf{R}(\mathbf{n}_O - \mathbf{p} \times \mathbf{f}); \mathbf{R}\mathbf{f})$ |
| X^{-1} | $(\mathbf{R}^T; -\mathbf{R}\mathbf{p})$ |
| $X^{-1}\mathbf{v}$ | $(\mathbf{R}^T\boldsymbol{\omega}; \mathbf{R}^T\mathbf{v}_O + \mathbf{p} \times \mathbf{R}^T\boldsymbol{\omega})$ |
| $(X^F)^{-1}\mathbf{f}$ | $(\mathbf{R}^T\mathbf{n}_O + \mathbf{p} \times \mathbf{R}^T\mathbf{f}; \mathbf{R}^T\mathbf{f})$ |
| X_1X_2 | $(\mathbf{R}_1\mathbf{R}_2; \mathbf{p}_2 + \mathbf{R}_2^T\mathbf{p}_1)$ |
| $I_1 + I_2$ | $(m_1 + m_2; \mathbf{h}_1 + \mathbf{h}_2; \bar{I}_1 + \bar{I}_2)$ |
| $I\mathbf{v}$ | $(\bar{I}\boldsymbol{\omega} + \mathbf{h} \times \mathbf{v}_O; m\mathbf{v}_O - \mathbf{h} \times \boldsymbol{\omega})$ |
| $X^T\mathbf{IX}$ | $(m; \mathbf{R}^T\mathbf{h} + m\mathbf{p}; \mathbf{R}^T\bar{I}\mathbf{R} - S(\mathbf{p})S(\mathbf{R}^T\mathbf{h}) - S(\mathbf{R}^T\mathbf{h} + m\mathbf{p})S(\mathbf{p}))$ |

For meaning of $X^T\mathbf{IX}$ see (2.32)

Spatial vectors are 6-D vectors that combine the linear and angular aspects of rigid-body motion, resulting in a compact notation that is very suitable for describing dynamics algorithms. To avoid a few name clashes with 3-D vectors, we have used bold upright letters to denote spatial vectors, while tensors are still denoted by italics. In the sections that follow, upright letters will be used to denote both spatial vectors and vectors that are concatenations of other vectors, like $\dot{\mathbf{q}}$.

Table 2.1 presents a summary of the spatial quantities and operators introduced in this section, together with the formulae that define them in terms of 3-D quantities and operators. It also presents data structures and formulae for efficient computer implementation of spatial arithmetic. This table should be read in conjunction with Tables 1.5 and 1.6, which shows how to compute the orientation, position, and spatial velocities for a variety of joint types. Note that ${}^j\mathbf{R}_i$ and ${}^j\mathbf{p}_i$ in these tables correspond to ${}^B\mathbf{R}_A^T$ and ${}^A\mathbf{p}_B$, respectively, when read in conjunction with Table 2.1.

and so on. Once these dependencies are understood, they are usually omitted. In (2.38), \mathbf{x} is a vector of operational-space coordinates, while \mathbf{v} and \mathbf{f} are spatial vectors denoting the velocity of the end-effector and the external force acting on it. If the robot is redundant, then the coefficients of this equation must be defined as functions of \mathbf{q} and $\dot{\mathbf{q}}$ rather than \mathbf{x} and \mathbf{v} .

These two equations are further explained below, along with a description of the Lagrange formulation of (2.37), and the impulsive equations of motion for impact.

2.3.1 Joint-Space Formulation

The symbols \mathbf{q} , $\dot{\mathbf{q}}$, $\ddot{\mathbf{q}}$, and $\boldsymbol{\tau}$ denote n -dimensional vectors of joint position, velocity, acceleration and force variables, respectively, where n is the number of degrees of motion freedom of the robot mechanism. \mathbf{H} is an $n \times n$ symmetric, positive-definite matrix, and is called the generalized, or joint-space, inertia matrix (**JSIM**). \mathbf{C} is an $n \times n$ matrix such that $\mathbf{C} \dot{\mathbf{q}}$ is the vector of Coriolis and centrifugal terms (collectively known as *velocity product* terms); and $\boldsymbol{\tau}_g$ is the vector of gravity terms. More terms can be added to this equation, as required, to account for other dynamical effects (e.g., viscous friction). The effects of a force \mathbf{f} exerted on the mechanism at the end-effector can be accounted for by adding the term $\mathbf{J}^T \mathbf{f}$ to the right side of (2.37), where \mathbf{J} is the Jacobian of the end-effector (Sect. 1.8.1).

\mathbf{q} specifies the coordinates of a point in the mechanism's configuration space. If the mechanism is a kinematic tree (see Sect. 2.4), then \mathbf{q} contains every joint variable in the mechanism, otherwise it contains only an independent subset. The elements of \mathbf{q} are generalized coordinates. Likewise, the elements of $\dot{\mathbf{q}}$, $\ddot{\mathbf{q}}$, and $\boldsymbol{\tau}$ are generalized velocities, accelerations, and forces.

2.3.2 Lagrange Formulation

Various methods exist for deriving the terms in (2.37). The two that are most commonly used in robotics are the Newton–Euler formulation and the Lagrange formulation. The former works directly with Newton's and Euler's equations for a rigid body, which are contained within the spatial equation of motion, (2.35). This formulation is especially amenable to the development of efficient recursive algorithms for dynamics computations, such as those described in Sections 2.5 and 2.6.

The Lagrange formulation proceeds via the Lagrangian of the robot mechanism,

$$L = T - U, \quad (2.39)$$

where T and U are the total kinetic and potential energy, respectively, of the mechanism. The kinetic energy is given by

$$T = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{H} \dot{\mathbf{q}}. \quad (2.40)$$

The dynamic equations of motion can then be developed using Lagrange's equation for each generalized coordinate:

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = \tau_i. \quad (2.41)$$

The resulting equation can be written in scalar form:

$$\sum_{j=1}^n H_{ij} \ddot{q}_j + \sum_{j=1}^n \sum_{k=1}^n C_{ijk} \dot{q}_j \dot{q}_k + \tau_{gi} = \tau_i, \quad (2.42)$$

which shows the structure of the velocity-product terms. C_{ijk} are known as Christoffel symbols of the first type, and are given by

$$C_{ijk} = \frac{1}{2} \left(\frac{\partial H_{ij}}{\partial q_k} + \frac{\partial H_{ik}}{\partial q_j} - \frac{\partial H_{jk}}{\partial q_i} \right). \quad (2.43)$$

They are functions of only the position variables, q_i . The elements of \mathbf{C} in (2.37) can be defined as

$$C_{ij} = \sum_{k=1}^n C_{ijk} \dot{q}_k. \quad (2.44)$$

However, \mathbf{C} is not unique, and other definitions are possible.

With the choice of \mathbf{C} given in (2.44), it is possible to show that the matrix \mathbf{N} , given by

$$\mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) = \dot{\mathbf{H}}(\mathbf{q}) - 2\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}), \quad (2.45)$$

is skew-symmetric [2.17]. Thus, for any $n \times 1$ vector $\boldsymbol{\alpha}$,

$$\boldsymbol{\alpha}^T \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) \boldsymbol{\alpha} = 0. \quad (2.46)$$

This property is quite useful in control, especially when considering $\boldsymbol{\alpha} = \dot{\mathbf{q}}$, which gives

$$\dot{\mathbf{q}}^T \mathbf{N}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} = 0. \quad (2.47)$$

By applying the principle of conservation of energy, it can be shown that (2.47) holds for any choice of the matrix \mathbf{C} [2.17, 18].

2.3.3 Operational-Space Formulation

In (2.38), \mathbf{x} is a 6-D vector of operational-space coordinates giving the position and orientation of the robot's end-effector; \mathbf{v} is the velocity of the end-effector; and \mathbf{f} is the force exerted on the end-effector. \mathbf{x} is typically a list of Cartesian coordinates, and Euler angles or quaternion components, and is related to \mathbf{v} via a differential equation of the form

$$\dot{\mathbf{x}} = \mathbf{E}(\mathbf{x}) \mathbf{v}. \quad (2.48)$$

\mathbf{A} is the operational-space inertia matrix, which is the apparent inertia of the end-effector taking into account the effect of the rest of the robot's mechanism (i.e., it is an articulated-body inertia). $\boldsymbol{\mu}$ and $\boldsymbol{\rho}$ are vectors of velocity-product and gravity terms, respectively.

Operational space (also known as task space) is the space in which high-level motion and force commands are issued and executed. The operational-space formulation is therefore particularly useful in the context of motion and force control systems (Sect. 6.2 and Sect. 7.2). Equation (2.38) can be generalized to operational spaces with dimensions other than six, and to operational spaces that incorporate the motions of more than one end-effector [2.19].

The terms in (2.37) and (2.38) are related by the following formulae

$$\mathbf{v} = \mathbf{J}\dot{\mathbf{q}}, \quad (2.49)$$

$$\dot{\mathbf{v}} = \mathbf{J}\ddot{\mathbf{q}} + \dot{\mathbf{J}}\dot{\mathbf{q}}, \quad (2.50)$$

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (2.51)$$

$$\boldsymbol{\Lambda} = (\mathbf{J}\mathbf{H}^{-1}\mathbf{J}^T)^{-1}, \quad (2.52)$$

$$\boldsymbol{\mu} = \boldsymbol{\Lambda}(\mathbf{J}\mathbf{H}^{-1}\mathbf{C}\dot{\mathbf{q}} - \dot{\mathbf{J}}\dot{\mathbf{q}}), \quad (2.53)$$

and

$$\boldsymbol{\rho} = \boldsymbol{\Lambda}\mathbf{J}\mathbf{H}^{-1}\boldsymbol{\tau}_g. \quad (2.54)$$

These equations assume that $m \leq n$ (m is the dimension of operational-space coordinates), and that the Jacobian \mathbf{J} has full rank. More details can be found in [2.20].

2.3.4 Impact Model

If a robot strikes a rigid body in its environment, then an impulsive force arises at the moment of impact and causes a step change in the robot's velocity. Let us assume that the impact occurs between the end effector and a rigid body in the environment, and that a spatial

impulse of \mathbf{f}' is exerted on the end-effector. This impulse causes a step change of $\Delta\mathbf{v}$ in the end-effector's velocity; and the two are related by the operational-space equation of impulsive motion [2.21],

$$\boldsymbol{\Lambda}\Delta\mathbf{v} = \mathbf{f}'. \quad (2.55)$$

In joint space, the equation of impulsive motion for a robot mechanism is

$$\boldsymbol{\Lambda}\Delta\dot{\mathbf{q}} = \boldsymbol{\tau}', \quad (2.56)$$

where $\boldsymbol{\tau}'$ and $\Delta\dot{\mathbf{q}}$ denote the joint-space impulse and velocity change, respectively. In the case of a collision involving the robot's end-effector, we have

$$\boldsymbol{\tau}' = \mathbf{J}^T \mathbf{f}' \quad (2.57)$$

and

$$\Delta\mathbf{v} = \mathbf{J}\Delta\dot{\mathbf{q}}, \quad (2.58)$$

which follow from (2.51) and (2.49). Equations (2.55)–(2.57) imply that

$$\Delta\dot{\mathbf{q}} = \bar{\mathbf{J}}\Delta\mathbf{v}, \quad (2.59)$$

where $\bar{\mathbf{J}}$ is the inertia-weighted pseudoinverse of \mathbf{J} and is given by

$$\bar{\mathbf{J}} = \mathbf{H}^{-1}\mathbf{J}^T\boldsymbol{\Lambda}. \quad (2.60)$$

$\bar{\mathbf{J}}$ is also known as the dynamically consistent generalized inverse of the Jacobian matrix [2.20]. Note that the expression $\boldsymbol{\Lambda}\mathbf{J}\mathbf{H}^{-1}$, which appears in (2.53) and (2.54), is equal to $\bar{\mathbf{J}}^T$ since \mathbf{H} and $\boldsymbol{\Lambda}$ are both symmetric. Although we have introduced $\bar{\mathbf{J}}$ in the context of impulsive dynamics, it is more typically used in normal (i.e., nonimpulsive) dynamics equations.

2.4 Dynamic Models of Rigid-Body Systems

A basic rigid-body model of a robot mechanism has four components: a connectivity graph, link and joint geometry parameters, link inertia parameters, and a set of joint models. To this model, one can add various force-producing elements, such as springs, dampers, joint friction, actuators, and drives. The actuators and drives, in particular, may have quite elaborate dynamic models of their own. It is also possible to add extra motion freedoms to model elasticity in the joint bearings or links (Chap. 13). This section describes a basic model. More on this topic can be found in books such as [2.3, 8, 22].

2.4.1 Connectivity

A connectivity graph is an undirected graph in which each node represents a rigid body and each arc represents a joint. The graph must be connected; and exactly one node represents a fixed base or reference frame. If the graph represents a mobile robot (i.e., a robot that is not connected to a fixed base), then it is necessary to introduce a fictitious 6-DOF joint between the fixed base and any one body in the mobile robot. The chosen body is then known as a *floating base*. If a single graph is to represent a collection of mobile robots, then each

robot has its own floating base, and each floating base has its own 6-DOF joint. Note that a 6-DOF joint imposes no constraints on the two bodies it connects, so the introduction of a 6-DOF joint alters the connectivity of the graph without altering the physical properties of the system it represents.

In graph-theory terminology, a loop is an arc that connects a node to itself, and a cycle is a closed path that does not traverse any arc more than once. In the connectivity graph of a robot mechanism, loops are not allowed, and cycles are called kinematic loops. A mechanism that contains kinematic loops is called a closed-loop mechanism; and a mechanism that does not is called an open-loop mechanism or a kinematic tree. Every closed-loop mechanism has a spanning tree, which defines an open-loop mechanism, and every joint that is not in the spanning tree is called a loop-closing joint. The joints in the tree are called tree joints.

The fixed base serves as the root node of a kinematic tree, and the root node of any spanning tree on a closed-loop mechanism. A kinematic tree is said to be branched if at least one node has at least two children, and unbranched otherwise. An unbranched kinematic tree is also called a kinematic chain, and a branched tree can be called a branched kinematic chain. A typical industrial robot arm, without a gripper, is a kinematic chain, while a typical humanoid robot is a kinematic tree with a floating base.

In a system containing N_B moving bodies and N_J joints, where N_J includes the 6-DOF joints mentioned above, the bodies and joints are numbered as follows. First, the fixed base is numbered body 0. The other bodies are then numbered from 1 to N_B in any order such that each body has a higher number than its parent. If the system contains kinematic loops then one must first choose a spanning tree, and commit to that choice, since the identity of a body's parent is determined by the spanning tree. This style of numbering is called a *regular numbering scheme*.

Having numbered the bodies, we number the tree joints from 1 to N_B such that joint i connects body i to its parent. The loop-closing joints, if any, are then numbered from $N_B + 1$ to N_J in any order. Each loop-closing joint k closes one independent kinematic loop, and we number the loops from 1 to N_L (where $N_L = N_J - N_B$ is the number of independent loops) such that loop l is the one closed by joint $k = N_B + l$. Kinematic loop l is the unique cycle in the graph that traverses joint k , but does not traverse any other loop-closing joint.

For an unbranched kinematic tree, these rules produce a unique numbering in which the bodies are

numbered consecutively from base to tip, and the joints are numbered such that joint i connects bodies i and $i - 1$. In all other cases, regular numberings are not unique.

Although the connectivity graph is undirected, it is necessary to assign a direction to each joint for the purpose of defining joint velocity and force. This is necessary for both tree joints and loop-closing joints. Specifically, a joint is said to connect from one body to another. We may call them the predecessor $p(i)$ and successor $s(i)$ for joint i , respectively. Joint velocity is then defined as the velocity of the successor relative to the predecessor; and joint force is defined as a force acting on the successor. It is standard practice (but not a necessity) for all tree joints to connect from the parent to the child.

The connectivity of a kinematic tree, or the spanning tree on a closed-loop mechanism, is described by an N_B -element array of parent body numbers, where the i -th element $p(i)$ is the parent of body i . Note that the parent

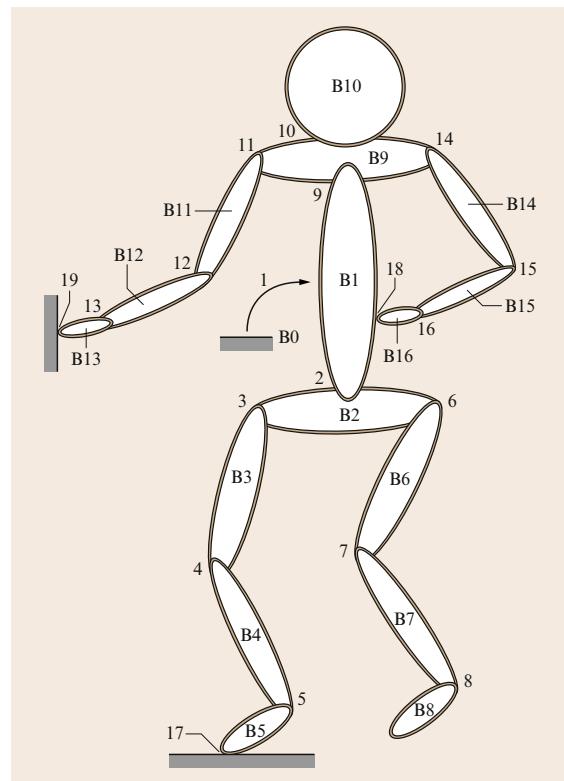

Fig. 2.3 Humanoid robot example. Note: to distinguish between body numbers and joint numbers in this figure, body numbers are preceded by a 'B' for clarity

Table 2.2 Loop-closing joints and roots of loops for the humanoid example

| Loop l | Loop-closing joint k | $p(k)$ | $s(k)$ | Root |
|----------|------------------------|--------|--------|------|
| 1 | 17 | 0 | 5 | 0 |
| 2 | 18 | 16 | 1 | 1 |
| 3 | 19 | 0 | 13 | 0 |

$p(i)$ for body i is also the predecessor $p(i)$ for joint i , and thus the common notation. Many algorithms rely on the property $p(i) < i$ to perform their calculations in the correct order. The set of all body numbers for the children of body i , $c(i)$, is also useful in many recursive algorithms.

The connectivity data for kinematic loops may be described in a variety of ways. A representation that facilitates use in recursive algorithms includes the following conventions. Loop-closing joint k joins bodies $p(k)$ (the predecessor) and $s(k)$ (the successor). The set $LR(i)$ for body i gives the numbers of the loops for which body i is the root. Using the property $p(i) < i$ for bodies in the spanning tree, the root of a loop is chosen as the body with the lowest number. In addition, the set $LB(i)$ for body i gives the numbers of the loops to which body i belongs but is not the root.

An example of a closed-loop system is given in Fig. 2.3. The system consists of a humanoid mechanism with topologically varying contacts, with the environment and within the mechanism, which form closed loops. The system has $N_B = 16$ moving bodies and $N_J = 19$ joints with $N_L = N_J - N_B = 3$ loops. The main body (1) is considered to be a *floating base* for this mobile robot system. It is connected to the fixed base (0) through a fictitious 6-DOF joint (1). To complete the example, the loop-closing joint and the body numbers $p(k)$ and $s(k)$ as well as the root body for each loop are given in Table 2.2. The body-based sets $c(i)$ and $LB(i)$ are given in Table 2.3. Note that $LR(0) = \{1, 3\}$ and $LR(1) = \{2\}$ and all other LR sets are null for this example.

2.4.2 Link Geometry

When two bodies are connected by a joint, a complete description of the connection consists of a description of the joint itself, and the locations of two coordinate frames, one in each body, which specify where in each body the joint is located. If there are N_J joints in the system, then there are a total of $2N_J$ joint-attachment frames. One half of these frames are identified with the

Table 2.3 Body-based sets for the humanoid example

| Body i | $c(i)$ | $LB(i)$ | Body i | $c(i)$ | $LB(i)$ |
|----------|--------|---------|----------|------------|---------|
| 0 | 1 | | 9 | 10, 11, 14 | 2, 3 |
| 1 | 2, 9 | 1, 3 | 10 | | |
| 2 | 3, 6 | 1 | 11 | 12 | 3 |
| 3 | 4 | 1 | 12 | 13 | 3 |

| 5 | | 1 | 14 | 15 | 2 |
| 6 | 7 | | 15 | 16 | 2 |
| 7 | 8 | | 16 | | 2 |
| 8 | | | | | |

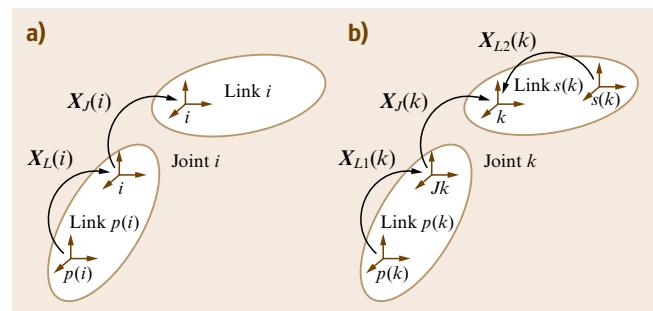

numbers 1 to N_J , and the remainder with the labels $J1$ to JN_J . Each joint i connects from frame Ji to frame i . For joints 1 to N_B (i.e., the tree joints), frame i is rigidly attached to body i . For joints $N_B + 1$ to N_J , frame k for loop-closing joint k will be rigidly attached to body $s(k)$. The second coordinate frame Ji is attached to the predecessor $p(i)$ for each joint i , whether it is a tree joint or a loop-closing joint. Coordinate frame Ji provides a base frame for joint i in that the joint rotation and/or translation is defined relative to this frame.

Figure 2.4 shows the coordinate frames and transforms associated with each joint in the system. The overall transform from frame $p(i)$ coordinates to frame i coordinates for a tree joint is given by:

$${}^iX_{p(i)} = {}^iX_{Ji} {}^JiX_{p(i)} = X_J(i)X_L(i). \quad (2.61)$$

The transform $X_L(i)$ is a fixed link transform which sets the base frame Ji of joint i relative to $p(i)$. It may be used to transform spatial motion vectors from $p(i)$ to Ji coordinates. The transform $X_J(i)$ is a variable joint transform which completes the transformation across joint i from Ji to i coordinates.

Similarly, the overall transform from frame $p(k)$ coordinates to frame k coordinates for a loop-closing joint

**Fig. 2.4a, b** Coordinate frames and transforms associated with a tree joint (a) and a loop-closing joint (b)

is given by:

$${}^kX_{p(k)} = {}^kX_{Jk} {}^{Jk}X_{p(k)} = X_J(k) X_{L1}(k). \quad (2.62)$$

An additional transform $X_{L2}(k)$ is defined from frame $s(k)$ coordinates to frame k coordinates and is given by:

$$X_{L2}(k) = {}^kX_{s(k)}. \quad (2.63)$$

Link and joint geometry data can be specified in a variety of different ways. The most common method is to use Denavit–Hartenberg parameters [2.23]. However, standard Denavit–Hartenberg parameters are not completely general, and are insufficient for describing the geometry for a branched kinematic tree, or for a mechanism containing certain kinds of multi-DOF joints. A modified form of Denavit–Hartenberg parameters [2.2] is used for single-DOF joints in this Handbook (Sect. 1.4). The parameters have been extended for branched kinematic trees [2.22] and closed-loop mechanisms.

2.4.3 Link Inertias

The link inertia data consists of the masses, positions of centers of mass, and rotational inertias of each link in the mechanism. The inertia parameters for link i are expressed in coordinate frame i , and are therefore constants.

2.4.4 Joint Models

The relationship between connected links is described using the general joint model of *Roberson and Schwertassek* [2.3]. For a kinematic tree or spanning tree on a closed-loop mechanism, an $n_i \times 1$ vector, \dot{q}_i , relates the velocity of link i to the velocity of its parent, link $p(i)$, where n_i is the number of degrees of freedom at the joint connecting the two links. For a loop-closing joint in a closed-loop mechanism, the relationship is between the velocity of link $s(i)$ (the successor) and the velocity of link $p(i)$ (the predecessor). In either case, the relationship is between the velocity of coordinate frames i and Ji .

Let \mathbf{v}_{rel} and \mathbf{a}_{rel} denote the velocity and acceleration across joint i , that is, the velocity and acceleration of link $s(i)$ relative to $p(i)$. The free modes of the joint are represented by the $6 \times n_i$ matrix Φ_i , such that \mathbf{v}_{rel} and \mathbf{a}_{rel} are given as follows:

$$\mathbf{v}_{\text{rel}} = \Phi_i \dot{q}_i \quad (2.64)$$

and

$$\mathbf{a}_{\text{rel}} = \Phi_i \ddot{q}_i + \dot{\Phi}_i \dot{q}_i, \quad (2.65)$$

where Φ_i and $\dot{\Phi}_i$ depend on the type of joint [2.3]. The matrix Φ_i has full column rank, so we can define a complementary matrix, Φ_i^c , such that the 6×6 matrix $(\Phi_i \Phi_i^c)$ is invertible. We can regard the columns of this matrix as forming a basis on M^6 such that the first n_i basis vectors define the directions in which motion is allowed, and the remaining $6 - n_i = n_i^c$ vectors define directions in which motion is not allowed. Thus, Φ_i^c represents the constrained modes of joint i .

The force transmitted across joint i from its predecessor to its successor, \mathbf{f}_i , is given as follows:

$$\mathbf{f}_i = (\Psi_i \Psi_i^c) \begin{pmatrix} \tau_i \\ \lambda_i \end{pmatrix}, \quad (2.66)$$

where τ_i is the $n_i \times 1$ vector of applied forces along the free modes, λ_i is the $(6 - n_i) \times 1$ vector of constraint forces, and Ψ_i and Ψ_i^c are computed as follows:

$$(\Psi_i \Psi_i^c) = (\Phi_i \Phi_i^c)^{-T}. \quad (2.67)$$

For most common joint types, it is possible to choose Φ_i and Φ_i^c such that the matrix $(\Phi_i \Phi_i^c)$ is numerically orthonormal, so that $(\Psi_i \Psi_i^c)$ is numerically equal to $(\Phi_i \Phi_i^c)$. Note that (2.67) implies the following relationships: $(\Psi_i)^T \Phi_i = \mathbf{1}_{n_i \times n_i}$, $(\Psi_i)^T \Phi_i^c = \mathbf{0}_{n_i \times (6-n_i)}$, $(\Psi_i^c)^T \Phi_i = \mathbf{0}_{(6-n_i) \times n_i}$, and $(\Psi_i^c)^T \Phi_i^c = \mathbf{1}_{(6-n_i) \times (6-n_i)}$. When applied to (2.66), the following useful relationship results:

$$\tau_i = \Phi_i^T \mathbf{f}_i. \quad (2.68)$$

The value of $\dot{\Phi}_i$ in (2.65) depends on the type of joint. The general formula is

$$\dot{\Phi}_i = \dot{\Phi}_i + \mathbf{v}_i \times \Phi_i, \quad (2.69)$$

where \mathbf{v}_i is the velocity of link i , and $\dot{\Phi}_i$ is the apparent derivative of Φ_i , as seen by an observer moving with link i , and is given by

$$\dot{\Phi}_i = \frac{\partial \Phi_i}{\partial q_i} \dot{q}_i. \quad (2.70)$$

For most common joint types, $\dot{\Phi}_i = \mathbf{0}$.

Single-DOF joints ($n_i = 1$) are especially straightforward to work with when using the Denavit–Hartenberg convention. Motion is chosen along (prismatic) or about (revolute) the \hat{z}_i coordinate axis. In this case, $\Phi_i = (0 \ 0 \ 0 \ 0 \ 0 \ 1)^T$ for a prismatic joint and $\Phi_i = (0 \ 0 \ 1 \ 0 \ 0 \ 0)^T$ for a revolute joint. Also, $\dot{\Phi}_i = \mathbf{0}$.

The fictitious 6-DOF joint for a floating base for a mobile robot is also handled relatively easily. For this case, $\Phi_i = \mathbf{1}$ (6×6 identity matrix) and $\dot{\Phi}_i = \mathbf{0}$.

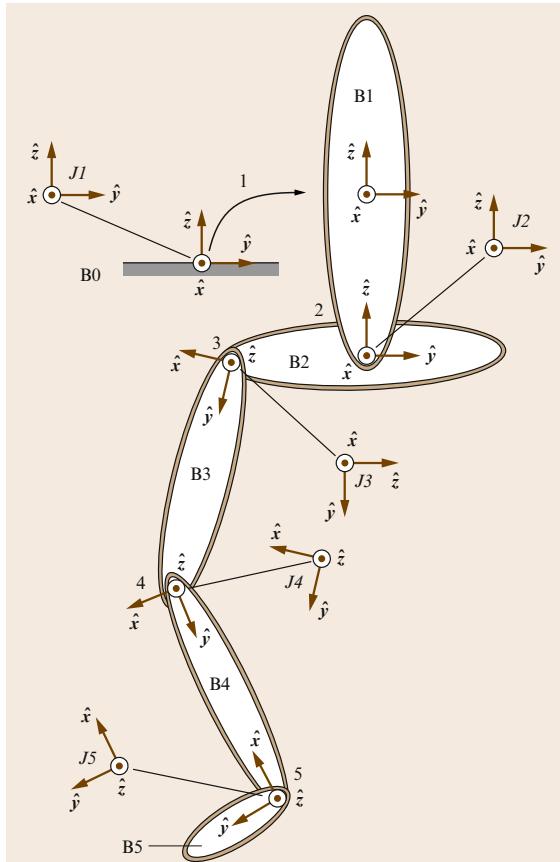

Fig. 2.5 Coordinate frames for the first five links and joints of the humanoid robot example

The revolute joint and floating-base joint, as well as the universal joint ($n_i = 2$) and spherical joint ($n_i = 3$) are illustrated in the example in the next section. For additional details on joint kinematics, see Sect. 1.3.

2.4.5 Example System

In order to illustrate the conventions used for the link and joint models, coordinate frames are attached to the first five links (bodies) and fixed base of the humanoid robot as shown in Fig. 2.5. Note that frame J_i is attached to link $p(i) = i - 1$ for each of the five joints. For this example, the origin of frame J_1 is set coincident with the origin of frame 0, and the origins of frames J_2, J_3, J_4 , and J_5 are coincident with the origins of frames 2, 3, 4, and 5, respectively. Note that J_1 could be set at any position/orientation on the fixed base (B_0) to permit the most convenient representation for the motion of the

Table 2.4 Number of degrees of freedom (n_i), fixed rotation (${}^J R_{p(i)}$) and position (${}^{p(i)} p_{Ji}$) from frame $p(i)$ to base frame J_i for joint i of the example system. Note that $2l_i$ is the nominal length of link i along its long axis

| Joint | n_i | ${}^J R_{p(i)}$ | ${}^{p(i)} p_{Ji}$ |
|-------|-------|----------------------------------------------------------------------|------------------------------------------------|
| 1 | 6 | $1_{3 \times 3}$ | $0_{3 \times 1}$ |
| 2 | 1 | $1_{3 \times 3}$ | $\begin{pmatrix} 0 \\ 0 \\ -l_1 \end{pmatrix}$ |
| 3 | 3 | $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ -l_2 \\ 0 \end{pmatrix}$ |
| 4 | 1 | $1_{3 \times 3}$ | $\begin{pmatrix} 0 \\ 2l_3 \\ 0 \end{pmatrix}$ |
| 5 | 2 | $\begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ | $\begin{pmatrix} 0 \\ 2l_4 \\ 0 \end{pmatrix}$ |

floating base (B_1) relative to the fixed base. Also, the origin of J_2 could be set anywhere along \hat{z}_2 .

The number of degrees of freedom, and fixed rotation and position of the base frames J_i for each joint of the example system, are given in Table 2.4. The rotation ${}^J R_{p(i)}$ transforms 3-D vectors in $p(i)$ coordinates to J_i coordinates. The position ${}^{p(i)} p_{Ji}$ is the vector giving the position of the origin O_{Ji} relative to $O_{p(i)}$, expressed in $p(i)$ coordinates. The spatial transform $X_L(i) = {}^J X_{p(i)}$ may be composed from these 3-D quantities through the equation for ${}^B X_A$ in Table 2.1. The humanoid has a floating base, the torso, a revolute joint between the torso and pelvis (about \hat{z}_2), a spherical joint at the hip, a revolute joint at the knee, and a universal joint at the ankle. As shown in Fig. 2.5, the leg is slightly bent and the foot is turned out to the side ($\approx 90^\circ$ rotation about \hat{y}_3 at the hip).

The free modes, velocity variables, and position variables for all of the joint types in the humanoid are given in Tables 1.5 and 1.6. The expressions for ${}^j R_i$ and ${}^j p_i$ in these tables give ${}^i R_{Ji}^T$ and ${}^j p_i$, respectively, through which the joint transform $X_J(i) = {}^i X_{Ji}$ may be composed. Revolute joints follow the Denavit–Hartenberg convention with rotation about the \hat{z}_i axis. The ankle has a pitch rotation of α_5 about the \hat{z}_{J5} axis followed by a roll rotation of β_5 about the \hat{y}_{J5} axis (see the Z–Y–X Euler angle definitions in Table 1.1). The hip is modeled as a ball-and-socket, spherical joint. To avoid the singularities that are associated with Euler angles, the quaternion ϵ_i may be used

to represent the orientation at the hip. The relationship between the quaternion rate $\dot{\epsilon}_i$ and the relative rotation rate $\omega_{i\text{ rel}}$ is given in (1.7) of the Handbook.

The floating base uses the position of the torso ${}^0\mathbf{p}_1$ and quaternion ϵ_1 for its position and orientation state variables, respectively. The position of the torso may

be computed by integrating the velocity for the link, as expressed in fixed base coordinates: ${}^0\mathbf{v}_1 = {}^0\mathbf{R}_1\mathbf{v}_1$, where \mathbf{v}_1 is the velocity of the torso in moving coordinates.

Note that $\Phi_i = 0$ for all joints except the universal joint. Since the components of \hat{z}_{J5} in link 5 coordinates vary with $\beta_5, \hat{z}_{J5} \neq 0$. See Sect. 1.3 of the Handbook for further details of the joint kinematics.

2.5 Kinematic Trees

The dynamics of a kinematic tree is simpler, and easier to calculate, than the dynamics of a closed-loop mechanism. Indeed, many algorithms for closed-loop mechanisms work by first calculating the dynamics of a spanning tree, and then subjecting it to the loop-closure constraints.

This section describes the following dynamics algorithms for kinematic trees: the recursive Newton–Euler algorithm (**RNEA**) for inverse dynamics, the articulated-body algorithm (**ABA**) for forward dynamics, the composite-rigid-body algorithm (**CRBA**) for calculating the joint-space inertia matrix (**JSIM**), and two algorithms to calculate the operational-space inertia matrix (**OSIM**).

2.5.1 The Recursive Newton–Euler Algorithm

This is an $O(n)$ algorithm for calculating the inverse dynamics of a fixed-base kinematic tree, and is based on the very efficient **RNEA** of Luh et al. [2.4]. A floating-base version can be found in [2.8, 15]. Given the joint position and velocity variables, this algorithm calculates the applied joint torque/force variables required to produce a given set of joint accelerations.

The link velocities and accelerations are first computed through an outward recursion from the fixed base to the leaf links of the tree. The resultant forces on each link are computed using the Newton–Euler equations (2.35) during this recursion. A second, inward recursion uses the force balance equations at each link to compute the spatial force across each joint and the value of each joint torque/force variable. The key step for computational efficiency is to refer most quantities to local link coordinates. Also, the effects of gravity on each link are efficiently included in the equations by accelerating the base of the mechanism upward.

The calculation proceeds in four steps, as follows, with two steps in each of the two recursions.

Step 1

Calculate the velocity and acceleration of each link in turn, starting with the known velocity and acceleration of the fixed base, and working towards the tips (i. e., the leaf nodes in the connectivity graph).

The velocity of each link in a kinematic tree is given by the recursive formula

$$\mathbf{v}_i = \mathbf{v}_{p(i)} + \Phi_i \dot{\mathbf{q}}_i, \quad (\mathbf{v}_0 = \mathbf{0}), \quad (2.71)$$

where \mathbf{v}_i is the velocity of link i , Φ_i is the motion matrix of joint i , and $\dot{\mathbf{q}}_i$ is the vector of joint velocity variables for joint i .

The equivalent formula for accelerations is obtained by differentiating (2.71), giving

$$\mathbf{a}_i = \mathbf{a}_{p(i)} + \Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}_i, \quad (\mathbf{a}_0 = \mathbf{0}) \quad (2.72)$$

where \mathbf{a}_i is the acceleration of link i , and $\ddot{\mathbf{q}}_i$ is the vector of joint acceleration variables.

The effect of a uniform gravitational field on the mechanism can be simulated by initializing \mathbf{a}_0 to $-\mathbf{a}_g$ instead of zero, where \mathbf{a}_g is the gravitational acceleration vector. In this case, \mathbf{a}_i is not the true acceleration of link i , but the sum of its true acceleration and $-\mathbf{a}_g$.

Step 2

Calculate the equation of motion for each link. This step computes the forces required to cause the accelerations calculated in step 1. The equation of motion for link i is

$$\mathbf{f}_i^a = \mathbf{I}_i \mathbf{a}_i + \mathbf{v}_i \times \mathbf{I}_i \mathbf{v}_i, \quad (2.73)$$

where \mathbf{I}_i is the spatial inertia of link i , and \mathbf{f}_i^a is the net force acting on link i .

Step 3

Calculate the spatial force across each joint. Referring to Fig. 2.6, the net force acting on link i is

$$\mathbf{f}_i^a = \mathbf{f}_i^e + \mathbf{f}_i - \sum_{j \in c(i)} \mathbf{f}_j,$$

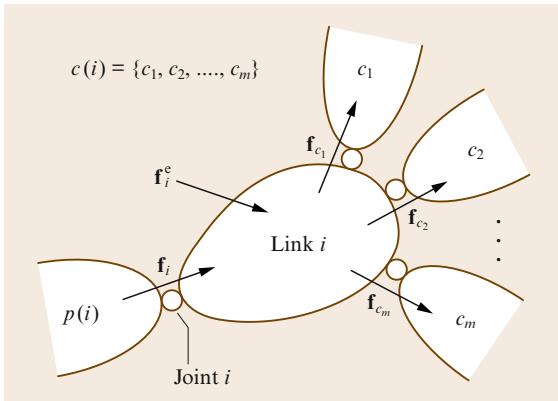

Fig. 2.6 Forces acting on link i

where \mathbf{f}_i is the force transmitted across joint i , \mathbf{f}_i^e is the sum of all relevant external forces acting on link i , and $c(i)$ is the set of children of link i . Rearranging this equation gives the following recursive formula for calculating the joint forces:

$$\mathbf{f}_i = \mathbf{f}_i^a - \mathbf{f}_i^e + \sum_{j \in c(i)} \mathbf{f}_j , \quad (2.74)$$

where i iterates from N_B to 1.

\mathbf{f}_i^e may include contributions from springs, dampers, force fields, contact with the environment, and so on, but its value is assumed to be known, or at least to be calculable from known quantities. If gravity has not been simulated by a fictitious base acceleration, then

    ai = ap(i) +  $\Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}$ 
     $\mathbf{f}_i = I_i \mathbf{a}_i + \mathbf{v}_i \times I_i \mathbf{v}_i - \mathbf{f}_i^e$ 
end
for  $i = N_B$  to 1 do
     $\tau_i = \Phi_i^T \mathbf{f}_i$ 
    if  $p(i) \neq 0$  then
         $\mathbf{f}_{p(i)} = \mathbf{f}_{p(i)} + \mathbf{f}_i$ 
    end
end

```

the gravitational force acting on link i must be included in \mathbf{f}_i^e .

Step 4

Calculate the joint force variables, τ_i . By definition, they are given by the equation

$$\tau_i = \Phi_i^T \mathbf{f}_i . \quad (2.75)$$

Coordinate-Free Algorithm

Equations (2.71)–(2.75) imply the algorithm shown in Table 2.5, which is the coordinate-free version of the **RNEA**. This is the simplest form of the algorithm, and it is suitable for mathematical analysis and related purposes. However, it is not suitable for numerical computation because a numerical version must use coordinate vectors.

Link-Coordinates Algorithm

In general, we say that an algorithm is implemented in link coordinates if a coordinate system is defined for each link, and the calculations pertaining to link i are performed in the coordinate system associated with link i . The alternative is to implement the algorithm in absolute coordinates, in which case all calculations are performed in a single coordinate system, typically that of the base link. In practice, the **RNEA** is more computationally efficient when implemented in link coordinates, and the same is true of most other dynamics algorithms.

To convert the **RNEA** to link coordinates, we first examine the equations to see which ones involve quantities from more than one link. Equations (2.73) and (2.75) each involve quantities pertaining to link i only, and therefore need no modification. Such equations are said to be local to link i . The remaining equations involve quantities from more than one link, and therefore require the insertion of coordinate transformation matrices. The modified versions of (2.71), (2.72), and (2.74) are

$$\mathbf{v}_i = {}^i X_{p(i)} \mathbf{v}_{p(i)} + \Phi_i \dot{\mathbf{q}}_i , \quad (2.76)$$

$$\mathbf{a}_i = {}^i X_{p(i)} \mathbf{a}_{p(i)} + \Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}_i , \quad (2.77)$$

and

$$\mathbf{f}_i = \mathbf{f}_i^a - {}^i X_0^F {}^0 \mathbf{f}_i^e + \sum_{j \in c(i)} {}^i X_j^F \mathbf{f}_j . \quad (2.78)$$

Equation (2.78) assumes that external forces are expressed in absolute (i.e., link 0) coordinates.

The complete algorithm is shown in Table 2.6. The function `j_type` returns the type code for joint i ; the

function `xjcalc` calculates the joint transformation matrix for the specified type of joint; and the functions `pcalc` and `pdcalc` calculate Φ_i and $\dot{\Phi}_i$. The formulae used by these functions for a variety of joint types can be found in Tables 1.5 and 1.6. In the general case, both `pcalc` and `pdcalc` are needed. However, for most common joint types, Φ_i is a known constant in link coordinates, and $\dot{\Phi}_i$ is therefore zero. If it is known in advance that all joints will have this property, then the algorithm can be simplified accordingly. The quantities \mathbf{I}_i and $X_L(i)$ are known constants in link coordinates, and are part of the data structure describing the robot mechanism.

The last assignment in the first loop initializes each \mathbf{f}_i to the expression $\mathbf{f}_i^a - {}^i\mathbf{X}_0^F {}^0\mathbf{f}_i^e$ (using the identity ${}^i\mathbf{X}_0^F = {}^i\mathbf{X}_0^{-T}$). The summation on the right-hand side of (2.78) is then performed in the second loop. This al-

    end
end

```

gorithm includes code to calculate ${}^i\mathbf{X}_0$, which is used to transform the external forces to link coordinates. If there are no external forces, then this code can be omitted. If there is only a single external force (e.g., a force at the end-effector of a robot arm) then this code can be replaced with code that transforms the external force vector successively from one link coordinate system to the next, using ${}^i\mathbf{X}_{p(i)}$.

Note: although the phrase ‘link coordinates’ suggests that we are using moving coordinate frames, the algorithm is in fact implemented in stationary coordinates that happen to coincide with the moving coordinates at the current instant.

3-D Vector RNEA

The original version of the RNEA was developed and expressed using 3-D vectors (e.g. [2.2,4]). Table 2.7 shows a special case of this algorithm, in which the joints are assumed to be revolute, and the joint axes are assumed

to coincide with the z axes of the link coordinate systems. (Without these assumptions, the equations would be a lot longer.) It also assumes that the external forces are zero.

In this algorithm, $\dot{\mathbf{v}}_g'$ is the linear acceleration due to gravity, expressed in base (link 0) coordinates; rot_z computes a rotation matrix representing a rotation of the coordinate frame about the z axis; $\mathbf{R}_L(i)$ is the rotational component of $X_L(i)$; ${}^i\mathbf{R}_{p(i)}$ is the rotational component of ${}^iX_{p(i)}$; p_{calc} and p_{dcalc} are not used because Φ_i is the known constant $(\hat{\mathbf{z}}^T \mathbf{0}^T)^T$; $\dot{\mathbf{v}}_i'$ is the linear acceleration of the origin of link i coordinates (O_i), and is the linear component of the classical acceleration of link i ; ${}^{p(i)}\mathbf{p}_i$ is the position of O_i relative to $O_{p(i)}$ expressed in $p(i)$ coordinates; and m_i , \mathbf{c}_i , and \bar{I}_i^{em} are the inertia parameters of link i . (See Table 2.1 for the equations relating these 3-D quantities to the corresponding spatial quantities.)

At first sight, the 3-D vector algorithm looks significantly different from the spatial vector algorithm. Nevertheless, it can be obtained directly from the spatial vector algorithm simply by expanding the spatial vectors to their 3-D components, restricting the joint type to revolute, converting spatial accelerations to classical accelerations (i.e., replacing each instance of $\dot{\mathbf{v}}_i$ with $\dot{\mathbf{v}}_i' - \boldsymbol{\omega}_i \times \mathbf{v}_i$ as per (2.22)), and applying some 3-D vector identities to bring the equations into the form shown in the table. The conversion from spatial to classical acceleration has one interesting side-effect: \mathbf{v}_i cancels out of the equation of motion, and therefore does not need to be calculated. As a result, the 3-D version of the algorithm has a slight speed advantage over the spatial version.

2.5.2 The Articulated-Body Algorithm

The **ABA** is an $O(N_B)$ algorithm for calculating the forward dynamics of a kinematic tree. However, under normal circumstances, $O(N_B) = O(n)$, so we shall refer to it as an $O(n)$ algorithm. The **ABA** was developed by Featherstone [2.1] and is an example of a constraint-propagation algorithm. Given the joint position, velocity, and applied torque/force variables, this algorithm calculates the joint accelerations. With the joint accelerations determined, numerical integration may be used to provide a simulation of the mechanism.

The key concept in the **ABA** is illustrated in Fig. 2.7. The subtree rooted at link i interacts with the rest of the kinematic tree only through a force \mathbf{f}_i that is transmitted across joint i . Suppose we break the tree at this point, and consider only the motion of the subtree subject to an

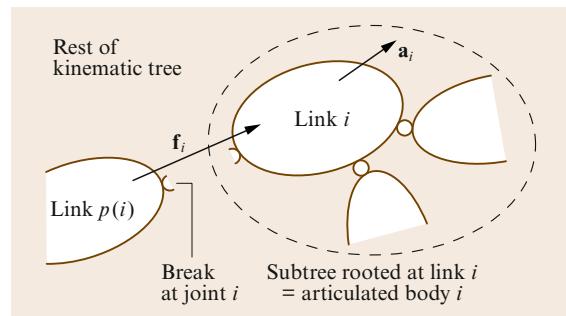

Fig. 2.7 Definition of articulated body i

unknown force, \mathbf{f}_i , acting on link i . It is possible to show that the acceleration of link i is related to the applied force according to the equation

$$\mathbf{f}_i = \mathbf{I}_i^A \mathbf{a}_i + \mathbf{p}_i^A, \quad (2.79)$$

where \mathbf{I}_i^A is called the articulated-body inertia of link i in the subtree (which we can now call an articulated body), and \mathbf{p}_i^A is the associated bias force, which is the force required to produce zero acceleration in link i . Note that \mathbf{p}_i^A depends on the velocities of the individual bodies in the articulated body. Equation (2.79) takes into account the complete dynamics of the subtree. Thus, if we happened to know the correct value of \mathbf{f}_i , then (2.79) would immediately give us the correct acceleration of link i .

The reason we are interested in the quantities \mathbf{I}_i^A and \mathbf{p}_i^A is that they allow us to calculate $\ddot{\mathbf{q}}_i$ from $\mathbf{a}_{p(i)}$, which in turn allows us to calculate \mathbf{a}_i , which then allows us to calculate more joint accelerations, and so on. Combining (2.79) with (2.75) and (2.72) gives

$$\tau_i = \Phi_i^T \mathbf{f}_i = \Phi_i^T (\mathbf{I}_i^A (\mathbf{a}_{p(i)} + \Phi_i \ddot{\mathbf{q}}_i + \dot{\Phi}_i \dot{\mathbf{q}}_i) + \mathbf{p}_i^A),$$

which can be solved for $\ddot{\mathbf{q}}_i$ to give

$$\ddot{\mathbf{q}}_i = \mathbf{D}_i (\mathbf{u}_i - \mathbf{U}_i^T \mathbf{a}_{p(i)}), \quad (2.80)$$

where

$$\mathbf{U}_i = \mathbf{I}_i^A \Phi_i,$$

$$\mathbf{D}_i = (\Phi_i^T \mathbf{U}_i)^{-1} = (\Phi_i^T \mathbf{I}_i^A \Phi_i)^{-1},$$

$$\mathbf{u}_i = \tau_i - \mathbf{U}_i^T \xi_i - \Phi_i^T \mathbf{p}_i^A$$

and

$$\xi_i = \dot{\Phi}_i \dot{\mathbf{q}}_i = \dot{\Phi}_i \dot{\mathbf{q}}_i + \mathbf{v}_i \times \Phi_i \dot{\mathbf{q}}_i.$$

\mathbf{a}_i can then be calculated via (2.72).

It turns out that the articulated-body inertias and bias forces can be calculated efficiently via the recursive formulae

$$\mathbf{I}_i^A = \mathbf{I}_i + \sum_{j \in c(i)} (\mathbf{I}_j^A - \mathbf{U}_j \mathbf{D}_j \mathbf{U}_j^T) \quad (2.81)$$

and

$$\mathbf{p}_i^A = \mathbf{p}_i + \sum_{j \in c(i)} (\mathbf{p}_j^A + \mathbf{I}_j^A \boldsymbol{\xi}_j + \mathbf{U}_j \mathbf{D}_j \mathbf{u}_j), \quad (2.82)$$

where

$$\mathbf{p}_i = \mathbf{v}_i \times \mathbf{I}_i \mathbf{v}_i - \mathbf{f}_i^e.$$

These formulae are obtained by examining the relationship between \mathbf{f}_i and \mathbf{a}_i in Fig. 2.7 and assuming that \mathbf{I}_j^A

and \mathbf{p}_j^A are already known for every $j \in c(i)$. For more details see [2.1, 8, 15, 24].

The complete algorithm is shown in Table 2.8. It is expressed in link coordinates, as per the RNEA in Table 2.6. It makes a total of three passes through the kinematic tree. The first pass iterates from the base out to the tips; it calculates the link velocities using (2.76), the velocity-product term $\boldsymbol{\xi}_i = \dot{\Phi}_i \dot{\mathbf{q}}_i$, and it initializes the variables \mathbf{I}_i^A and \mathbf{p}_i^A to the values \mathbf{I}_i and $\mathbf{p}_i (= \mathbf{v}_i \times \mathbf{I}_i \mathbf{v}_i - {}^i\mathbf{X}_0^T {}^0\mathbf{f}_i^e)$, respectively. The second pass iterates from the tips back to the base; it calculates the articulated-body inertia and bias force for each link using (2.81) and (2.82). The third pass iterates from the base to the tips; it calculates the link and joint accelerations using (2.80) and (2.77).

2.5.3 The Composite-Rigid-Body Algorithm

The CRBA is an algorithm for calculating the joint-space inertia matrix (JSIM) of a kinematic tree. The most common use for the CRBA is as part of a forward dynamics algorithm. It first appeared as method 3 in [2.5].

Forward dynamics, in joint space, is the task of calculating $\ddot{\mathbf{q}}$ from \mathbf{q} , $\dot{\mathbf{q}}$, and τ . Starting from (2.37), the most obvious way to proceed is to calculate \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$, and then solve the linear equation

$$\mathbf{H}\ddot{\mathbf{q}} = \tau - (\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g) \quad (2.83)$$

for $\ddot{\mathbf{q}}$. If the mechanism is a kinematic tree, then \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be computed in $O(n^2)$ and $O(n)$ operations, respectively, and (2.83) can be solved in $O(n^3)$ operations. Algorithms that take this approach are therefore known collectively as $O(n^3)$ algorithms. However, this figure of $O(n^3)$ should be regarded as the worst-case complexity, since the actual complexity depends on the amount of branching in the tree [2.25]. Furthermore, even in the worst case, the n^3 term has a small coefficient, and does not dominate until approximately $n = 60$.

$\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be calculated using an inverse dynamics algorithm. If $ID(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ is the result of an inverse dynamics calculation with arguments \mathbf{q} , $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$, then

$$ID(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}) = \tau = \mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g,$$

so

$$\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = ID(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{0}). \quad (2.84)$$

Thus, the value of $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ for a kinematic tree can be calculated efficiently using the RNEA with $\ddot{\mathbf{q}} = \mathbf{0}$.

The key concept in the CRBA is to note that the JSIM only depends on the joint positions, and not their rates. The CRBA makes the simplifying assumption that the

rate at each joint is zero. By also assuming that gravity is zero, $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ is eliminated from (2.83). Furthermore, for a revolute joint, a unit of joint acceleration applied at the j -th joint produces the j -th column of the JSIM. This partitions the mechanism into two composite rigid bodies connected by the j -th joint, and simplifies the dynamics considerably. This concept has been generalized so that the CRBA may be applied to any joint type within a kinematic tree structure.

It can be shown that the general form of the JSIM for a kinematic tree is

$$\mathbf{H}_{ij} = \begin{cases} \boldsymbol{\Phi}_i^T \mathbf{I}_i^C \boldsymbol{\Phi}_j & \text{if } i \in c^*(j) \\ \boldsymbol{\Phi}_j^T \mathbf{I}_j^C \boldsymbol{\Phi}_i & \text{if } j \in c^*(i) \\ \mathbf{0} & \text{otherwise,} \end{cases} \quad (2.85)$$

where $c^*(i)$ is the set of links in the subtree rooted at link i , including link i itself, and

$$\mathbf{I}_i^C = \sum_{j \in c^*(i)} \mathbf{I}_j. \quad (2.86)$$

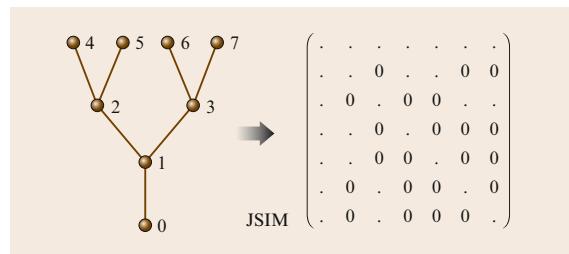

Fig. 2.8 Branch-induced sparsity: branches in the kinematic tree cause certain elements in the JSIM to be zero

See [2.8, 15]. In fact, \mathbf{I}_i^C is the inertia of the composite rigid body formed by the rigid assembly of all the links in $c^*(i)$, and this is where the algorithm gets its name.

Equations (2.85) and (2.86) are the basis of the algorithm shown in Table 2.9, which is the CRBA in link coordinates. This algorithm assumes that the matrices ${}^i\mathbf{X}_{p(i)}$ and $\boldsymbol{\Phi}_i$ have already been calculated, e.g., during the calculation of $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$. If this is not the case, then the relevant lines from Table 2.6 can be inserted into the first loop. The matrix \mathbf{F} is a local variable. The first step, $\mathbf{H} = \mathbf{0}$, can be omitted if there are no branches in the tree.

Having calculated $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ and \mathbf{H} , the final step is to solve (2.83) for $\ddot{\mathbf{q}}$. This can be done using a standard Cholesky or LDL^T factorization. Note that \mathbf{H} can be highly ill-conditioned [2.26], reflecting an underlying ill-conditioning of the kinematic tree itself, so it is recommended to use double-precision arithmetic for every step in the forward dynamics calculation. (This advice applies also to the ABA.)

Exploiting Sparsity

Equation (2.85) implies that some elements of \mathbf{H} will automatically be zero if there are branches in the kinematic tree. An example of this effect is shown in Fig. 2.8. Observe that nearly half of the elements are zero. It is possible to exploit this sparsity using the factorization algorithms described in [2.25]. Depending on the amount of branching in the tree, the sparse algorithms can run many times faster than the standard algorithms.

2.5.4 Operational-Space Inertia Matrix

Two different algorithms are presented to calculate the OSIM. The first is an $O(n^3)$ algorithm that uses the basic definition of the OSIM along with efficient factorization of the JSIM. The second is an $O(n)$ algorithm that is based on efficient solution of the forward dynamics problem.

Algorithm Using Basic Definition

If a robot has a relatively small number of freedoms (e.g., six), then the most efficient method for calculating the OSIM is via (2.52). The procedure is as follows.

1. Calculate \mathbf{H} via the CRBA.
2. Factorize \mathbf{H} into $\mathbf{H} = \mathbf{L}\mathbf{L}^T$ (Cholesky factorization).
3. Use back-substitution to calculate $\mathbf{Y} = \mathbf{L}^{-1}\mathbf{J}^T$.
4. $\Lambda^{-1} = \mathbf{Y}^T\mathbf{Y}$.
5. Factorize Λ^{-1} (optional).

The final step is only possible if the end-effector has a full six DOFs, and is only necessary if the application requires Λ rather than Λ^{-1} . In the second step, an \mathbf{LDL}^T factorization can be used instead of Cholesky, or one can use one of the efficient factorizations described in [2.25] for branched kinematic trees.

The other terms in (2.38) can be calculated via (2.53) and (2.54). In particular, (2.38) can be rewritten in the form

$$\dot{\mathbf{v}} + \Lambda^{-1}(\mathbf{x})[\mu(\mathbf{x}, \mathbf{v}) + \rho(\mathbf{x})] = \Lambda^{-1}(\mathbf{x})\mathbf{f}, \quad (2.87)$$

and the quantity $\Lambda^{-1}(\mu + \rho)$ can be calculated from the formula

$$\Lambda^{-1}(\mu + \rho) = \mathbf{J}\mathbf{H}^{-1}(\mathbf{C}\dot{\mathbf{q}} + \tau_g) - \mathbf{J}\dot{\mathbf{q}}. \quad (2.88)$$

The term $\mathbf{J}\dot{\mathbf{q}}$ is the velocity-product acceleration of the end-effector (2.50). It is calculated as a by-product of calculating $\mathbf{C}\dot{\mathbf{q}} + \tau_g$ via the RNEA (2.84). Specifically, $\mathbf{J}\dot{\mathbf{q}} = \mathbf{a}_{ee} - \mathbf{a}_0$, where \mathbf{a}_{ee} is the calculated acceleration of the end-effector (expressed in the same coordinates as $\dot{\mathbf{v}}$) and \mathbf{a}_0 is the acceleration of the base ($-\mathbf{a}_g$).

$O(n)$ Algorithm

For a sufficiently large value of n , it becomes more efficient to use an $O(n)$ algorithm. Several such algorithms can be found in [2.27–29]. In this section, a more straightforward algorithm is given, which is based on an $O(n)$ calculation of the joint-space forward dynamics problem, e.g., via the ABA. It is a variation of the unit force method [2.28] and computes the inverse of the OSIM.

Starting with (2.87), observe that Λ^{-1} is a function of position only, and certain terms in the dynamic equations can be neglected without affecting its value. Specifically, if the joint rates, $\dot{\mathbf{q}}$, joint forces, τ , and gravitational forces are all set to zero, the value of Λ will remain unchanged. Under these conditions,

$$\dot{\mathbf{v}} = \Lambda^{-1}\mathbf{f}. \quad (2.89)$$

Let us define $\hat{\mathbf{e}}_i$ to be a 6-D coordinate vector with a 1 in the i -th coordinate and zeros elsewhere. If we set

$\mathbf{f} = \hat{\mathbf{e}}_i$ in (2.89), then $\dot{\mathbf{v}}$ will equal column i of Λ^{-1} . Let us also define the function $FD(i, j, \mathbf{q}, \dot{\mathbf{q}}, \mathbf{a}_0, \tau, \mathbf{f})$, which performs a forward-dynamics calculation and returns the true acceleration of link i (i.e., $\mathbf{a}_i - \mathbf{a}_0$), expressed in the same coordinates as \mathbf{f} (typically the base coordinates). The arguments \mathbf{q} , $\dot{\mathbf{q}}$ and τ set the values of the joint position, velocity, and force variables, while j and \mathbf{f} specify that an external force of \mathbf{f} is to be applied to link j . The argument \mathbf{a}_0 specifies a fictitious base acceleration to include gravitational effects, and is set to either $\mathbf{0}$ or $-\mathbf{a}_g$.

With these definitions, we have

$$(\Lambda^{-1})^i = FD(ee, ee, \mathbf{q}, \dot{\mathbf{q}}, \mathbf{0}, \mathbf{0}, \hat{\mathbf{e}}_i) \quad (2.90)$$

and

$$\Lambda^{-1}(\mu + \rho) = -FD(ee, ee, \mathbf{q}, \dot{\mathbf{q}}, -\mathbf{a}_g, \tau, \mathbf{0}), \quad (2.91)$$

where $(\Lambda^{-1})^i$ is column i of Λ^{-1} , and ee is the body number of the end-effector. It therefore follows that the coefficients of (2.87) can be calculated using the algorithm shown in Table 2.10. This algorithm is $O(n)$.

The efficiency of the algorithm may be increased significantly when computing Λ^{-1} by noting that: (1) \mathbf{v}_i , ζ_i , and τ_i in the ABA calculation (Table 2.8) may be set to zero, and (2) \mathbf{I}_i^A and the quantities that depend upon it (\mathbf{U}_i and \mathbf{D}_i) need only be computed once, since they do not vary with the applied force. Also, note that the algorithm may be applied to multiple end-effectors by modifying FD to accept a list of end-effector body numbers in its first argument, and return a composite vector containing the accelerations of all the specified bodies. The algorithm in Table 2.10 is then enclosed in a `for` loop that controls the second argument to FD , and iterates over all the end-effector body numbers [2.19]. However, with several end-effectors, the force propagation method of Lilly [2.28] should probably be used for enhanced computational efficiency. If there are m end-effectors, then the complexity is $O(m n)$.

Table 2.10 Algorithm to compute the inverse of the operational-space inertia matrix and other terms

```

     $\dot{\mathbf{v}}^j = FD(ee, ee, \mathbf{q}, \mathbf{0}, \mathbf{0}, \mathbf{0}, \hat{\mathbf{e}}_j)$ 
end

 $\Lambda^{-1} = [\dot{\mathbf{v}}^1 \dot{\mathbf{v}}^2 \dots \dot{\mathbf{v}}^6]$ 
 $\Lambda^{-1}(\mu + \rho) = -FD(ee, ee, \mathbf{q}, \dot{\mathbf{q}}, -\mathbf{a}_g, \tau, \mathbf{0})$ 

```

2.6 Kinematic Loops

All of the algorithms in the last section were for kinematic trees. In this section, a final algorithm is provided for the forward dynamics of closed-loop systems. The algorithm supplements the dynamic equations of motion for a spanning tree of the closed-loop system, with the loop-closure constraint equations. Three different methods are given to solve the resulting linear system of equations. An efficient algorithm is given to compute the loop-closure constraints.

Systems with closed kinematic loops exhibit more complicated dynamics than kinematic trees. For example:

1. The degree of motion freedom of a kinematic tree is fixed, but that of a closed-loop system can vary.
2. The degree of instantaneous motion freedom is always the same as the degree of finite motion freedom in a kinematic tree, but they can be different in a closed-loop system.
3. Every force in a kinematic tree can be determined, but some forces in a closed-loop system can be indeterminate. This occurs whenever a closed-loop system is overconstrained.

Two examples of these phenomena are shown in Fig. 2.9. The mechanism in Fig. 2.9a has no finite motion freedom, but it has two degrees of infinitesimal motion freedom. The mechanism in Fig. 2.9b has one degree of freedom when $\theta \neq 0$, but if $\theta = 0$ then the two arms, A and B, are able to move independently, and the mechanism has two degrees of freedom. Moreover, at the boundary between these two motion regimes, the mechanism has three degrees of infinitesimal motion freedom. Both these mechanisms are planar, and are therefore overconstrained.

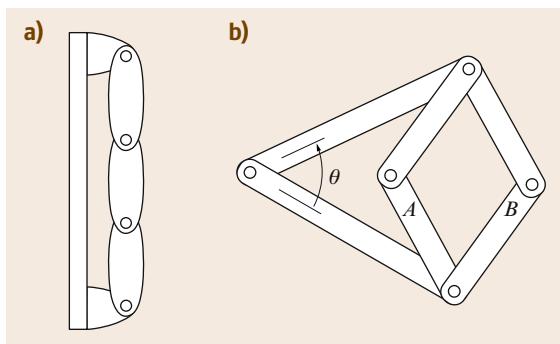

Fig. 2.9 Pathological closed-loop systems

As a result, the out-of-plane components of the joint constraint forces are indeterminate. This kind of indeterminacy has no effect on the motions of these mechanisms, but it does complicate the calculation of their dynamics.

2.6.1 Formulation of Closed-Loop Algorithm

A closed-loop system can be modeled as a spanning tree subject to a set of loop-closure constraint forces. If

$$\mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = \boldsymbol{\tau}$$

is the equation of motion of the spanning tree on its own, then the equation of motion for the closed-loop system is

$$\mathbf{H}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g = \boldsymbol{\tau} + \boldsymbol{\tau}^a + \boldsymbol{\tau}^c, \quad (2.92)$$

where $\boldsymbol{\tau}^a$ and $\boldsymbol{\tau}^c$ are vectors of loop-closure active and constraint forces, respectively, expressed in the generalized force coordinates of the spanning tree. $\boldsymbol{\tau}^a$ is a known quantity, and $\boldsymbol{\tau}^c$ is unknown. $\boldsymbol{\tau}^a$ comes from the force elements acting at the loop-closing joints (springs, dampers and actuators). If there are no such force elements, then $\boldsymbol{\tau}^a = \mathbf{0}$.

The loop-closure constraints restrict the motion of the spanning tree. At the acceleration level, these constraints can be expressed in the form of a linear equation,

$$\mathbf{L}\ddot{\mathbf{q}} = \mathbf{l}, \quad (2.93)$$

where \mathbf{L} is an $n^c \times n$ matrix. n^c is the number of constraints due to the loop-closing joints, and is given by the formula

$$n^c = \sum_{k=N_B+1}^{N_J} n_k^c, \quad (2.94)$$

where n_k^c is the number of constraints imposed by joint k . If $\text{rank}(\mathbf{L}) < n^c$ then the loop-closure constraints are linearly dependent, and the closed-loop mechanism is overconstrained. The mobility of a closed-loop system (i.e., its degree of motion freedom) is given by the formula

$$\text{mobility} = n - \text{rank}(\mathbf{L}). \quad (2.95)$$

Given a constraint equation in the form of (2.93), it follows that the constraint forces can be expressed in the form

$$\tau^c = \mathbf{L}^T \lambda, \quad (2.96)$$

where $\lambda = (\lambda_{N_B+1}^T \dots \lambda_{N_J}^T)^T$ is an $n^c \times 1$ vector of unknown constraint-force variables (or Lagrange multipliers). If the mechanism is overconstrained, then \mathbf{L}^T will have a null space, and the component of λ lying in this null space will be indeterminate.

It is often possible to identify redundant constraints in advance. For example, if a kinematic loop is known to be planar, then the out-of-plane loop-closure constraints are redundant. In these circumstances, it is advantageous to remove the corresponding rows of \mathbf{L} and elements of \mathbf{I} and λ . The removed elements of λ can be assigned a value of zero.

Combining (2.92), (2.93), and (2.96) produces the following equation of motion for a closed-loop system:

$$\begin{pmatrix} \mathbf{H} & \mathbf{L}^T \\ \mathbf{L} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{q}} \\ -\lambda \end{pmatrix} = \begin{pmatrix} \boldsymbol{\tau} + \boldsymbol{\tau}^a - (\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g) \\ \mathbf{I} \end{pmatrix}. \quad (2.97)$$

The system matrix is symmetric, but indefinite. If \mathbf{L} has full rank, then the system matrix will be nonsingular, otherwise it will be singular, and one or more elements of λ will be indeterminate.

Equation (2.97) can be solved in any of the following ways:

1. solve it directly for $\ddot{\mathbf{q}}$ and λ
2. solve for λ first, and then use the result to solve for $\ddot{\mathbf{q}}$
3. solve (2.93) for $\ddot{\mathbf{q}}$, substitute the result into (2.92), eliminate the unknown constraint forces, and solve for the remaining unknowns

Method 1 is the simplest, but generally also the least efficient. This method is appropriate when the system matrix is nonsingular. As the size of the system matrix is $(n + n^c) \times (n + n^c)$, this method is $O((n + n^c)^3)$.

Method 2 is particularly useful if $n \gg n^c$, and offers the opportunity to use $O(n)$ algorithms on the spanning tree [2.6]. From (2.97),

$$\mathbf{L}\mathbf{H}^{-1}\mathbf{L}^T\lambda = \mathbf{I} - \mathbf{L}\mathbf{H}^{-1}[\boldsymbol{\tau} + \boldsymbol{\tau}^a - (\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g)]. \quad (2.98)$$

This equation can be formulated in $O(n(n^c)^2)$ operations via $O(n)$ algorithms, and solved in $O((n^c)^3)$. Once λ is known, $\boldsymbol{\tau}^c$ can be calculated via (2.96) in $O(n n^c)$ operations, and (2.92) solved by an $O(n)$ al-

gorithm; so the total complexity is $O(n(n^c)^2 + (n^c)^3)$. If \mathbf{L} is rank deficient, then $\mathbf{L}\mathbf{H}^{-1}\mathbf{L}^T$ will be singular; but it is still a positive-semidefinite matrix, and presents a slightly easier factorization problem than a singular instance of the indefinite system matrix in (2.97).

Method 3 is useful if $n - n^c$ is small, or if \mathbf{L} is expected to be rank deficient. Equation (2.93) is solved using a special version of Gaussian elimination (or similar procedure), which is equipped with a numerical rank test, and which is designed to solve underdetermined systems. The solution is an equation of the form

$$\ddot{\mathbf{q}} = \mathbf{K}\mathbf{y} + \ddot{\mathbf{q}}_0,$$

where $\ddot{\mathbf{q}}_0$ is any particular solution to (2.93), \mathbf{K} is an $n \times (n - \text{rank}(\mathbf{L}))$ matrix with the property $\mathbf{L}\mathbf{K} = \mathbf{0}$, and \mathbf{y} is a vector of $n - \text{rank}(\mathbf{L})$ unknowns. (Typically, \mathbf{y} is a linearly independent subset of the elements of $\ddot{\mathbf{q}}$.) Substituting this expression for $\ddot{\mathbf{q}}$ into (2.92), and premultiplying both sides by \mathbf{K}^T to eliminate $\boldsymbol{\tau}^c$, produces

$$\mathbf{K}^T \mathbf{H} \mathbf{K} \mathbf{y} = \mathbf{K}^T (\boldsymbol{\tau} + \boldsymbol{\tau}^a - (\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g) - \mathbf{H}\ddot{\mathbf{q}}_0). \quad (2.99)$$

This method also has cubic complexity, but it can be the most efficient if $n - n^c$ is small. It is also reported to be more stable than method 1 [2.30].

2.6.2 Closed-Loop Algorithm

Algorithms for calculating \mathbf{H} and $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ can be found in Sections 2.5.3 and 2.5.1, respectively, which just leaves \mathbf{L} , \mathbf{I} and $\boldsymbol{\tau}^a$. To keep things simple, we will assume that all loop-closing joints are zero-DOF joints. There is no loss of generality with this assumption: one simply breaks open the loops by cutting links instead of joints (see Fig. 2.10). However, there may be some loss of efficiency. With this assumption, we only need to calculate \mathbf{L} and \mathbf{I} , since $\boldsymbol{\tau}^a = \mathbf{0}$.

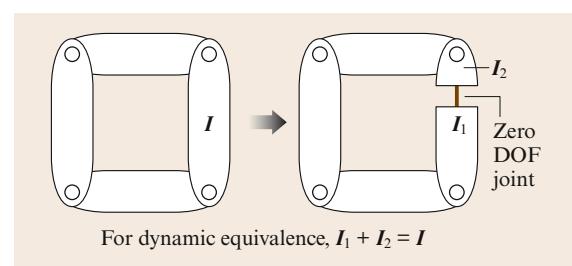

Fig. 2.10 Inserting a zero-DOF joint in preparation for cutting the loop open at that joint

Loop Constraints

In the general case, the velocity constraint equation for loop k is

$$(\Psi_k^c)^T (\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) = \mathbf{0}, \quad (2.100)$$

and the acceleration constraint is

$$(\Psi_k^c)^T (\mathbf{a}_{s(k)} - \mathbf{a}_{p(k)}) + (\dot{\Psi}_k^c)^T (\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) = \mathbf{0}. \quad (2.101)$$

However, if every loop-closing joint has zero DOF, then these equations simplify to

$$\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)} = \mathbf{0} \quad (2.102)$$

and

$$\mathbf{a}_{s(k)} - \mathbf{a}_{p(k)} = \mathbf{0}. \quad (2.103)$$

Let us define a loop Jacobian, \mathbf{J}_k , with the property that

$$\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)} = \mathbf{J}_k \dot{\mathbf{q}}. \quad (2.104)$$

\mathbf{J}_k is a $6 \times n$ matrix defined by the formula

$$\mathbf{J}_k = (e_{1k} \Phi_1 \cdots e_{N_B k} \Phi_{N_B}), \quad (2.105)$$

where

$$e_{ik} = \begin{cases} +1 & \text{if } s(k) \in c^*(i) \text{ and } p(k) \notin c^*(i), \\ -1 & \text{if } p(k) \in c^*(i) \text{ and } s(k) \notin c^*(i), \\ 0 & \text{otherwise.} \end{cases}$$

In other words, $e_{ik} = +1$ if joint i lies on the path to $s(k)$ but not the path to $p(k)$; $e_{ik} = -1$ if joint i lies on the path to $p(k)$ but not the path to $s(k)$; and $e_{ik} = 0$ if joint i lies on both paths or on neither.

The loop acceleration constraint can now be written

$$\begin{aligned} \mathbf{0} &= \mathbf{a}_{s(k)} - \mathbf{a}_{p(k)} \\ &= \mathbf{J}_k \ddot{\mathbf{q}} + \dot{\mathbf{J}}_k \dot{\mathbf{q}} \\ &= \mathbf{J}_k \ddot{\mathbf{q}} + \mathbf{a}_{s(k)}^{vp} - \mathbf{a}_{p(k)}^{vp}, \end{aligned} \quad (2.106)$$

where \mathbf{a}_i^{vp} is the velocity-product acceleration of link i , which is the acceleration it would have if $\dot{\mathbf{q}}$ were zero. The velocity-product acceleration of every link is calculated during the calculation of the vector $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$ (2.84). If the RNEA is used to calculate $\mathbf{C}\dot{\mathbf{q}} + \boldsymbol{\tau}_g$, then

\mathbf{a}_i^{vp} will be the value of \mathbf{a}_i calculated by the RNEA with its acceleration argument set to zero.

The matrices \mathbf{L} and \mathbf{l} can now be expressed as follows:

$$\mathbf{L} = \begin{pmatrix} \mathbf{L}_{N_B+1} \\ \vdots \\ \mathbf{L}_{N_J} \end{pmatrix} \quad \text{and} \quad \mathbf{l} = \begin{pmatrix} \mathbf{l}_{N_B+1} \\ \vdots \\ \mathbf{l}_{N_J} \end{pmatrix}, \quad (2.107)$$

where

$$\mathbf{L}_k = \mathbf{J}_k \quad (2.108)$$

and

$$\mathbf{l}_k = \mathbf{a}_{p(k)}^{vp} - \mathbf{a}_{s(k)}^{vp}. \quad (2.109)$$

Constraint Stabilization

In practice, it is necessary to stabilize loop-closure constraints, or they will simply fly apart during simulation because of numerical integration errors. The standard technique is due to Baumgarte [2.3, 7, 31], and consists of replacing each constraint equation of the form

$$a_e = 0$$

with one of the form

$$a_e + K_v v_e + K_p p_e = 0,$$

where a_e , v_e , and p_e are the acceleration, velocity, and position errors, respectively, and K_v and K_p are positive constants. Typically, one chooses a time constant, t_c , according to how quickly one wants the position and velocity errors to decay. K_p and K_v are then given by the formulae $K_v = 2/t_c$ and $K_p = 1/t_c^2$. However, there is no good rule for choosing t_c . If t_c is too long, then loop-constraint errors accumulate faster than they decay; if t_c is too short, then the equations of motion become excessively stiff, causing a loss of numerical integration accuracy. A reasonable value for a large, slow industrial robot is $t_c = 0.1$, while a smaller, faster robot might need $t_c = 0.01$.

To incorporate stabilization terms into the loop constraint equation, we replace (2.109) with

$$\mathbf{l}_k = \mathbf{a}_{p(k)}^{vp} - \mathbf{a}_{s(k)}^{vp} - K_v(\mathbf{v}_{s(k)} - \mathbf{v}_{p(k)}) - K_p \mathbf{p}_{ek}, \quad (2.110)$$

where \mathbf{p}_{ek} is a vector representing the position error in loop k . In absolute coordinates (i.e., link 0 coordinates), \mathbf{p}_{ek} is given by

$$\mathbf{p}_{ek} = \text{x_to_vec}({}^0\mathbf{X}_{p(k)} \mathbf{X}_{L1}^{-1}(k) \mathbf{X}_{L2}(k)^{s(k)} \mathbf{X}_0), \quad (2.111)$$

where the $\mathbf{X}_{L1}(k)$ and $\mathbf{X}_{L2}(k)$ transforms are defined in (2.62) and (2.63), and shown in Fig. 2.4 for joint k , and $\text{x_to_vec}({}^B\mathbf{X}_A)$ computes a vector approximating the displacement from frame A to frame B , assuming this displacement to be infinitesimal. x_to_vec can be defined as

$$\text{x_to_vec}(\mathbf{X}) = \frac{1}{2} \begin{pmatrix} X_{23} - X_{32} \\ X_{31} - X_{13} \\ X_{12} - X_{21} \\ X_{53} - X_{62} \\ X_{61} - X_{43} \\ X_{42} - X_{51} \end{pmatrix}. \quad (2.112)$$

Algorithm

Table 2.11 shows an algorithm for calculating \mathbf{L} and \mathbf{I} for the special case when all the loop-closing joints have zero DOF. It combines simplicity with good performance by transforming every quantity that is needed to formulate the loop-closure constraints into a single coordinate system, in this case absolute (link 0) coordinates, so that no further transforms are needed.

The first loop calculates the transforms from absolute to link coordinates, and uses them to transform $\boldsymbol{\Phi}_i$ to absolute coordinates. Only the $\boldsymbol{\Phi}_i$ that are needed in the loop-closure constraints are transformed.

The second loop calculates the nonzero elements of \mathbf{L} (which can be sparse), according to (2.105). The inner while loop terminates on the root of the loop, which is the highest-numbered common ancestor of links $p(k)$ and $s(k)$. It could be the fixed base if they have no other common ancestor. The second loop ends with the calculation of \mathbf{I} , in absolute coordinates, according to (2.110).

Table 2.11 Algorithm to calculate loop-closure constraints

inputs: *model*, *RNEA partial results*

outputs: \mathbf{L}, \mathbf{I}

model data: $N_B, p(i), N_J, p(k), s(k), LB(i),$

$\mathbf{X}_{L1}(k), \mathbf{X}_{L2}(k), K_p, K_v$

RNEA data: $\boldsymbol{\Phi}_i, {}^i\mathbf{X}_{p(i)}, \mathbf{v}_{p(k)}, \mathbf{v}_{s(k)}, \mathbf{a}_{p(k)}^{vp}, \mathbf{a}_{s(k)}^{vp}$

for $i = 1$ to N_B **do**

if $p(i) \neq 0$ **then**

${}^i\mathbf{X}_0 = {}^i\mathbf{X}_{p(i)} {}^{p(i)}\mathbf{X}_0$

end

if $LB(i) \neq \text{null}$ **then**

${}^0\boldsymbol{\Phi}_i = {}^i\mathbf{X}_0^{-1} \boldsymbol{\Phi}_i$

end

end

$\mathbf{L} = \mathbf{0}$

for $k = N_B + 1$ to N_J **do**

$i = p(k)$

$j = s(k)$

while $i \neq j$ **do**

if $i > j$ **then**

$\mathbf{L}_{k,i} = -{}^0\boldsymbol{\Phi}_i$

$i = p(i)$

else

$\mathbf{L}_{k,j} = {}^0\boldsymbol{\Phi}_j$

$j = p(j)$

end

end

$\mathbf{a}_e = {}^{s(k)}\mathbf{X}_0^{-1} \mathbf{a}_{s(k)}^{vp} - {}^{p(k)}\mathbf{X}_0^{-1} \mathbf{a}_{p(k)}^{vp}$

$\mathbf{v}_e = {}^{s(k)}\mathbf{X}_0^{-1} \mathbf{v}_{s(k)} - {}^{p(k)}\mathbf{X}_0^{-1} \mathbf{v}_{p(k)}$

$\mathbf{p}_e = \text{x_to_vec}({}^{p(k)}\mathbf{X}_0^{-1} \mathbf{X}_{L1}^{-1}(k) \mathbf{X}_{L2}(k)^{s(k)} \mathbf{X}_0)$

$\mathbf{l}_k = -\mathbf{a}_e - K_v \mathbf{v}_e - K_p \mathbf{p}_e$

end

2.7 Conclusions and Further Reading

This chapter has presented the fundamentals of rigid-body dynamics as they apply to robot mechanisms. It has covered the following topics: the spatial vector algebra, which provides a concise notation for describing and implementing dynamics equations and algorithms; the canonical equations of motion that are most frequently used in robotics; how to construct a dynamic model of

a robot; and several efficient model-based algorithms for calculating inverse dynamics, forward dynamics, and the joint-space and operational-space inertia matrices.

There are many topics in dynamics that have not been mentioned in this chapter, but can be found in later chapters of this handbook. The dynamics of robots with elastic links and joints is covered in Chap. 13; the prob-

lem of identifying the parameters of a dynamic model is covered in Chap. 14; the dynamics of physical contact between a robot and the objects in its environment is described in Chap. 27; and the dynamics of robots with floating bases is described in Chap. 45.

We conclude this chapter by noting that a brief history of robot dynamics can be found in [2.32], and that a more extensive treatment of robot dynamics can be found in books such as [2.8, 10, 15, 28, 33–35]. Finally, some suggestions for further reading are listed below.

2.7.1 Multibody Dynamics

Robot dynamics can be regarded as a subset (or a specific application) of the broader discipline of multibody dynamics. Books on multibody dynamics include [2.3, 14, 31, 36–41]. Of course, multibody dynamics is, in turn, a subset of classical mechanics; and the mathematical foundations of the subject can be found in any good book on classical mechanics, such as [2.13].

2.7.2 Alternative Representations

This chapter has used spatial vectors to express the equations of motion. There are various alternatives to the use of spatial vectors: other kinds of 6-D vector, 3-D vectors, 4×4 matrices, and the spatial operator algebra. All 6-D vector formalisms are similar, but are not exactly the same. The main alternatives to spatial vectors are: screws [2.10–12], motors [2.42], Lie algebras [2.12, 43], and ad hoc notations. (An ad hoc notation is one in which 3-D vectors are grouped into pairs for the purpose of reducing the volume of algebra.) Three-dimensional vectors are the formalism used in most classical mechanics and multibody texts, and are also a precursor to 6-D vector and 4×4 matrix formalisms. 4×4 matrices are popular in robotics because they are very useful for kinematics. However, they are not so useful for dynamics. 4×4 matrix formulations of dynamics can be found in [2.33, 44, 45]. The spatial operator algebra was developed at the Jet Propulsion Laboratory (JPL) by Rodriguez, Jain, and others. It uses $6N$ -dimensional vectors and $6N \times 6N$ matrices, the latter regarded as linear operators. Examples of this notation can be found in [2.46–48].

2.7.3 Alternative Formulations

This chapter used a vectorial formulation of the equations of motion that is usually called the Newtonian or Newton–Euler formulation. The main alternative is

the Lagrangian formulation, in which the equations of motion are obtained via Lagrange's equation. Examples of the Lagrangian formulation can be found in [2.9, 10, 17, 49, 50]. Kane's method has also been applied in robotics [2.51, 52].

2.7.4 Efficiency

Because of the need for real-time implementation, especially in control, the robotics community has focused on the problem of computational efficiency. For *inverse dynamics*, the $O(n)$ recursive Newton–Euler algorithm (**RNEA**) of Luh et al. [2.4] remains the most important algorithm. Further improvements to the algorithm are given in [2.53, 54]. For *forward dynamics*, the two algorithms presented in this chapter remain the most important for computational considerations: the $O(n)$ articulated-body algorithm (**ABA**) developed by Featherstone [2.1] and the $O(n^3)$ algorithm based on the composite-rigid-body algorithm (**CRBA**) of Walker and Orin [2.5]. Improvements were made in the **ABA** over the years [2.15, 16, 24] so that it was more efficient than the **CRBA**-based algorithm for decreasingly smaller values of n . However, recent application of the **CRBA** to branched kinematic trees [2.25] and robotic systems with motion-controlled appendages [2.55] continue to show the viability of the **CRBA** approach.

For the *joint-space inertia matrix*, the **CRBA** [2.5] is the most important algorithm. A number of improvements and modifications have been made over the years to increase its computational efficiency [2.15, 56–58]. For the *operational-space inertia matrix*, efficient $O(n)$ algorithms have been developed [2.27–29] and applied to increasingly complex systems [2.19].

2.7.5 Accuracy

Concerns can arise over the numerical accuracy of a dynamics algorithm, the accuracy of a simulation (i.e., numerical integration accuracy), or the accuracy of a dynamic model. The numerical accuracy of dynamics algorithms has received relatively little attention compared with efficiency. The **RNEA**, **CRBA**, and **ABA** have all been tested for accuracy on a large variety of rigid-body systems, but the same cannot be said of most other algorithms. Rigid-body systems are often ill-conditioned, in the sense that a small change in the applied force (or a model parameter) can produce a large change in the resulting acceleration. This phenomenon was studied by Featherstone [2.26], who discovered that the ill-conditioning gets worse with in-

creasing body count, and that it can grow in proportion to $O(n^4)$ in the worst case. Other publications on this topic include [2.8, 30, 59, 60].

2.7.6 Software Packages

A number of software packages have been developed to provide dynamic simulation capabilities for multibody systems, and in particular, robotic systems. Several have been written in MATLAB® for ease of integration with other analysis, control, and simulation programs. While many of these are open source, some are offered at a relatively low cost to the user. They differ in their capabilities in a variety of ways including: speed, topologies and joint models supported, accuracy, underlying dynamic formulation and associated order of complexity, user interface, graphics support, numerical integration routines, integration with other code, application support, and cost. Among those commonly cited are: Adams [2.61], Autolev [2.62], DynaMechs [2.63], Open Dynamics Engine [2.64], Robotics Studio [2.65], Robotics Toolbox [2.66], SD/FAST [2.67], SimMechanics [2.68], and Webots [2.69].

2.7.7 Symbolic Simplification

The technique of symbolic simplification takes a general-purpose dynamics algorithm, and applies it symbolically to a specific dynamic model. The result is a list of assignment statements detailing what the algorithm would have done if it had been executed for real. This list is then inspected and pruned of all unnecessary calculations, and the remainder is output to a text file in the form of computer source code. This code can run as much as ten times faster than the original general-purpose algorithm, but it is specific to one dynamic model. Both Autolev [2.62] and SD/FAST [2.67] use this technique. Other publications on symbolic simplification for dynamics include [2.70–75].

2.7.8 Algorithms for Parallel Computers

In order to speed up the common dynamics computations, a number of algorithms have been developed for parallel and pipelined computers. For *inverse dynamics*, early work focused on speeding up the $O(n)$ RNEA on up to n processors [2.76, 77] while subsequent work resulted in $O(\log_2 n)$ algorithms [2.78, 79]. For the $O(n^2)$ CRBA to compute the *joint-space inertia matrix*, early work resulted in $O(\log_2 n)$ algorithms for n processors to compute the composite-rigid-body inertias and diagonal elements of the matrix [2.80, 81]. Subsequent work resulted in $O(\log_2 n)$ algorithms for $O(n^2)$ processors to compute the entire matrix [2.82, 83]. For *forward dynamics*, speedup was obtained for a multiple manipulator system on a parallel/pipelined supercomputer [2.84]. The first $O(\log_2 n)$ algorithm for n processors was developed for an unbranched serial chain [2.85]. More recent work has focused on $O(\log_2 n)$ algorithms for more complex structures [2.60, 86, 87].

2.7.9 Topologically-Varying Systems

There are many robot mechanisms whose topology varies over time because of a change of contact conditions, especially with the environment. In legged vehicles, use of a compliant ground-contact model to compute the contact forces reduced the closed-loop structure to a tree structure [2.88]. However, for cases in which the contacts are very stiff, numerical integration problems may result. In more recent work [2.35, 89] in which hard contact constraints are assumed, an efficient method was used to reduce the large number of coordinate variables from that which may be necessary in general-purpose motion analysis systems [2.38]. Also, they were able to automatically identify the variables as the structure varied and developed a method for computing the velocity boundary conditions after configuration changes [2.35, 89].

Mechanisms

3. Mechanisms and Actuation

Victor Scheinman, J. Michael McCarthy

This chapter focuses on the principles that guide the design and construction of robotic systems. The kinematics equations and Jacobian of the robot characterize its range of motion and mechanical advantage, and guide the selection of its size and joint arrangement. The tasks a robot is to perform and the associated precision of its movement determine detailed features such as mechanical structure, transmission, and actuator selection. Here we discuss in detail both the mathematical tools and practical considerations that guide the design of mechanisms and actuation for a robot system.

The following sections discuss characteristics of the mechanisms and actuation that affect the performance of a robot. The first four sections discuss the basic features of a robot manipulator and their relationship to the mathematical model that is used to characterize its performance. The next two sections focus on the details of the structure and actuation of the robot and how they combine to yield various types of robots. The final section relates these design features to various performance metrics.

3.1 Overview

The physical structure such as the beams, links, castings, shafts, slides, and bearings of a robot that create its movable skeleton is termed the mechanical structure or mechanism of the robot. The motors, hydraulic or pneumatic pistons, or other elements that cause the

links of the mechanism to move are called actuators. In this chapter we consider the variety of designs for the mechanisms and actuators that result in a machine system that transforms computer commands into versatile physical movement.

Early robots were designed with general motion capability under the assumption that they would find the largest market if they could perform the widest variety of tasks; this emphasis on flexibility proved to be expensive in both cost and performance. Robots are now beginning to be designed with a specific set of tasks in mind.

Robot design focuses on the number of joints, physical size, payload capacity, and the movement requirements of the end-effector. The configuration of the movable skeleton and the overall size of the robot are determined by task requirements for reach, workspace, and reorientation ability. These features affect the precision of end-effector path control needed for arc-welding

and for the smooth movement of paint spraying. They also define the absolute positioning capability necessary for assembly, the repeatability needed for materials handling, and the fine resolution that allows precise, real-time sensor-based motions.

A critical concern in robotic system design is the range of tasks the robot is expected to perform. The robot should be designed to have the flexibility it needs to perform the range of tasks for which it is intended. This determines the topology of the robot mechanism and the actuator system. The choices of geometry, material, sensors, and cable routing follow from these basic decisions.

3.2 System Features

The primary features that characterize a robot are its work envelope and load capacity.

3.2.1 Work Envelope

The space in which a robot can operate is its work envelope, which encloses its workspace. While the workspace of the robot defines positions and orientations that it can achieve to accomplish a task, the work envelope also includes the volume of space the robot itself occupies as it moves. This envelope is defined by the types of joints, their range of movement and the lengths of the links that connect them. The physical size of this envelope and the loads on the robot within this envelope are of primary consideration in the design of the mechanical structure of a robot.

Fig. 3.1 The PUMA 560 robot

Robot work envelope layouts must include considerations of regions of limited accessibility where the mechanical structure may experience movement limitations. These constraints arise from limited joint travel range, link lengths, the angles between axes, or a combination of these. Revolute joint manipulators generally work better in the middle of their work envelopes than at extremes (Fig. 3.1). Manipulator link lengths and joint travel should be chosen to leave margins for variable sensor-guided controlled path motions and for tool or end-effector changes, as offsets and length differences will often alter the work envelope.

3.2.2 Load Capacity

Load capacity, a primary robot specification, is closely coupled with acceleration and speed. For assembly robots, mechanism acceleration and stiffness (structure and drive stiffness) are often more important design parameters than peak velocity or maximum load capacity, as minimizing small pick-and-place motion cycle time, while maintaining placement precision, is generally a top priority. In the case of arc-welding, where slow controlled-path motion is required, velocity jitter and weld path-following accuracy are important. Load capacity should be seen as a variable. It is wise to design and specify a manipulator in terms of useful payload as a function of performance rather than just in terms of maximum capacity.

Load capacity specifications must take into account gravity and inertial loading seen at the end-effector. These factors strongly affect wrist, end-effector design and drive selection. In general, load capacity is

more a function of manipulator acceleration and wrist torque than any other factor. The load rating also affects manipulator static structural deflection, steady-state motor torque, system natural frequency, damping, and the choice of servosystem control parameters for best performance and stability.

3.2.3 Kinematic Skeleton

Manipulator shape and size is determined by requirements on its workspace shape and layout, the precision of its movement, its acceleration and speed, and its construction. Cartesian manipulators (with or without revolute wrist axes) have the simplest transform and control equation solutions. Their prismatic (straight-line motion), perpendicular axes make motion planning and computation easy and relatively straightforward. Because their major motion axes do not couple dynamically (to a first order), their control equations are also simplified. Manipulators with all revolute joints are generally harder to control, but they feature a more compact and efficient structure for a given working volume. It is generally easier to design and build a good revolute joint than a long motion prismatic joint. The workspaces of revolute joint manipulators can easily overlap for coordinated multirobot installations, in contrast to gantry-style robots.

Final selection of the robot configuration should capitalize on specific kinematic, structural or performance requirements. For example, a requirement for a very precise vertical straight-line motion may dictate the choice of a simple prismatic vertical axis rather than two or three revolute joints requiring coordinated control.

Six degrees of freedom (DOFs) are the minimum required to place the end-effector or tool of a robotic manipulator at any arbitrary location (position and orientation) within its accessible workspace. Most simple or preplanned tasks can be performed with fewer than six DOFs. This is because they can be carefully set up to eliminate certain axis motions, or because the tool or task does not require full specification of location. An example of this is vertical assembly using a powered screwdriver, where all operations can be achieved with three degrees of freedom.

Some applications require the use of manipulators with more than six DOFs, in particular when mobility or obstacle avoidance are necessary. For example, a pipe-crawling maintenance robot requires control of the robot's shape as well as precise positioning of its end-effector. Generally, adding degrees of freedom increases cycle time and reduces load capacity and accuracy for a given manipulator configuration and drive system.

3.3 Kinematics and Kinetics

The dynamics of a robot can be separated into the properties of the movement that depend upon the geometry of its mechanical structure, termed *kinematics*, and those that depend on forces that act on the system, known as *kinetics*. It is a law of dynamics that the difference between the change in energy of the moving robot and the work performed by the forces acting on it does not change over small variations of its trajectory. This is called the *principle of virtual work* and states that variations in work and energy must cancel for all virtual displacements [3.1, 2].

Because machines such as robots are designed to minimize energy losses, often due to joint friction and material strain losses, we can assume that the variation in energy is small. This means that the work input of the actuators is nearly equal to the work of the output forces.

If we consider this relationship over a small duration of time, we have that the time rate of input work, or input

power is nearly equal to the associated output power. Because power is force times velocity, we obtain the fundamental relationship that the ratio of input to output forces is the reciprocal of the ratio of input to output speeds. Another way of saying this is that, in the ideal machine, *the mechanical advantage of a machine is the inverse of its speed ratio*.

3.3.1 Robot Topology

The kinematic skeleton of a robot is modeled as a series of links connected by either hinged or sliding joints forming a serial chain. This skeleton has two basic forms, that of a single serial chain called a *serial robot* (Fig. 3.1) and as a set of serial chains supporting a single end-effector, called a *parallel robot*, such as the platform shown in Fig. 3.2. Robots can be configured to work in parallel such as the individual legs of walking machines (Figs. 3.3 and 3.4) [3.3], as

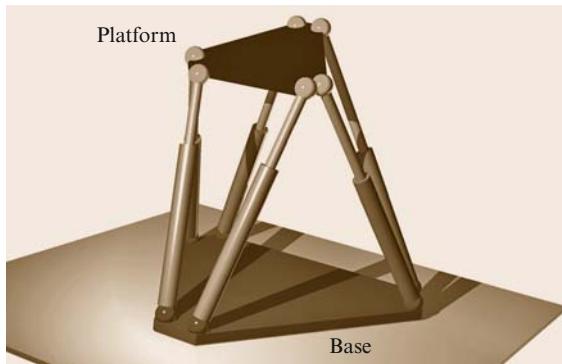

Fig. 3.2 A parallel robot can have as many as six serial chains that connect a platform to the base frame

Fig. 3.3 A photograph of the adaptive suspension vehicle (ASV) walking machine

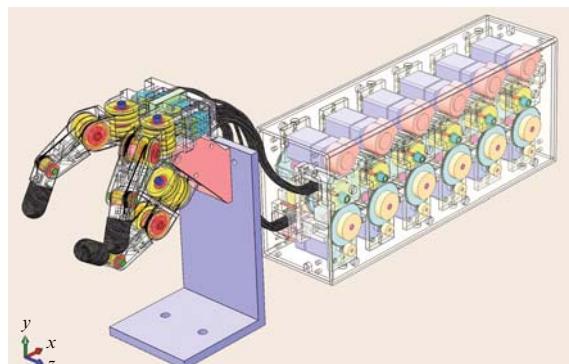

Fig. 3.5 The Salisbury three-fingered robot hand with its cable drive system

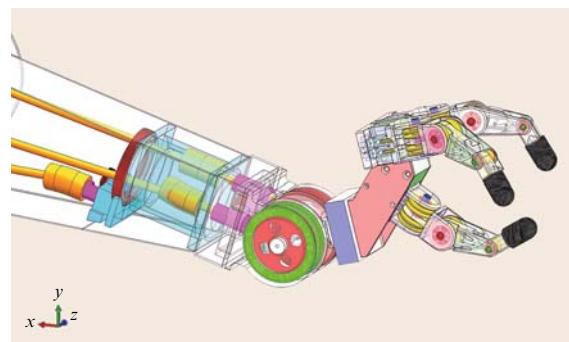

Fig. 3.6 The Salisbury hand as the end-effector of a PUMA robot (the drive system is not shown)

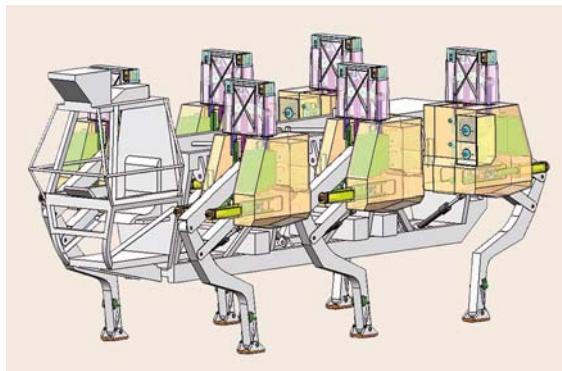

Fig. 3.4 The adaptive suspension vehicle walking machine

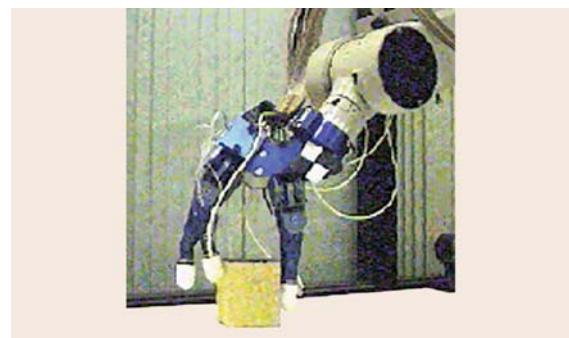

Fig. 3.7 A photograph of the Salisbury three-fingered hand grasping a block

well as the fingers of mechanical hands (Figs. 3.6 and 3.7) [3.4].

The robot end-effector is the preferred tool for interaction with the environment, and the ability to position and orient this end-effector is defined by the skeleton of

the robot. In a general serial robot, a chain of six joints provides full control over the end-effector. In a general parallel robot, there are more than six joints and the six actuators may be applied to these joints in a variety of ways to control the movement of the end-effector.

3.3.2 Kinematics Equations

A robot is designed so that specifying the values of local joint parameters, such as the angle of rotary joints and the travel of sliding joints, specifies the position of every component of a machine using its kinematics equations. To do this the robot is described by a sequence of lines representing the axes \hat{z}_j of equivalent revolute or prismatic joints and the common normal lines \hat{x}_j which form the kinematic skeleton of the chain (Fig. 3.2). This construction allows the specification of the location of each link of the robot relative to the base by the matrix equation

$$\mathbf{T} = \mathbf{Z}(\theta_1, d_1) \mathbf{X}(\alpha_1, a_1) \mathbf{Z}(\theta_2, d_2) \dots \mathbf{X}(\alpha_{m-1}, a_{m-1}) \mathbf{Z}(\theta_m, d_m), \quad (3.1)$$

known as the *kinematics equations* of the chain [3.5, 6] (see Chap. 1; (1.44)). The set of all positions \mathbf{T} that the end-effector can reach for all values of the joint parameters is called the *workspace* of the robot.

The matrices $\mathbf{Z}(\theta_j, d_j)$ and $\mathbf{X}(\alpha_j, a_j)$ are 4×4 matrices that define screw displacements around and along the joint axes \hat{z}_j and \hat{x}_j , respectively [3.7]. The parameters α_j and a_j define the dimensions of the links in the chain. The parameter θ_j is the joint variable for revolute joints and d_j is the variable for prismatic joints. The trajectory ${}^F\mathbf{p}(t)$ of a point ${}^M\mathbf{p}$ in the end-effector is obtained from the joint trajectory, $\mathbf{q}(t) = (q_1(t), \dots, q_m(t))^\top$, where q_i is either θ_i or d_i depending on the joint, given by

$${}^F\mathbf{p}(t) = \mathbf{T}(\mathbf{q}(t)) {}^M\mathbf{p}. \quad (3.2)$$

If the end-effector is connected to the base frame by more than one serial chain (Fig. 3.2) then we have a set of kinematics equations for each chain,

$$\mathbf{T} = \mathbf{B}_j \mathbf{T}(\mathbf{q}_j) \mathbf{E}_j, \quad j = 1, \dots, n, \quad (3.3)$$

where \mathbf{B}_j locates the base of the j -th chain and \mathbf{E}_j defines the position of its attachment to the part, or end-effector. The set of positions \mathbf{T} that simultaneously satisfy all of these equations is the workspace of the part. This imposes constraints on the joint variables that must be determined to define its workspace completely [3.8, 9].

3.3.3 Configuration Space

The kinematics equations of the robot relate the range of values available for the joint parameters, called the configuration space of the robot, to the workspace of the end-effector. This configuration space is a fundamental

tool in robot path planning for obstacle avoidance [3.10]. Though any link in the chain forming a robot may hit an obstacle, it is the end-effector that is intended to approach and move around obstacles such as the table supporting the robot and the fixtures for parts it is to pick up. Obstacles define forbidden positions and orientations in the workspace which map back to forbidden joint angles in the configuration space of the robot. Robot path planners seek trajectories to a goal position through the free space around these joint space obstacles [3.11].

3.3.4 Speed Ratios

The speed ratios of a robot relate the velocity ${}^F\dot{\mathbf{p}}$ of a point ${}^F\mathbf{p}$ in the end-effector to the joint rates $\dot{\mathbf{q}} = (\dot{q}_1, \dots, \dot{q}_m)^\top$, that is

$${}^F\dot{\mathbf{p}} = \mathbf{v} + \boldsymbol{\omega} \times ({}^F\mathbf{p} - \mathbf{d}), \quad (3.4)$$

where \mathbf{d} and \mathbf{v} are the position and velocity of a reference point, respectively, and $\boldsymbol{\omega}$ is the angular velocity of the end-effector.

The vectors \mathbf{v} and $\boldsymbol{\omega}$ depend on the joint rates \dot{q}_j through the formula

$$\begin{pmatrix} \mathbf{v} \\ \boldsymbol{\omega} \end{pmatrix} = \begin{pmatrix} \frac{\partial \mathbf{v}}{\partial \dot{q}_1} & \frac{\partial \mathbf{v}}{\partial \dot{q}_2} & \dots & \frac{\partial \mathbf{v}}{\partial \dot{q}_m} \\ \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_1} & \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_2} & \dots & \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_m} \end{pmatrix} \begin{pmatrix} \dot{q}_1 \\ \vdots \\ \dot{q}_m \end{pmatrix}, \quad (3.5)$$

or

$$\mathbf{v} = \mathbf{J}\dot{\mathbf{q}}. \quad (3.6)$$

The coefficient matrix \mathbf{J} in this equation is called the *Jacobian* and is a matrix of speed ratios relating the velocity of the tool to the input joint rotation rates [3.6, 9].

3.3.5 Mechanical Advantage

If the end-effector of the robot exerts a force \mathbf{f} at the point ${}^F\mathbf{p}$, then the power output is

$$P_{\text{out}} = \mathbf{f} \cdot {}^F\dot{\mathbf{p}} = \sum_{j=1}^m \mathbf{f} \cdot \left[\frac{\partial \mathbf{v}}{\partial \dot{q}_j} + \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_j} \times ({}^F\mathbf{p} - \mathbf{d}) \right] \dot{q}_j. \quad (3.7)$$

Each term in this sum is the portion of the output power that can be associated with an actuator at joint S_j , if one exists.

The power input at joint S_j is the product $\tau_j \dot{q}_j$ of the torque τ_j and joint angular velocity \dot{q}_j . Using the principle of virtual work for each joint we can compute

$$\tau_j = \mathbf{f} \cdot \frac{\partial \mathbf{v}}{\partial \dot{q}_j} + ({}^F\mathbf{p} - \mathbf{d}) \times \mathbf{f} \cdot \frac{\partial \boldsymbol{\omega}}{\partial \dot{q}_j}, \quad j = 1, \dots, m. \quad (3.8)$$

We have arranged this equation to introduce the force-torque vector $\mathbf{f} = (f, (\mathbf{f} \cdot \mathbf{p} - \mathbf{d}) \times \mathbf{f})^\top$ at the reference point \mathbf{d} .

The equations (3.8) can be assembled into the matrix equation

$$\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{f}, \quad (3.9)$$

where \mathbf{J} is the *Jacobian* defined above in (3.5). For a chain with six joints this equation can be solved for the output force-torque vector \mathbf{f} ,

$$\mathbf{f} = (\mathbf{J}^\top)^{-1} \boldsymbol{\tau}. \quad (3.10)$$

Thus, the matrix that defines the mechanical advantage for this system is the inverse of the matrix of speed ratios.

3.4 Serial Robots

A serial chain robot is a sequence of links and joints that begins at a base and ends with an end-effector (Fig. 3.8). The links and joints of a robot are often configured to provide separate translation and orientation structures. Usually, the first three joints are used to position a reference point in space and the last three form the *wrist* which orients the end-effector around this point [3.12, 13]. This reference point is called the *wrist center*. The volume of space in which the wrist center can be placed is called the *reachable workspace* of the robot. The rotations available at each of these points is called the *dexterous workspace*.

The design of a robot is often based on the symmetry of its reachable workspace. From this point of view there are three basic shapes: rectangular, cylindrical, and spherical [3.6]. A rectangular workspace is provided by three mutually perpendicular prismatic (P) joints which form a PPPS chain called a *Cartesian* robot – S denotes a spherical wrist which allows all rotations about its center point. A rotary base joint combined with two prismatic joints forms a CPS chain with a cylindrical workspace – C denotes a rotary (R) and sliding (P) joint with the same axis. The P-joint can be replaced by a revolute (R) joint that acts as an elbow in order to provide the same radial movement. Finally, two rotary joints at right angles form a T-joint at the base of the robot that

supports rotations about a vertical and horizontal axes. Radial movement is provided either by a P-joint, or by an R-joint configured as an elbow. The result is a TPS or TRS chain with a spherical workspace.

It is rare that the workspace is completely symmetrical because joint axes are often offset to avoid link collisions and there are limits to joint travel which combine to distort the shape of the workspace.

3.4.1 Design Optimization

Another approach to robot design uses a direct specification of the workspace as a set of positions for the end-effector of a robotic system [3.14–17] which we call the *task space*. A general serial robot arm has two design parameters, link offset and twist, for each of five links combined with four parameters each that locate the base of the robot and the workpiece in its end-effector, making a total of 18 design variables. The link parameters are often specified so the chain has a spherical wrist and specific workspace shape. The design goal is usually to determine the workspace volume and locate the base and workpiece frames so that the workspace encloses the specified task space.

The task space is defined by a set of 4×4 transformations $\mathbf{D}_i, i = 1, \dots, k$. The problem is solved iteratively by selecting a design and using the associated kinematics equations $\mathbf{T}(\mathbf{q})$ to evaluate relative displacements in the objective function

$$f(\mathbf{r}) = \sum_{i=1}^k \|\mathbf{D}_i \mathbf{T}^{-1}(\mathbf{q}_i)\|. \quad (3.11)$$

Optimization techniques yield the design parameter vector \mathbf{r} that minimizes this objective function.

This optimization depends on the definition of the distance measure between the positions reached by the end-effector and the desired workspace. Park [3.18], Martinez and Duffy [3.19], Zefran et al. [3.20], Lin and

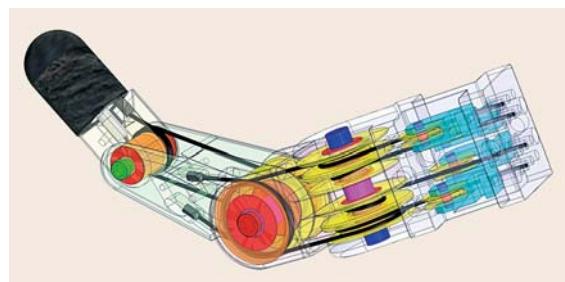

Fig. 3.8 A single finger of the Salisbury hand is a serial chain robot

Burdick [3.21], and others have shown that there is no distance metric that is coordinate frame invariant. This means that, unless this objective function can be forced to zero so the workspace completely contains the task space, the resulting design will not be *geometric* in the sense that the design is not independent of the choice of coordinates.

3.4.2 Speed Ratios

A six-axis robot has a 6×6 Jacobian \mathbf{J} obtained from (3.5) that is an array of speed ratios relating the components of the velocity \mathbf{v} of the wrist center and the angular velocity $\boldsymbol{\omega}$ of the end-effector to each of the joint velocities. Equation (3.9) shows that this Jacobian defines the force-torque vector \mathbf{f} exerted at the wrist center in terms of the torque applied by each of the actuators. The link parameters of the robot can be selected to provide a Jacobian \mathbf{J} with specific properties.

The sum of the squares of the actuator torques of a robot is often used as a measure of *effort* [3.22, 23]. From (3.9) we have

$$\boldsymbol{\tau}^\top \boldsymbol{\tau} = \mathbf{f}^\top \mathbf{J} \mathbf{J}^\top \mathbf{f} . \quad (3.12)$$

The matrix $\mathbf{J} \mathbf{J}^\top$ is square and positive definite. Therefore, it can be viewed as defining a hyperellipsoid in

six-dimensional space [3.24]. The lengths of the semi-diameters of this ellipsoid are the inverse of the absolute value of the eigenvalues of the Jacobian \mathbf{J} . These eigenvalues may be viewed as *modal* speed ratios that define the amplification associated with each joint velocity. Their reciprocals are the associated *modal* mechanical advantages, so the shape of this ellipsoid illustrates the force amplification properties of the robot.

The ratio of the largest of these eigenvalues to the smallest, called the condition number, gives a measure of the anisotropy or *out-of-roundness* of the ellipsoid. A sphere has a condition number of one and is termed *isotropic*. When the end-effector of a robot is in a position with an isotropic Jacobian there is no amplification of the speed ratios or mechanical advantage. This is considered to provide high-fidelity coupling between the input and output because errors are not amplified [3.25, 26]. Thus, the condition number is used as a criterion in a robot design [3.27].

In this case, it is assumed that the basic design of the robot provides a workspace that includes the task space. Parameter optimization finds the internal link parameters that yield the desired properties for the Jacobian. As in minimizing the distance to a desired workspace, optimization based on the Jacobian depends on a careful formulation to avoid coordinate dependency.

3.5 Parallel Robots

A robotic system in which two or more serial chain robots support an end-effector is called a *parallel robot*. For example, the adaptive suspension vehicle (ASV) leg (Fig. 3.9), is a pantograph mechanism driven by parallel actuation. Each supporting chain of a parallel robot may have as many as six degrees of freedom, however, in general only a total of six joints in the entire system are actuated. A good example is the Stewart platform formed from six TPS robots in which usually only the prismatic joint (P-joint) in each chain is actuated (Fig. 3.2) [3.9, 28, 29].

The kinematics equations of the TPS legs are

$$\mathbf{T} = \mathbf{B}_j \mathbf{T}(\theta_j) \mathbf{E}_j, \quad j = 1, \dots, 6 , \quad (3.13)$$

where \mathbf{B}_j locates the base of the leg and \mathbf{E}_j defines the position of its attachment to the end-effector. The set of positions \mathbf{T} that simultaneously satisfy all of these equations is the workspace of the parallel robot.

Often the workspace of an individual chain of a parallel robot can be defined by geometric constraints, for

example, a position \mathbf{T} is in the workspace of the j -th supporting TPS chain if it satisfies the constraint equation

$$(\mathbf{T}\mathbf{x}_j - \mathbf{p}_j) \cdot (\mathbf{T}\mathbf{x}_j - \mathbf{p}_j) = \rho_j^2 . \quad (3.14)$$

This equation defines the distance between the base joint \mathbf{p}_j and the point of attachment ${}^F\mathbf{x}_j = \mathbf{T}\mathbf{x}_j$ to the platform as the length ρ_j is controlled by the actuated prismatic joint. In this case the workspace is the set of positions \mathbf{T} that satisfy all six equations, one for each leg.

3.5.1 Workspace

The workspace of a parallel robot is the intersection of the workspaces of the individual supporting chains. However, it is not the intersection of the reachable and dexterous workspaces separately. These workspaces are intimately combined in parallel robots. The dexterous workspace is usually largest near the center of the reachable workspace and shrinks as the reference point moves

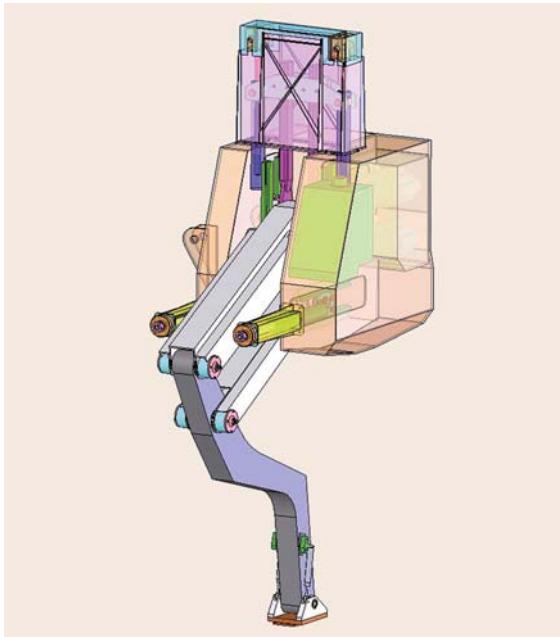

Fig. 3.9 One leg of the ASV walking machine is a parallel robot

toward the edge. A focus on the symmetry of movement allowed by supporting leg designs has been an important design tool resulting in many novel parallel designs [3.30, 31]. Simulation of the system is used to evaluate its workspace in terms of design parameters.

Another approach is to specify directly the positions and orientations that are to lie in the workspace and solve the algebraic equations that define the leg constraints to determine the design parameters [3.32, 33]. This is known as kinematic synthesis and yields parallel robots that are asymmetric but have specified reachable and dexterous workspaces, see *McCarthy* [3.34].

3.5.2 Mechanical Advantage

The force amplification properties of a parallel robot are obtained by considering the Jacobians of the individual supporting chains. Let the linear and angular velocity of the platform be defined by the six-vector $\mathbf{v} = (\mathbf{v}, \boldsymbol{\omega})^\top$, then from the kinematics equations of each of the support legs we have

$$\mathbf{v} = J_1 \dot{\rho}_1 = J_2 \dot{\rho}_2 = \cdots = J_6 \dot{\rho}_6 . \quad (3.15)$$

Here we assume that the platform is supported by six chains, but it can be fewer, such as when the fingers of a mechanical hand grasp an object [3.4].

The force on the platform applied by each chain is obtained from the principle of virtual work as

$$\mathbf{f}_j = (J_j^\top)^{-1} \boldsymbol{\tau}_j, \quad j = 1, \dots, 6 . \quad (3.16)$$

There are only six actuated joints in the system so we assemble the associated joint torques into the vector $\boldsymbol{\tau} = (\tau_1, \dots, \tau_6)^\top$. If \mathbf{f}_i is the force-torque vector obtained from (3.16) for $\tau_i = 1$ and the remaining torques to zero, then the resultant force-torque \mathbf{w} applied to the platform is

$$\mathbf{w} = (\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_6) \boldsymbol{\tau} , \quad (3.17)$$

or

$$\mathbf{w} = \boldsymbol{\Gamma} \boldsymbol{\tau} . \quad (3.18)$$

The elements of the coefficient matrix $\boldsymbol{\Gamma}$ define the mechanical advantage for each of the actuated joints. In the case of a Stewart platform the columns of this matrix are the Plücker coordinates of the lines along each leg [3.29].

The principle of virtual work yields the velocity of the platform in terms of the joints rates $\dot{\rho}$ as

$$\boldsymbol{\Gamma}^\top \mathbf{v} = \dot{\rho} . \quad (3.19)$$

Thus, the inverse of $\boldsymbol{\Gamma}$ defines the speed ratios between the actuated joints and the end-effector. The same equation can be obtained by computing the derivative of the geometric constraint equations (3.14), and $\boldsymbol{\Gamma}$ is the Jacobian of the parallel robot system [3.35].

The Jacobian $\boldsymbol{\Gamma}$ is used in parameter optimization algorithms to design parallel robots [3.36] with isotropic mechanical advantage. The square root of the determinant $|\boldsymbol{\Gamma} \boldsymbol{\Gamma}^\top|$ measures the six-dimensional volume spanned by the column vectors \mathbf{f}_j . The distribution of the percentage of this volume compared to its maximum within the workspace is also used as a measure of the overall performance [3.37, 38]. A similar performance measure normalizes this Jacobian by the maximum joint torques available and the maximum component of force and torque desired, and then seeks an isotropic design [3.39].

3.5.3 Specialized Parallel Robots

Another approach to the design of parallel robots has been to separate their functionality into orientation and translational platforms. *Tsai* and *Joshi* [3.40] and *Jin* and *Yang* [3.41] survey designs for a class of parallel chains that generate pure translation. *Kong* and *Gosselin* [3.42] and *Hess-Coelho* [3.43] do the same for parallel chains that provide rotational movement in space.

3.6 Mechanical Structure

For the purposes of dynamic modeling, the links of a robot are generally considered to be rigid. However, a robot is not a rigid structure. Like all structures it deflects under applied loads, such as its own weight and the weight of the payload, termed gravity loading; see Figs. 3.10 and 3.11. The issue is a matter of degree. The more force that is needed to cause a deflection in the links, the more the robot moves like a connected set of rigid bodies. Rigid robots have links designed to be stiff so the deflections under load are less than the positioning accuracy required for their range of tasks. This allows the dynamic model and control algorithms to ignore link deflection. Most commercially available robot arms are of this type (see *Rivin* [3.44]).

It is possible to improve the positioning accuracy of a rigid robot by augmenting a control algorithm that includes a model of link deflection resulting from gravity loading. It is also possible to use strain sensors to measure loads and deflections. These *semirigid* robots assume small structural deflections that are linearly related to known applied loads.

Flexible robots require that the dynamic model include the deflection of its various links under gravity loading as well as under the forces associated with link acceleration, called inertia loading. The robot control algorithms must control the vibration of the system as well as its gross motion. Management of vibration is required even in rigid robots to achieve high speed and manipulate large payloads.

3.6.1 Links

For industrial robots a critical concern is the link stiffness in bending and in torsion. To provide this stiffness, robot links are designed either as beams or shell (monocoque) structures. Monocoque structures have lower weight or higher strength-to-weight ratios, but are more costly and generally more difficult to manufacture. Cast, extruded, or machined beam-based links are often more cost effective; see *Juvinal and Marshek* [3.45], and *Sigley and Mischke* [3.46,47].

Another important consideration is whether the link structure includes bolted, welded, or adhesive bonded assemblies of cast, machined, and fabricated elements. Screw and bolted connections may seem straightforward, inexpensive, and easily maintained, but the inevitable deflection of a link even in the manufacturing process introduces creep in these multiple element assemblies that changes the dimensions and performance

of the robot. Welded and cast structures are much less susceptible to creep and the associated hysteresis deformation, though in many cases they require secondary manufacturing operations such as thermal stress relieving and finish machining.

The minimum practical wall or web thickness for castings may be thicker than necessary for stiffness. Thin walls can be achieved with structural skin (monocoque) structures but this is offset by the potential for denting, permanent deformation, and damage in the event of slight collisions. Therefore, the performance requirements must be considered when selecting the construction and fabrication details of the robot.

Fig. 3.10 The hydraulic Skywash aircraft cleaning robot

Fig. 3.11 The DeLaval VMS milking robot

Performance- and application-specific materials and geometry are used to reduce the weight of the links and therefore the associated gravity and inertial loading. For structures that move in a straight line, aluminum or magnesium alloy extrusions of constant cross section are convenient. Carbon and glass-fiber composites provide lower mass for robots that require high acceleration (painting robots). Thermoplastic materials provide low-cost link structures though at reduced load capacity. Stainless steel is often used in robots for medical and food service applications. Because rotary joints generate linear accelerations that increase with the distance from the axis, links attached to these joints are often designed to taper in cross section or wall thickness to reduce the associated inertial loading.

3.7 Joint Mechanisms

A robot joint mechanism consists of at least four major components: the joint axis structure, an actuator, transmission, and state sensor (usually for position feedback, but velocity and force sensors are also common).

For low-performance manipulators that accelerate the payload at less than a peak of 0.5 g , system inertia is not as important as gravity forces and torques. This means the actuators can be placed near the joints, and their suspended weight compensated using counterbalancing masses, springs, or gas pressure.

In high-performance robots where peak payload accelerations reach $3\text{--}10\text{ g}$ or more, minimizing system inertia is important. The actuators are placed near the first joint axis of a serial link manipulator to minimize its inertial contribution, and drive links, belts or cables or gear transmissions are used to drive the joints.

While a longer transmission distance can reduce mass and gravity moments and inertia, it introduces flexibility and thus reduces the system stiffness. The design of the actuator placement and transmission for each joint is a tradeoff between weight, inertia, stiffness, and complexity. This choice dictates the major physical characteristics of a manipulator design. To illustrate this point, consider the Adept 1 assembly robot which has four degrees of freedom, each with a different structure. The first axis has a direct motor drive. The second axis is driven by a band drive, and the third by a belt drive. Finally, the fourth axis uses a linear ball-screw drive. For a variety of useful joint mechanisms see *Sclater and Chironis* [3.48].

3.6.2 Joints

Joints for most robots allow either rotary or linear movement, termed revolute and prismatic joints. Other joints that are available are the ball-in-socket, or spherical joint, and the Hooke-type universal joint.

Integration of the mechanical structure of the robot with its joint mechanism, which includes the actuator and joint motion sensor, is a source of structural flexibility. Deformation in the joint at the bearing housings can reduce shaft and gear preloads, allowing backlash or free play, which reduces precision. Structural flexibility can also introduce changes in gear center spacing, introducing forces and torques and associated deflection, binding, jamming, and wear.

3.7.1 Joint Axis Structures

Revolute Joints

Revolute or rotary motion joints are designed to perform pure rotation while minimizing other displacements and motions. The most important measure of the quality of a revolute joint is its stiffness or resistance to all undesired motion. Key factors to be considered in design for stiffness are shaft diameter, clearances and tolerances, mounting configuration of the bearings, and the implementation of proper bearing preloading. Shaft diameter and bearing size are not always based on load-carrying capacity; rather, they often will be selected to be compatible with a rigid mounting configuration and also have a bore large enough to pass cables, hoses, and even drive elements for other joints. Because joint shafts will frequently be torque-transmitting members, they and their supporting structure must be designed both for bending and torsional stiffness. The first axis of the PUMA robot is an example of such a joint with its large-diameter tubular configuration.

An important factor in maintaining stiffness in a revolute joint is the choice of bearing-mounting configuration. The mounting arrangement and mount must be designed to accommodate manufacturing tolerances, thermal expansion and bearing preload. Axial preloading of ball or tapered roller bearings improves system accuracy and stiffness by minimizing bearing radial and axial play. Preloads can be achieved through selective assembly or elastic (spring) elements, shim spacers,

threaded collars, four-point contact bearings, duplex bearing arrangements, and tight manufacturing tolerances.

Prismatic Joints

There are two basic types of prismatic or linear motion joints: single-stage and telescoping joints. Single-stage joints are made up of a moving surface that slides linearly along a fixed surface. Telescoping joints are essentially sets of nested or stacked single-stage joints. Single-stage joints feature simplicity and high stiffness, whereas the primary advantage of telescoping joints is their retracted-state compactness and large extension ratio. Telescoping joints have a lower effective joint inertia for some motions because part of the joint may remain stationary or move with reduced acceleration.

The primary functions of bearings in prismatic joints are to facilitate motion in a single direction and to prevent motion in all other directions. Preventing these unwanted motions poses the more challenging design problem. Deformations in the structure can significantly affect bearing surface configuration, which affects performance. In severe cases, roller deflection under load may cause binding, which precludes motion. For high-precision prismatic joints, ways must be made straight over long distances. The required precision grinding on multiple surfaces can be expensive. Expensive and bulky covers are required to shield and seal a prismatic bearing and way.

The primary criterion for evaluating higher number (in or near the wrist or end-effector) linear motion joints or axes is the stiffness-to-weight ratio. Achieving a good stiffness-to-weight ratio requires the use of a hollow or thin-walled structure rather than solid members for the moving elements.

Bearing spacing is extremely important in design for stiffness. If this spacing is too short, system stiffness will be inadequate no matter how great the bearing stiffness. Major causes for failure in prismatic joints are foreign particle contamination and surface fatigue wear (brinelling) of the ways caused by excessive ball loading due to high preload, moment loads and shock loads.

The large exposed precision surfaces in most prismatic joints make them much more sensitive than revolute joints to improper handling and environmental effects. They are also significantly more difficult to manufacture, properly assemble, and align.

Common types of sliding elements for prismatic motion are bronze or thermoplastic impregnated bushings. These bushings have the advantage of being low in cost,

of having relatively high load capacity, and of working with unhardened or superficially hardened (i.e., plated or anodized) surfaces. Because the local or contact stress on the moving element is distributed and is low this element may be made of thin tubing. Another type of bushing in common use is the ball bushing. Ball bushings have the advantages of lower friction and greater precision than plain bushings. However, they require that the contacting surface of the joint be heat treated or hardened (generally to $Rc\ 55$ or greater) and of sufficient case and wall thickness to support the ball point contact loads and resulting high stresses.

Ball and roller slides are also commonly used in robot prismatic joints. There are two basic categories of these slides; recirculating and non-recirculating. Non-recirculating ball and roller slides are used primarily for short-travel applications. They feature high precision and very low friction at the expense of being more sensitive to shock and relatively poor at accommodating moment loading. Recirculating ball slides are somewhat less precise but can carry higher loads than non-recirculating ball slides. They can also be set up to handle relatively large moment loads. Travel range can be up to several meters. Commercial recirculating ball slides and ways have greatly simplified the design and construction of linear axes, particularly in gantry and track manipulators.

Another common type of prismatic robot joint is made up of cam followers, rollers, or wheels rolling on extruded, drawn, machined, or ground surfaces. In high-load applications the surfaces must be hardened before they are finish ground. Cam followers can be purchased with eccentric mounting shafts to facilitate setup and adjustment. Elastomer rollers provide quiet, smooth operation.

Fig. 3.12 RobotWorld is an integrated workcell with multiple robot modules that move on air bearings

Two less common types of linear or prismatic joints feature flexures and air bearings. Flexure-based joints, whose motion results from elastic bending deformations of beam support elements, are used primarily for small, high-resolution, quasilinear motions. Air bearings require smooth surfaces and close control of tolerances as well as a constant supply of filtered, oil-free compressed air. Two- and three-degree-of-freedom air bearings (x, y, θ) can enable multiaxis motion with few moving parts; see Fig. 3.12.

Joint Travel

For revolute joint configurations, the shoulder and elbow joints and links determine the gross volume of the work envelope (reachable workspace) of a robot manipulator arm. The wrist joints generally determine the orientation range (dexterous workspace) about a point within this work envelope. Larger joint travel may increase the number of possible manipulator configurations that will reach a particular location (increased task space). Wrist joint travel in excess of 360° and up to 720° can be useful for situations requiring controlled-path (e.g., straight-line) motion, synchronized motion such as conveyor tracking, or sensor-modified motions. Continuous last-joint rotation is desirable in certain cases like loading or unloading a rotating machine or mating threaded parts.

Additional joints and links, sometimes in the robot but more often in the end-effector, and specialized tooling also serve to increase the task space of a robot. Continuous and controlled-path robot motion requires planning to avoid singularities (regions where two or more joints may become aligned or nearly aligned) and the resulting unstable end-effector motion in these regions. Manipulator design coordinated with a well-planned workcell layout can improve the useful task space by placing critical motions well away from singularity regions. For example, a standard three-axis robot wrist has singularities 180° apart, which can be increased to 360° by implementing a somewhat more complex reduced singularity wrist. Such a wrist is used in a sheep-shearing robot to achieve multiple, long, continuous, smooth, constant-velocity, sensor-guided passes over the contoured body of a sheep to shear its wool [3.49, 50].

3.7.2 Actuators

Actuators supply the motive power for robots. Most robot actuators are commercially available components, which are adapted or modified, as necessary, for a specific robot application. The three commonly used actuators are hydraulic, pneumatic, and electromagnetic.

Hydraulic Actuators

Hydraulic actuators, chosen as power sources for the earliest industrial robots, offer very large force capability and high power-to-weight ratios. In a hydraulic system the power is provided mechanically from an electric motor or engine driven high-pressure fluid pump, see Fig. 3.10. Actuators are most commonly linear cylinders, rotary vane actuators, and hydraulic motors. Actuator control is through a solenoid valve (on/off control) or a servovalve (proportional control), which is driven electrically from a low-power electronic control circuit. The hydraulic power supply is bulky and the cost of the proportional, fast-response servo-valves are high. Leaks and maintenance issues have limited the use and application of hydraulically powered robots.

Pneumatic Actuators

Pneumatic actuators are primarily found in simple manipulators. Typically they provide uncontrolled motion between mechanical limit stops. These actuators provide good performance in point-to-point motion. They are simple to control and are low in cost. Although a few small actuators may be run with typical factory air supplies, extensive use of pneumatic-actuated robots requires the purchase and installation of a costly dedicated compressed-air source. Pneumatic actuators have low energy efficiency.

Proportional, closed-loop, servo-controlled pneumatic manipulators have been developed and successfully applied, principally in applications where safety, environmental, and application conditions discourage electric drives. An example is an early version of the DeLaval International AB Tumba, Sweden VMS (Voluntary Milking System) cow-milking robot, which used pneumatic actuators and electro-pneumatic proportional valve joint controls in a farm, milking stall, environment (Fig. 3.11).

Electromagnetic Actuators

The most common types of actuators in robots today are electromagnetic actuators.

Stepper Motors. Small, simple robots, such as benchtop adhesive dispensing robots, frequently use stepper or pulse motors of the permanent magnet (PM) hybrid type or sometimes the variable reluctance (VR) type (see Fig. 3.13). These robots use open-loop position and velocity control. They are relatively low in cost and interface easily to electronic drive circuits. Microstep control can produce 10 000 or more discrete

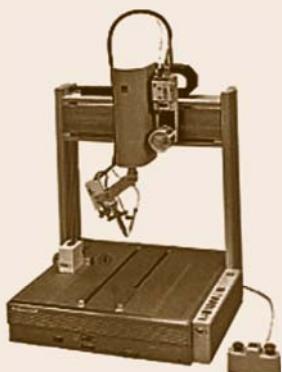

Fig. 3.13 The Sony robot uses open-loop permanent-magnet stepper motors

Fig. 3.14 The Adept robot uses closed-loop control and variable-reluctance motors

robot joint positions. In open-loop step mode the motors and robot motions have a significant settling time, which can be damped either mechanically or through the application of control algorithms. Power-to-weight ratios are lower for stepper motors than for other types of electric motors. Stepper motors operated with closed-loop control function similarly to direct-current (DC) or alternating-current (AC) servomotors (Fig. 3.14).

Permanent-Magnet DC Motor. The permanent-magnet, direct-current, brush-commutated motor is widely available and comes in many different types and configurations. The lowest-cost permanent-magnet motors use ceramic (ferrite) magnets. Robot toys and hobby robots often use this type of motor. Neodymium (NEO) magnet motors have the highest energy-product magnets, and in general produce the most torque and power for their size.

Ironless rotor motors, often used in small robots, typically have copper wire conductors molded into epoxy or composite cup or disk rotor structures. The advantages of these motors include low inductance, low friction, and no cogging torque. Disk armature motors have several advantages. They have short overall lengths, and because their rotors have many commutation segments, they produce a smooth output with low torque ripple. A disadvantage of ironless armature motors is that they have a low thermal capacity due to low mass and limited thermal paths to their case. As a result, when driven at high power levels they have rigid duty-cycle limitations or require forced-air cooling.

Brushless Motors. Brushless motors, also called AC servomotors or brushless DC motors, are widely used in industrial robots (see Figs. 3.15 and 3.16). They substitute magnetic or optical sensors and electronic switching circuitry for the graphite brushes and copper bar commutator, thus eliminating the friction, sparking, and wear of commutating parts. Brushless motors generally have good performance at low cost because of the decreased complexity of the motor. However, the controllers for these motors are more complex and expensive than brush-type motor controllers. The brush-

Fig. 3.15 The Baldor AC servomotor

Fig. 3.16 The Anorad brushless linear motor

less motor's passive multipole neodymium magnet rotor and wire-wound iron stator provide good heat dissipation and excellent reliability. Linear brushless motors function like unrolled rotary motors. They typically have a long, heavy, multiple magnet passive stator and a short, lightweight, electronically commutated wire-wound forcer (slider).

Other Actuators. A wide variety of other types of actuators have been applied to robots. A sampling of these include, thermal, shape-memory alloy (**SMA**), bimetallic, chemical, piezoelectric, magnetostrictive, electroactive polymer (EPAM), bladder, and micro-electromechanical system (**MEMS**) actuators (see Figs. 3.17 and 3.18). Most of these actuators have been

applied to research and special application robots rather than volume production industrial robots. An example of a piezoelectric actuator powered robot is the six-axis PI piezo hexapod with sub-nanometer resolution shown in Fig. 3.19.

3.7.3 Transmissions

The purpose of a transmission or drive mechanism is to transfer mechanical power from a source to a load. The design and selection of a robot drive mechanism requires consideration of motion, load, and power requirements and the placement of the actuator with respect to the joint. The primary considerations in transmission design are stiffness, efficiency, and cost. Backlash and windup impact drive stiffness especially in robot applications where motion is constantly reversing and loading is highly variable. High transmission stiffness and low or no backlash result in increased friction losses. Most robot transmission elements have good efficiencies when they are operating at or near their rated power levels but not necessarily when lightly loaded. Larger than necessary drives add weight, inertia and friction loss to the system. Underdesigned drives have lower stiffness, can wear rapidly in continuous or in high duty cycle operation or fail due to accidental overloads.

Joint actuation in robots is generally performed by drive mechanisms which interface the actuator (mechanical work source) to the robot links through the joints in an energy-efficient manner. A variety of drive mechanisms are incorporated in practical robots. The transmission ratio of the drive mechanism sets the torque, speed, and inertia relationship of the actuator to the link. Proper placement, sizing, and design of the drive mechanisms set the stiffness, mass, and overall operational performance of the robot. Most modern robots incorporate efficient, overload damage resistant, back-driveable drives.

Direct Drives

The direct drive is kinematically the simplest drive mechanism. In the case of pneumatic or hydraulic actuated robots, the actuator is directly connected between the links. Electric direct-drive robots employ high-torque, low-speed motors directly interfaced to the links. The complete elimination of free play and smooth torque transmission are features of a direct drive. However, there is often a poor dynamic (inertia ratio) match of the actuator to the link requiring a larger, less energy efficient, actuator.

Band Drives

A variant of direct drive is band drive. A thin alloy steel or titanium band is fixed between the actuator shaft and the driven link to produce limited rotary or linear motion. Drive ratios in the order of up to 10 : 1 (10 actuator revolutions for 1 revolution of the joint) can be obtained. Actuator mass is also moved away from the joint – usually toward the base, to reduce robot inertia and gravity loading. It is a smoother and generally stiffer drive than a cable or belt drive.

Belt Drives

Synchronous (toothed) belts are often employed in drive mechanisms of smaller robots and some axes of larger robots. These function much the same as band drives, but have the ability to drive continuously. Multiple stages (two or three) of belts are occasionally used to produce large drive ratios (up to 100 : 1). Tension is controlled with idlers or center adjustment. The elasticity and mass of long belts can cause drive instability and thus increased robot settling time.

Gear Drives

Spur or helical gear drives provide reliable, sealed, low-maintenance power transmission in robots. They are used in robot wrists where multiple axes intersect and compact drive arrangements are required. Large-diameter, turntable, gears are used in the base joints of larger robots to handle high torques with high stiffness. Gears are often used in stages and often with long drive shafts, enabling large physical separation between ac-

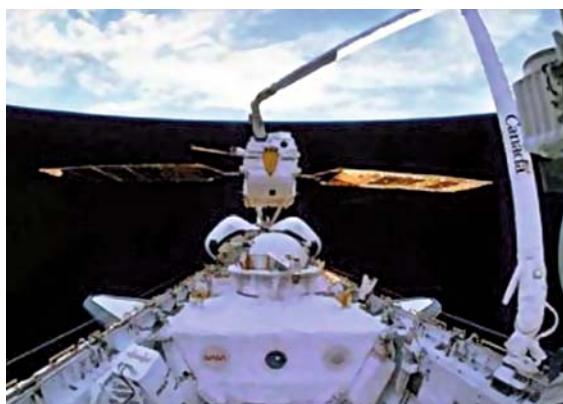

Fig. 3.20 The Space Shuttle robot arm has planetary gear joint drives

tuator and driven joint. For example, the actuator and one stage of reduction may be located near the elbow driving another stage of gearing or differential in a wrist through a long hollow drive shaft (Fig. 3.1).

Planetary gear drives are often integrated into compact servomotors (Fig. 3.20). Minimizing backlash (free play) in a joint gear drive requires careful design, high-precision and rigid support to produce a drive mechanism which does not sacrifice stiffness, efficiency and accuracy for low backlash. Backlash in robots is controlled by a number of methods including selective assembly, gear center adjustment, and proprietary anti-backlash designs.

Worm Gear Drives

Worm gear drives are occasionally used in low-speed robot manipulator applications. They feature right-angle and offset drive capability, high ratios, simplicity, good stiffness and load capacity. They also have poor efficiency which makes them non-back-driveable at high ratios. This causes the joints to hold their position when unpowered but also makes them prone to damage by attempts to manually reposition the robot.

Fig. 3.21 The harmonic drive

Fig. 3.22 The Nabtesco RV drive

Proprietary Drives

Proprietary drives are widely used in standard industrial manipulators. The harmonic drive and the rotary vector (RV) drive are two examples of compact, low-backlash, high-torque-capability drives using special gears, cams, and bearings (see Figs. 3.21 and 3.22).

Harmonic drives are frequently used in very small to medium-sized robots. These drives have low backlash, but the flexspline allows elastic windup and low stiffness during small reversing movements. RV drives are usually used in larger robots, especially those subject to overloads and shock loading.

Linear Drives

Direct-drive linear actuators incorporate a linear motor with a linkage to a linear axis. This linkage is often merely a rigid or flexure connection between the actuator forcer and the robot link. Alternatively, a packaged linear motor with its own guideways is mechanically connected directly to a linear axis. Direct linear electromagnetic drives feature zero backlash, high stiffness, high speeds, and excellent performance but are heavy, have poor energy efficiency, and cost more than other types of linear drives.

Ball Screws

Ball-screw-based linear drives efficiently and smoothly convert rotary actuator motion into linear motion. Typically, a recirculating ball nut mates with a ground and hardened alloy steel screw to convert rotary motion into linear motion. Ball screws can be easily integrated into linear axes. Compact actuator/drive packages are available, as well as components for custom integration. Stiffness is good for short and medium travel, however it is lower for long motions because the screw can only be supported at its ends. Low or zero backlash can be obtained with precision-ground screws. Speeds are limited by screw dynamic stability so rotating nuts enable higher speeds. Low-cost robots may employ plain screw drives featuring thermoplastic nuts on smooth rolled thread screws.

3.8 Robot Performance

Industrial robot performance is often specified in terms of functional operations and cycle time. For assembly robots the specification is often the number of typical pick-and-place cycles per minute. Arc-welding robots are specified with a slow weld pattern and weave speed

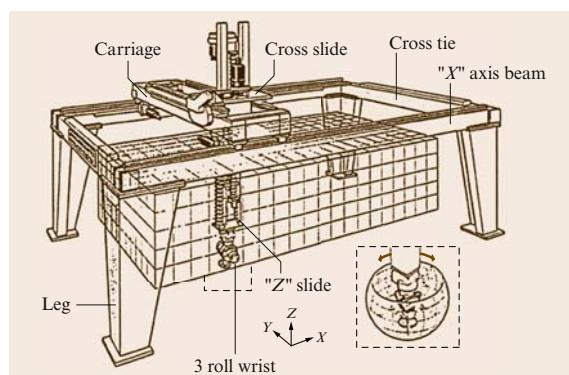

Fig. 3.23 The NASA gantry robot

Rack-and-Pinion Drives

These traditional components are useful for long motions where the guideways are straight or even curved. Stiffness is determined by the gear/rack interface and independent of length of travel. Backlash can be difficult to control as rack-to-pinion center tolerances must be held over the entire length of travel. Dual pinion drives are sometimes employed to deal with backlash by providing active preload. Forces are generally lower than with screws due to lower ratios. Small-diameter (low teeth count) pinions have poor contact ratios, resulting in vibration. Sliding involute tooth contact requires lubrication to minimize wear. These catalog stock drive components are often used on large gantry robots and track-mounted manipulators (Fig. 3.23).

Other Drive Components

Splined shafts, kinematic linkages (four-bar, slider-crank mechanisms, etc.) chains, cables, flex couplings, clutches, brakes, and limit stops are some examples of other mechanical components used in robot drive mechanisms (Fig. 3.8). The Yaskawa RobotWorld assembly and process automation robots are magnetically suspended, translate on air a planar (two-DOF) bearing, and are powered by a direct electromagnetic drive planar motor with no internal moving parts (Fig. 3.12).

as well as by a fast repositioning speed. For painting robots, the deposition or coverage rate and spray pattern speed are important. Peak robot velocity and acceleration catalog data are generally just calculated numbers and will vary due to dynamic (inertia) and static (grav-

ity) coupling between robot joints due to configuration changes as a robot moves.

3.8.1 Robot Speed

Maximum joint velocity (angular or linear) is not an independent value. For longer motions it is often limited by servomotor bus voltage or maximum allowable motor speed. For manipulators with high accelerations, even short point-to-point motions may be velocity limited. For low-acceleration robots, only gross motions will be velocity limited. Typical peak end-effector speeds can range up to 20 m/s for large robots.

3.8.2 Robot Acceleration

In most modern manipulators, because the payload mass is small when compared with the manipulator mass, more power is spent accelerating the manipulator than the load. Acceleration affects gross motion time as well as cycle time (gross motion time plus settling time). Manipulators capable of greater acceleration tend to be stiffer manipulators. In high-performance robot manipulators, acceleration and settling time are more important design parameters than velocity or load capacity. Maximum acceleration for some assembly and material handling robots is in excess of 10 g with light payloads.

3.8.3 Repeatability

This specification represents the ability of the manipulator to return repeatedly to the same location. Depending on the method of teaching or programming the manipulator, most manufacturers intend this figure to indicate the radius of a sphere enclosing the set of locations to which the arm returns when sent from the same origin by the same program with the same load and setup conditions. This sphere may not include the target point because calculation round-off errors, simplified calibration, precision limitations, and differences during the teaching and execution modes can cause significantly larger errors than those just due to friction, unresolved joint and drive backlash, servo system gain, and structural and mechanical assembly clearances and play. The designer must seriously consider the real meaning of the required repeatability specification. Repeatability is important when performing repetitive tasks such as blind assembly or machine loading. Typical repeatability specifications range from 1–2 mm for large spot-welding robots to 0.005 mm ($5\text{ }\mu\text{m}$) for precise micropositioning manipulators.

3.8.4 Resolution

This specification represents the smallest incremental motion that can be produced by the manipulator. Resolution is important in sensor-controlled robot motion and in fine positioning. Although most manufacturers calculate system resolution from the resolution of the joint position encoders, or from servomotor and drive step size, this calculation is misleading because system friction, windup, backlash, and kinematic configuration affect the system resolution. Typical encoder or resolver resolution is 10^{14} – 10^{25} counts for full-axis or joint travel, but actual physical resolution may be in the range 0.001–0.5 mm. The useful resolution of a multi-joint serial-link manipulator is worse than that of its individual joints.

3.8.5 Accuracy

This specification covers the ability of a robot to position its end-effector at a preprogrammed location in space. Robot accuracy is important in the performance of non-repetitive types of tasks programmed from a database, or for taught tasks that have been remapped or offset owing to measured changes in the installation.

Accuracy is a function of the precision of the arm kinematic model (joint type, link lengths, angles between joints, any accounting for link or joint deflections under load, etc.), the precision of the world, tool, and fixture models, and the completeness and accuracy of the arm solution routine. Although most higher-level robot programming languages support arm solutions, these solutions usually model only simplified rigid-body kinematic configurations. Thus, manipulator accuracy becomes a matter of matching the robot geometry to the robot solution in use by precisely measuring and calibrating link lengths, joint angles, and mounting positions.

Typical accuracies for industrial manipulators range from $\pm 10\text{ mm}$ for uncalibrated manipulators that have poor computer models to $\pm 0.01\text{ mm}$ for machine-tool-like manipulators that have controllers with accurate kinematic models and solutions and precisely manufactured and measured kinematic elements.

3.8.6 Component Life and Duty Cycle

The three subassemblies in an electrically powered robot with the greatest failure problems are the actuators (servomotors), transmissions, and power and signal cables. Mean time between failures (MTBF) should be

a minimum of 2000 h on line, and ideally at least 5000 operating hours should pass between major component preventive maintenance replacement schedules.

Worst-case motion cycles must be assumed as most current robot installations are used in generally repetitive tasks. Small-motion design-cycle life (less than 5% of joint travel range) for assembly robots should be 20–100 million full bidirectional cycles. Large-motion cycle life (greater than 50% of full joint range) should typically be 5–40 million cycles.

Short-term peak performance is frequently limited by maximum drive loading, whereas long-term, continuous, performance is limited by motor heating. Rather than design for equal levels of short- and long-term performance, cost savings and performance improvements can result from designing for an anticipated duty cycle. This allows the use of smaller, lower-inertia, lighter motors. Industrial robots usually become obsolete and are replaced before they reach their design cycle life.

3.8.7 Collisions

In the course of operation, unforeseen or unexpected situations may occasionally result in a collision involving the manipulator, its tools, the workpiece, or other objects in the workplace. These accidents may result in no, little, or extensive damage, depending in large part on the design of the manipulator. Crash-resistant design options should be considered early in the design process if the time lost or cost of such accidents could be significant. Typical damage due to accidents include fracture or shear failures of gear teeth or shafts, dented or bent link structures, slipping of gears or pulleys on shafts, cut or severely abraded or deformed wires, cables or hoses, and broken connectors, fittings, limit stops or switches. Compliant elements such as overload (slip) clutches, elastic members, and padded surfaces can be incorporated to reduce shock loads and help decouple or isolate the actuators and drive components in the event of such collisions.

3.9 Conclusions and Further Reading

The mechanical design of a robot is an iterative process involving engineering, technical, and application-specific considerations evaluations, and choices. The final design should reflect consideration of detailed task requirements rather than simply broad specifications. Proper identification and understanding of these requirements is a key to achieving the design goals.

Design and choice of specific components involves tradeoffs. A purely static, rigid-body approach to manipulator design is often used, but is not always sufficient. Mechanical system stiffness, natural frequencies, control system compatibility, and intended robot applications and installation requirements must be considered.

There are many opportunities for further reading on the design of the mechanisms and actuation that form the core of a robotic system. A well-known and useful reference for robot design is *Rivin* [3.44].

Craig [3.6] and *Tsai* [3.9] provide the mathematical relations between the mechanical structure of a robot and its workspace and mechanical advantage. *Slater* and *Chironis* [3.48] is a reprint of a valuable compendium of devices useful for a variety of applications, such as joint drives and transmissions. See *McCarthy* [3.34] for geometric techniques to design specialized mechanisms.

Juvinal and *Marshek* [3.45] and *Shigley* and *Mishke* [3.46,47] are important references for the design of the components such as the link structure, bearings, and transmissions that are central to the effective mechanical performance of robotic systems.

Although many design decisions can be made through the application of straightforward algorithms and equations, a multitude of other important considerations transform the challenge of robot design into one requiring good engineering judgment.

Sensing and Estimation

Henrik I. Christensen, Gregory D. Hager

Sensing and estimation are essential aspects of the design of any robotic system. At a very basic level, the state of the robot itself must be estimated for feedback control. At a higher level, perception, which is defined here to be task-oriented interpretation of sensor data, allows the integration of sensor information across space and time to facilitate planning.

This chapter provides a brief overview of common sensing methods and estimation techniques that have found broad applicability in robotics. The presentation is structured according to a process model that includes sensing, feature extraction, data association, parameter estimation, and model integration. Several common sensing modalities are introduced and characterized. Common methods for estimation in linear and nonlinear systems are discussed, including statistical estimation, the Kalman filter, and sample-based methods. Strategies for robust estimation are also briefly described. Finally,

several common representations for estimation are introduced.

Controlling a robotic system would be relatively simple if a complete model of the environment was available, and if the robot actuators could execute motion commands perfectly relative to this model. Unfortunately, in most cases of interest a complete world model is not available, and perfect control of mechanical structures is never a realistic assumption. Sensing and estimation are a means of compensating for this lack of complete information. Their role is to provide information about the state of the environment and the state of the robot system as a basis for control, decision making, and interaction with other agents in the environment, such as humans.

For the purposes of discussion, we will differentiate between sensing and estimation to recover the state of the robot itself, referred to as *proprioception*, versus sensing and estimation to recover the state of the external

world, referred to as *exteroception*. In practice, most robot systems are designed to have the proprioception necessary to estimate and control their own physical state. On the other hand, recovering the state of the world from sensor data is usually a much larger and more complex problem.

Early work on computational perception for robotics assumed that one could recover a complete general-purpose model of the environment, use such a model to make decisions, and subsequently act on them, as for example presented by [4.1]. More recently it has become apparent that such an approach is not realistic. Indeed, considering that sensor-based robots now appear in diverse applications such as mobile surveillance, high-performance manipulation, and medical interventions, it is clear that appropriate sensing and estimation for a given system must be highly task dependent. Conse-

quently, the discussion here is organized along the lines of task-oriented sensing and estimation of the external world.

Sensing and estimation together can be viewed as the process of transforming a physical quantity into a computer representation that can be used for further processing. Sensing is thus closely tied to transducers that transform some physical entity into a signal that can be processed by a computer. Sensing is also intimately tied to perception, the process of representing the sensory information in a task-oriented model of the world. However, sensor data is usually corrupted in various ways that complicate this process. Statistical noise arises from the transducer, discretization is introduced in the digitization process, and ambiguity is introduced by poor sensor selectivity to name a few examples.

Estimation methods are thus introduced to support appropriate integration of information into models of the environment and for improvement of the signal-to-noise ratio.

In this chapter the general characteristics of sensing and estimation are introduced, while more in-depth presentations of select topics are provided in Part C of the handbook. In Sect. 4.1 the overall sensing/perception process is introduced. In Sect. 4.2 different kinds of sensors are introduced and some key characteristics are presented. Estimation of world representations can utilize a number of different methods involving both parametric and nonparametric techniques as discussed in Sect. 4.3. For model-based integration a variety of different representations can be used, as described in Sect. 4.4.

4.1 The Perception Process

The input to the perception process is typically twofold: (1) digital data from a number of sensors/transducers, and (2) a partial model of the environment (a world model) that includes information about the state of the robot and other relevant entities in the external world. The sensor data itself can take on a number of different forms such as a scalar or vector value $x(\alpha, \beta)$ acquired over a time series $x(t)$, a scan $x_t(\theta_i)$, a vector field x or a three-dimensional volume $x(\rho, \theta, \phi)$. In many cases, a system must integrate data from several disparate sensors, for example, an estimate of the position of a mobile robot may integrate data from axis encoders, vision, global positioning system (GPS) data, and inertial sensors.

To further structure the discussion in this chapter, we adopt a general model of the perception process as shown in Fig. 4.1. In this model, we have included the most common operations applied to integrate sensor data with

a world model. Depending on the task in question, some of the included modules may be missing, and others may themselves take on a complicated structure. However, the supplied model suffices to illustrate many of the issues in sensing and estimation. In the remainder of this section, we discuss an example from mobile localization to illustrate this model.

The initial problem in sensory processing is data preprocessing and feature extraction. The role of preprocessing is to reduce noise from the transducer, to remove any systematic errors, and to enhance relevant aspects of the data. In some cases, sensory information might also have to be temporally or spatially aligned for subsequent integration. There are innumerable ways that data can be preprocessed to enhance or extract features that are used in the integration. One common approach is model fitting, as illustrated for a laser scanner in Fig. 4.2. Once sensor information is available,

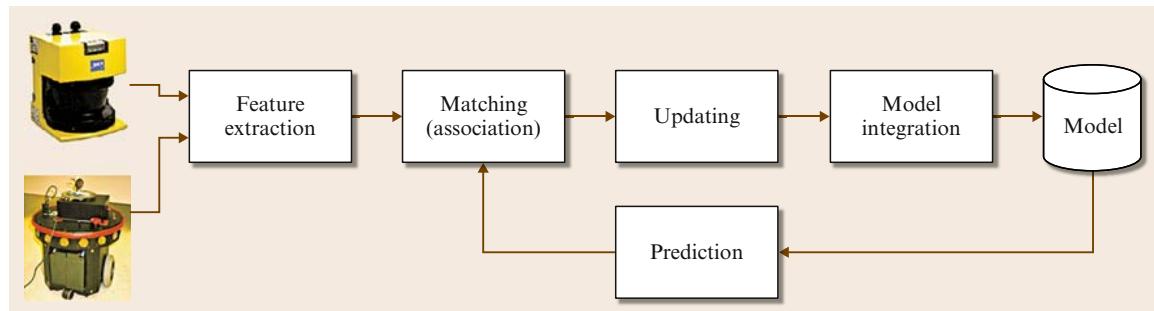

Fig. 4.1 Example of a perception process as discussed in this chapter

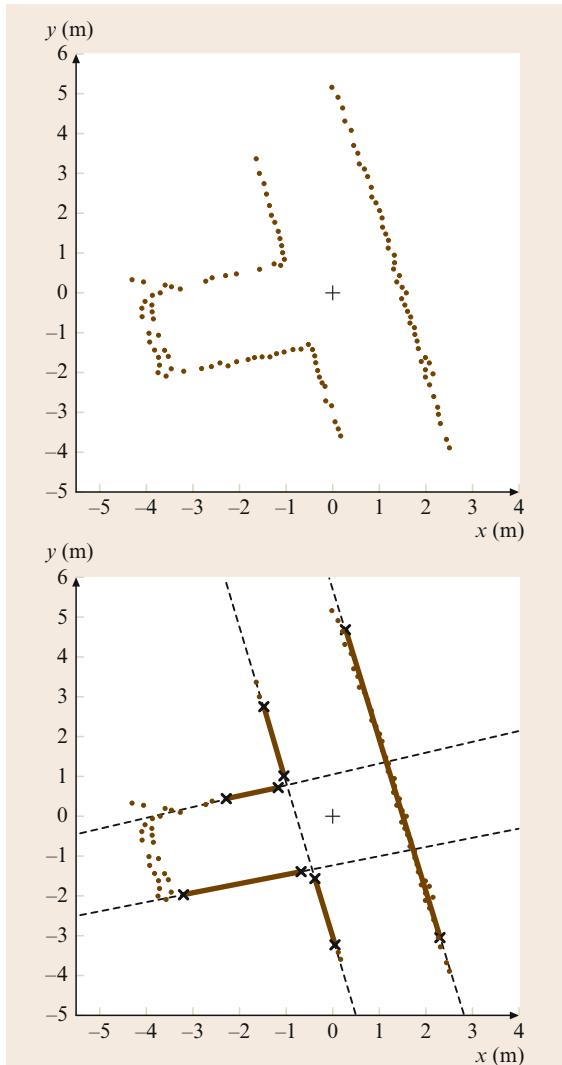

Fig. 4.2 An example of feature extraction from a laser scan (after [4.2])

it is often necessary to match the data with an existing model (Fig. 4.3). This model may be based on a priori known structure [e.g., a computer-aided design (**CAD**) model of the environment], or may have been built up from previously acquired data. Data association methods are commonly employed to estimate the relationship between sensor data and the model of the en-

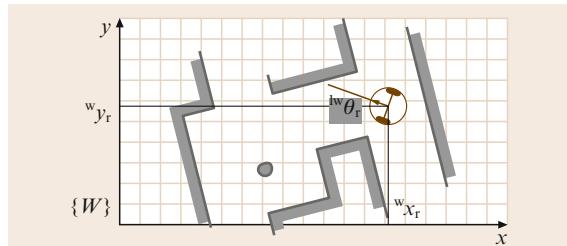

Fig. 4.3 An example environmental model for mobile robot localization (after [4.2])

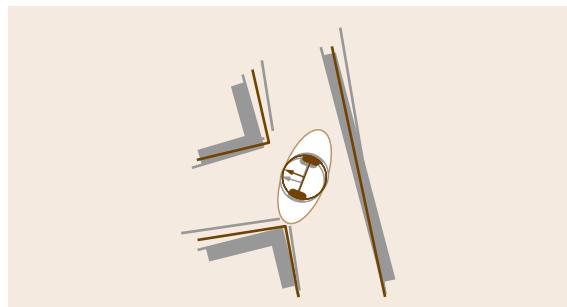

Fig. 4.4 Estimation of position and orientation for the example mobile robot (after [4.2])

vironment. In our mobile robot localization example, the extracted line features are matched against a polygonal world model. This matching process can be performed in several different ways, but in general it is an optimization that maximizes the alignment of features to the model.

Once sensory data has been matched against the world model it is possible to update the model with new information contained in the sensor data. In the example, the orientation and position of the robot relative to the world model can be updated (Fig. 4.4) from the matched line segments.

Finally, it may be possible to develop a dynamical system model of the underlying state being estimated. Using such a system model, it is possible to predict how the world changes over time until new sensory data is acquired. This can be used within a feed-forward prediction process, which in turn simplifies data association for new sensory readings, as shown in Fig. 4.1.

With this as a prologue, we now turn to discuss each step of the perception process in greater detail.

4.2 Sensors

There are a variety of ways to classify sensors depending on what they measure, and how they measure it. As noted previously, proprioceptive sensors are used to measure the internal state of a robot, which might include position of different degrees of freedom, temperature, voltage on key components, motor current, force applied to an effector, and so forth. Exteroceptive sensors, on the other hand, generate information about the external environment in terms of distance to an object, interaction forces, tissue density, and so forth.

Sensors may also be differentiated based on whether they are passive or active. In general, an active sensor is one that emits energy into the environment, and measures properties of the environment based on the response. A passive sensor is one that is not active. Active sensors are generally more robust than passive sensors since they exert some control over the measured signal. For example, a passive stereo camera system must rely on the appearance of viewed surfaces when performing feature matching for triangulation (Chap. 22), whereas structured light systems project a pattern onto the scene and are thus less sensitive to scene characteristics. Even so, absorption, scattering or interference of the emitted signal can affect the performance of active sensors.

Proprioceptive sensors are typically passive and usually measure physical properties of the robot such as joint position, velocity, or acceleration, motor torque, and so forth. Exteroceptive sensors, on the other hand, can be further divided into contact and noncontact sensing. The contact sensors are typically the same modalities as used for proprioception, while noncontact sensor sensors involve most of the modalities that can be used for estimation of physical properties at a distance including intensity, range, direction, size, and so forth.

A classification of typical sensors according to method and typical application is shown in Table 4.1. More detail on methods of sensing, characterization of

sensors, and general applications can for example be found in the Handbook of Modern Sensors [4.3] and in Part C of this handbook.

Table 4.1 Classification of sensors frequently used in robotics according to sensing objective [proprioception (PC)/exteroception (EC)] and method (active/passive)

| Classification | Sensor type | Sens | A/P |
|--------------------------------------------------------|-----------------------------------|-------|-----|
| Tactile sensors | Switches/bumpers | EC | P |

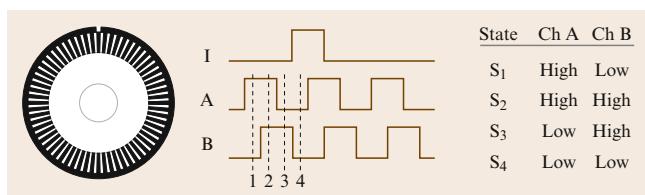

Fig. 4.5 Sketch of the quadrature encoder disc, and output from photodetectors placed over each of the two patterns. The corresponding state changes are shown on the right

Estimation of rotational motion is fundamental to control of robot manipulators and also for estimation of ego-motion for mobile systems. The most common sensor for measurement of rotation is the quadrature encoder. It is composed of a transparent disc, with two periodic patterns that are out of phase, as shown in Fig. 4.5. Through the use of counters it is possible to directly compute the motion and its direction (the phasing between sensors A and B in Fig. 4.5). In addition the disc is frequently fitted with a single dot on the outer rim for indexing (specification of a zero index). The density of the pattern determines the resolution of the measurements. When fitting the sensor to a motor before a reduction gear it is easy to achieve accuracies beyond $1/1\,000^\circ$.

For the estimation of force and torque at an end-effector it is possible to use piezoelectric elements. These elements generate a voltage that is proportional to the introduced deformation. Through careful placement it is possible to measure both force and torque. The sensors are used in robotic manipulation as part of assembly systems, deburring, etc. and also in medical applications for the estimation of stress and contact. Force/torque sensors are widely available in a range of sizes and dy-

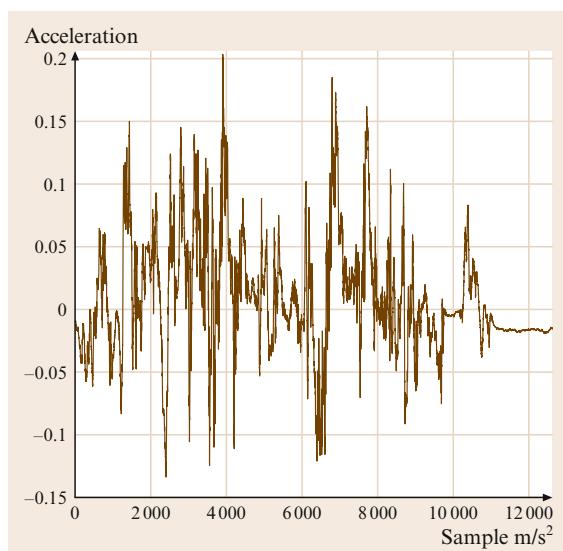

Fig. 4.7 Example data from an IMU unit for driving on an unpaved road

namic ranges, including new flexible arrays that can be mounted on a variety of end-effectors (Fig. 4.6). Potential problems with force sensors are a dead band on initial contact, and noisy data from the basic sensing elements, which calls for signal processing to clean up the data.

Ego-motion estimation is an important part of almost all robotic systems. To this end it is possible to use inertial measurement units (IMU). An IMU typically includes both accelerometers and gyros. Accelerometers are sensitive to all types of acceleration, which implies that both translation motion and rotation (centripetal forces) are measured in combination. Joint IMU units allow the estimation of rotation and translation, and allow for double integration to estimate the velocity, orientation, and position of a system, as for example reported in [4.4]. One of the problems associated with the use of an IMU is the need for double integration. Small biases and noise can result in significant divergence in the final estimate, which calls for use of detailed models and careful calibration and identification of sensor characteristics. An example of data from a cross-bow DMU-6x unit for a car driving on an unpaved road is shown in Fig. 4.7.

Much early work on mobile robotics, underwater robots, and some medical robotics relies on ultrasonic ranging. The general class of sensors are often termed sound navigation and ranging (sonars). The general principle is that the systems emits a sound pulse and awaits the return of echoes that have bounced off objects in

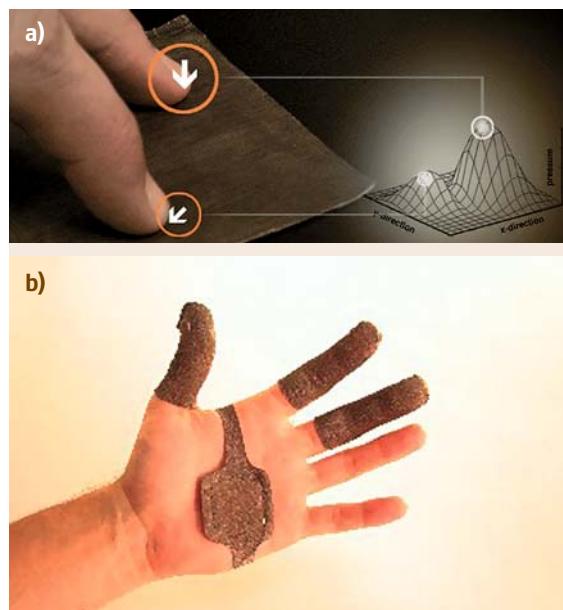

Fig. 4.6 (a) TactArray, a flexible capacitive array tactile sensor from Pressure Profile Systems, Inc., is appropriate for sensing contact locations and areas under sliding conditions. (b) Conformable TactArray sensors can fit on a human or robotic hand (courtesy Pressure Profile Systems, Inc.)

Fig. 4.8 Example laser ranging sensor (SICK LMS291) that is widely used in mobile robotics

the environment. Knowing the transmission speed in the medium and the time of flight it is possible to compute the distance. The method was widely used in early robotics due to the availability of low-cost sensors with adequate performance. In underwater robotics this is still a primary sensor. The sonar is discussed in detail in Chap. 21.

Recent progress, in particular on environmental modeling and navigation, has in many respects been due to the emergence of low-cost high-fidelity laser scanning systems. The SICK series of laser scanners are time-of-flight scanners. The scanner sends out a pulse of light and measures the time to return. The standard scanner enables estimation of distances up to 80 m at centimeter or millimeter accuracy. The scanner measures distances in a plane with an angular resolution of 0.5–1°. The field of view is 180° resulting in 181–361 range measurements. The sensor data are contaminated by uniformly distributed noise, which must be considered in the detection of features or integration of data into a raw sensor map.

Imaging sensors are a rich source of information for sensing and estimation. Imaging sensors come in a wide variety of configurations, varying according to imaging geometry, image resolution, sensor technology and the range of sensed spectral bands. Most readers are no doubt familiar with the traditional three-CCD, perspective color camera. In this case, there are three charge-coupled detector (CCD) arrays, each receiving a portion of the visible spectrum corresponding roughly to the human perception of red, green, and blue colors. A common and less expensive alternative is a so-called single-chip CCD camera. In this case, a special spatial array of color filters, usually referred to as a Bayer filter after its inventor Bryce Bayer, is employed. The result-

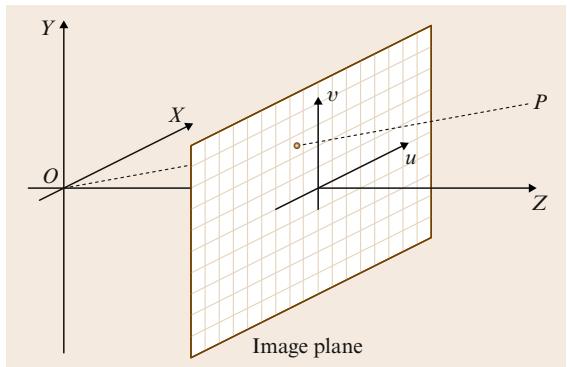

Fig. 4.9 The pinhole camera model

ing spatial array is subsequently processed (a process referred to as demosaicing) to provide color information for each pixel.

In the United States, image sensors traditionally contained 480 rows of 640 pixels according to the NTSC standard created for analog transmission of television signals. The corresponding European standard, PAL, has 576 lines of 768 pixels. More recently, the advent of

Fig. 4.10 Catadioptric image and the same image mapped to a cylindrical surface

digital interfaces such as IEEE 1394 and USB 2.0 have allowed camera systems to be developed with significantly improved resolution ranging into the millions of pixels. At the same time, cost-effective infrared (IR) and ultraviolet (UV) cameras have become available, allowing the development of advanced multispectral image interpretation systems.

A traditional imaging sensor contains an optical system that focuses light on a planar imaging array. In most cases, this system can be modeled using the classical pinhole camera model (shown in Fig. 4.9). Given a point $(x, y, z)^\top$ in Euclidean space, the corresponding camera pixel coordinates $(u, v)^\top$ are given by

$$\begin{aligned} (u - u_c) &= \frac{f}{s_x} \frac{x}{z}, \\ (v - v_c) &= \frac{f}{s_y} \frac{y}{z}, \end{aligned} \quad (4.1)$$

where f is the focal length of the lens system, u_c and v_c are the pixel coordinates of the center of projection, and s_x and s_y are the size of a single pixel on the imaging array. In practice, these models are also augmented with low-order models of image distortion.

The values of these parameters for a given camera system can be determined experimentally using a variety of methods [4.5].

By combining a traditional perspective camera with a mirror, creating a so-called catadioptric system, it is possible to create imaging geometries that map fields of view as large as a hemisphere into a single image. Such systems are useful, for example, for surveillance, and their geometric properties provide for stable position referencing for mobile navigation [4.6]. An example image is shown in Fig. 4.10 together with the corresponding image when mapped to a cylindrical surface.

The discussion above has touched on the most commonly employed robotic sensing devices. Many special-purpose sensors are employed for specific applications. In medicine (Chap. 52), ultrasound, X-ray, computed tomography, and magnetic resonance imaging are commonly employed. Underground mapping makes use of ground-penetrating radar [4.7]. Underwater robotics makes use of many variations on acoustical sensors. Further discussions of these more task-specific sensing modalities can be found in the application chapters in Part C of this handbook.

4.3 Estimation Processes

As discussed in the introduction, there are many different techniques for combining information from sensors. The appropriate set of techniques depends, to a great degree, on what is known a priori about the environment, what information is necessary for the task at hand, and what models for the sensing system are appropriate. Common methodologies include simple voting-based methods, parametric and nonparametric statistical estimation techniques, fuzzy logic-based systems, and Dempster–Shafer theory.

To illustrate this point, consider the robot localization problem introduced in Sect. 4.1. At the outset, if nothing is known about the environment, the robot may acquire a laser scan and try to produce an initial model of the environment using line segments. Since nothing is known a priori, the system must estimate: (1) the number of line segments, (2) the data association between line segments and observed data values, and (3) the parameters of the line segments themselves. This is a challenging problem that can be attacked by simple voting techniques such as the Hough transform [4.8] or RANSAC [4.9] or more sophisticated unsupervised clustering methods such as k -means [4.10], expecta-

tion maximization (EM) [4.11], or GPCA [4.12]. In many cases, this is a computationally intensive, iterative process.

Conversely, if a prior CAD model for the environment is known, then the problem is to produce a small set of parameters (translation and rotation) of the model to match the data. This problem can be solved, using feature matching by aligning observed points to the model with iterative closest-point algorithms (ICP) [4.13] or other efficient combinatorial matching algorithms such as Monte Carlo methods [4.14]. The best method to apply again depends to a great degree on the structure of the environment and what is known a priori.

Once an initial registration is known, new data can take advantage of the fact that strong prior knowledge is available. In particular, as the robot moves, the sensor data should change in a predictable fashion. Thus is it possible to make use of predictor–corrector methods such as the Kalman filter [4.15, 16] or sequential importance sampling [4.17], provided appropriate statistical characterizations of the sensing system are available. The data association problem, if present, can be addressed using a variety of general techniques such as

EM [4.10] or more specialized modifications to the previously cited predictor–corrector methods [4.18].

It is often the case that sensor data is corrupted by occasional nonsensical values. For example, the laser range finder in our example may occasionally return a spurious range value due to a reflection. Many commonly used estimation techniques are not robust to such so-called data outliers. Techniques from robust statistics [4.19] can be used to improve the performance of sensing and estimation systems in such cases.

Finally, we may want to consider what information is actually important for the task at hand. Most of the techniques above presume that the goal is to produce an accurate estimate of a set of continuous parameters closely related to the underlying data. However, in some tasks, the parameter values themselves may not be what is of interest. For example, suppose that the goal of our robot is to drive through a doorway. Although this clearly depends on an ability to estimate the width of the door (a continuous parameter), the decision is ultimately binary. This problem can be codified as a *decision problem*. Decision problems can be modeled using concepts from *decision theory* [4.20] including zero–one loss functions, likelihood ratios, or probability ratios. For example, in the case of fitting through a door, for a low-priority task there may be a low cost associated with not attempting to move through this particular door (necessitating replanning to find an alternative route) relative to attempting to navigate through an opening that is too small (risking damage to the robot or the door, or both). Conversely, if the task is urgent, more risky behavior may be warranted.

For any given task (or decision), the amount of information necessary to reach the decision may vary, for example, if the doorway is quite wide, it may require relatively little information to safely navigate through it. Conversely, a tight fit may require close inspection before a decision can be reached. The problem of determining the type and/or amount of information necessary to reach a decision is referred to variously as the *sequential sampling problem* [4.20], the sensor control problem, or the sensor planning problem [4.21–23].

4.3.1 Point Estimation

In our robot localization example we saw several cases where the key problem was to estimate an unknown quantity that can be represented as a point in a vector space. Examples include the location of a two-dimensional (2-D) or three-dimensional (3-D) point or the location of a robot. We also saw examples where

the problem was to locate the pose (position and orientation) of the robot, or parameters of a line segment. The latter differ in that the underlying parameter space is not a vector space. This introduces some additional unique problems. We refer the reader to [4.24, 25] for further discussion, and in the remainder of this chapter restrict our attention to *point estimation* problems on vector spaces. In our discussion, we assume the reader is familiar with multivariate Gaussian distributions as described in [4.26] and basic linear algebra [4.27].

In the remainder of this section, we consider the following general problem.

Given: an observation model

$$y = f(x, \eta). \quad (4.2)$$

Estimate: $x \in \text{Re}(n)$ from observations $y \in \text{Re}(m)$ where η is an unknown disturbance taking values in $\text{Re}(k)$ and f is a known mapping from $\text{Re}(k+n)$ to $\text{Re}(m)$.

We divide our discussion into two topical areas:

- methods for performing estimation on batch and sequential data when f is linear
- methods for performing estimation on sequential data when f is nonlinear

Estimation Techniques for Batch and Sequential Data with Linear Models

In this section, we discuss linear and linearized estimation techniques for sequential data, including the Kalman filter and extensions thereof. Our goal is to provide an overview of techniques available. The reader may also wish to consult more in-depth references such as [4.16, 28, 29] and (Chap. 25) for additional information.

We first consider the case when f in (4.2) is linear in its arguments. In this case, we can write

$$y = Fx + B\eta, \quad (4.3)$$

where $F \in \text{Re}(m \times n)$ defines the (linear) relationship between the unknown x and the observation y and $B \in \text{Re}(m \times m)$. For the moment, we will drop B and assume that η represents the complete disturbance model of the system.

The *least-squares* method of estimating x from y proceeds by solving the optimization problem

$$\min_x \|Fx - y\|^2. \quad (4.4)$$

This optimization has a unique solution \hat{x} if and only if the matrix F has full column rank. In this case, the

solution can be computed by solving the following linear system:

$$F^\top F \hat{x} = F^\top y . \quad (4.5)$$

In some cases, there may be reason to believe that some observed elements are more reliable than others, and hence should contribute more to the final estimate. This information can be incorporated by modifying (4.4) to include a diagonal positive-definite weighting matrix W as

$$\min_x (Fx - y)^\top W(Fx - y) . \quad (4.6)$$

The solution is then given by solving:

$$(F^\top WF)\hat{x} = F^\top Wy . \quad (4.7)$$

Although (4.3) included a disturbance component (in the form of η), the parameter estimates computed in (4.5) or (4.7) made no explicit use of this quantity. However, we can often model the noise characteristics of the underlying sensor using a statistical model and recast our original estimation problem to incorporate this information. One common method is to compute the *maximum-likelihood estimate* (MLE), which is a value \hat{x} such that

$$p(y|\hat{x}) = \max_x p(y|x) . \quad (4.8)$$

For the linear additive model of (4.3), the likelihood function can be expressed in a particularly simple form. Suppose that η is described by a fixed, known probability density function D . The likelihood function is then given by

$$p(y|x) = D(y - Fx) . \quad (4.9)$$

The MLE can be related to the previous least-squares method as follows. Suppose that $\eta \sim N(0, \Lambda)$, where N denotes a multivariate Gaussian density function with (mean) 0 and covariance Λ . Upon observing that the maximizing the value of the likelihood function is equivalent to minimizing the negative log of the likelihood function, a short series of calculations shows that the optimal maximum-likelihood estimate is computed by weighted least squares with $W = \Lambda^{-1}$.

Finally, there is often a reason to include the idea that some parameters are more likely a priori to occur as others. For example, when observing a car driving on an expressway, a velocity of 60 mph is much more likely than either 20 mph or 300 mph. This information can be captured in *prior statistics* on the unknown value x .

Given a prior probably density on x , $p(x)$, Bayes theorem states that

$$p(x|y) = \frac{p(y|x)p(x)}{p(y)} = \frac{p(y|x)p(x)}{\int p(y|x)p(x)dx} . \quad (4.10)$$

The *maximum a posteriori probability* (MAP) estimate is the value \hat{x} such that

$$p(\hat{x}|y) = \max_x p(x|y) . \quad (4.11)$$

In general, the solution to this optimization problem can be quite complex. Rather than pursue this course further, we consider another alternative. Namely, provided the second moments of $p(x|y)$ exist, it is possible to produce a *least-squares* estimate, in a statistical sense, by solving the following optimization problem over an unknown function δ :

$$\min_{\delta} E \|\delta(y) - x\|^2 . \quad (4.12)$$

That is, the best function δ is one that produces an estimate of x from y with *minimum mean-square error* (MMSE). Thus, the estimator δ is often referred to as a MMSE estimator.

It can be shown that, in the general case, the *optimal* decision rule δ^* is the conditional mean [4.20]

$$\delta^*(y) = E[x | y] . \quad (4.13)$$

Unfortunately, this expression, as with the MAP estimate defined above, can be extremely difficult to compute for the general case. Later we consider methods for computing approximations to (4.13). For now, we again consider our previous linear observation model (4.3) (without B). Additionally, we suppose that x and η are *independent* random variables with finite second moments, and both are *zero-mean* random variables. Note that the latter is not really a restriction since it can be accomplished by simply defining a new variable $x' = x - E[x]$. Finally, we will consider only *linear* functions δ , that is, we can write $\hat{x} = \delta(y) = Ky$.

With this, (4.12) can be expanded as

$$\begin{aligned} E \|\delta(y) - x\|^2 &= E \|Ky - x\|^2 \\ &= E \|K(Fx + \eta) - x\|^2 \\ &= E \|(KF - I)x\|^2 + E \|K\eta\|^2 \\ &= \text{tr}[(KF - I)\Lambda(KF - I)^\top + K\Sigma K^\top] . \end{aligned} \quad (4.14)$$

Here, the independence of x and η and the fact that they are both zero mean has eliminated several terms. The final step makes use of the fact that $\|x\|^2 = \text{tr}(xx^\top)$.

Taking derivatives with respect to K and setting them equal to zero yields the solution

$$K = \Lambda F^\top (F \Lambda F^\top + \Sigma)^{-1}. \quad (4.15)$$

Thus, in this case the optimal estimate is given by a linear function of the observation, where the linear term depends only on the variance of the underlying random variables and the linear term defining the observation system.

If x is not zero-mean, but has mean μ , it is not hard to show that the optimal estimate is

$$\hat{x} = Ky + (I - KF)\mu, \quad (4.16)$$

and that the variance of the estimate Λ^+ is

$$\Lambda^+ = (I - KF) \Lambda. \quad (4.17)$$

The interested reader may wish to work this out for a few simple cases, for example, if $\Lambda = \Sigma$ and $F = I$, $K = 1/2I$ and thus $\hat{x} = y + \mu$ – a simple average – with variance $\Lambda^+ = 1/2\Lambda$.

When both the observation noise and prior statistics are Gaussian distributions, then it can be shown that the solution we have derived is also the **MAP** estimate for the unknown x [4.20].

The Kalman Filter. With this as background, we are now in a position to define the discrete-time Kalman–Bucy filter [4.30] for linear systems. Consider the following time-series model:

$$x_{t+1} = Gx_t + w_t, \quad (4.18)$$

$$y_t = Fx_t + \eta_t, \quad (4.19)$$

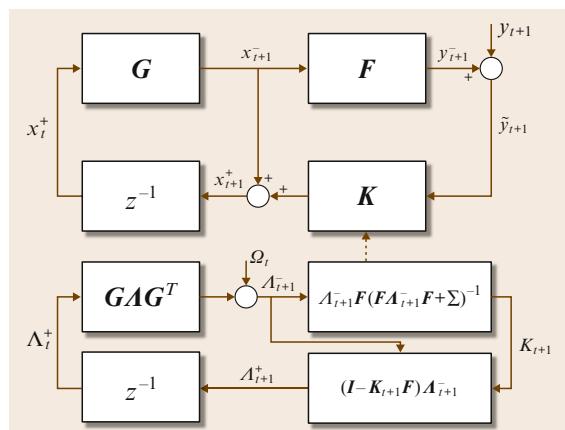

Fig. 4.11 A summary of the Kalman filter

where G is an $n \times n$ matrix describing the system time evolution and x_0 is distributed according to a Gaussian distribution with mean \hat{x}_0 and variance Λ_0 . In addition w_t and η_t are zero-mean Gaussian independent random variables for all t , w_t is independent of $w_{t'}$ for all $t \neq t'$, and likewise η_t is independent of $\eta_{t'}$ for all $t \neq t'$. Finally, η_t has variance Ω_t and w_t has variance Ω_t .

Given an observation y_1 it is possible, using the derivation of the previous section, to compute an updated estimate \hat{x}_1 with variance Λ_1 . Note, that the solution is a linear combination of two Gaussian random variables: the observation value y_1 and the prior estimate \hat{x}_0 . As any linear combination of Gaussian random variables is also a Gaussian random variable, it follows that the updated estimate is also Gaussian.

Now, we add one additional step: projection through the dynamic model. To describe this, superscripts minus and plus will denote before and after the estimation step, respectively. Thus, given an estimate \hat{x}_t^+ with variance Λ_t^+ , the projection ahead one time step produces

$$\hat{x}_{t+1}^- = Gx_t^+, \quad (4.20)$$

$$\Lambda_{t+1}^- = G\Lambda_t^+G^\top + \Omega_t. \quad (4.21)$$

At this point, a new observation y_{t+1} is acquired and the cycle repeats. The summarization of the complete Kalman filtering algorithm for linear systems is shown in Fig. 4.11.

It is possible to show that the Kalman filter is the *optimal* filter, under the stated assumptions, in the mean-square sense. It is also the optimal *linear* filter when either or both Gaussian assumptions do not hold.

Nonlinear Estimation Techniques for Sequential Data. The results of the previous subsection presume a linear form for the relationship between the observation and system state, additive noise, and a linear relationship describing the state evolution. Furthermore, the stated results are globally optimal for systems with Gaussian observation and driving noise, but are only the best *linear* estimator if the noise sources are non-Gaussian.

As noted at the outset, the more general nonlinear (discrete-time) system description is

$$\begin{aligned} x_{t+1} &= g_t(x_t) + w_t, \\ y_t &= f_t(x_t) + \eta_t, \end{aligned} \quad (4.22)$$

where, for the moment, the noise model continues to be additive.

Although this model contains nonlinear elements, it is still possible to apply a variant of the Kalman filter,

the extended Kalman filter (**EKF**) by making use of the Taylor-series expansion of the nonlinear elements about the current estimates. Let J_f (resp. J_g) denote the Jacobian matrix of the function f (resp. g). Supposing that an estimate at time step $t-1$ exists, the first-order expansion of (4.22) about this point yields

$$x_{t+1} = g_t(\hat{x}_{t-1}) + J_{g_t}(\hat{x}_{t-1})(x_t - \hat{x}_{t-1}) + w_t, \quad (4.23)$$

$$y_t = f_t(\hat{x}_{t-1}) + J_{f_t}(x_t - \hat{x}_{t-1}) + \eta_t. \quad (4.24)$$

Rearranging yields a linear form appropriate for the previously defined Kalman filter

$$\tilde{x}_{t+1} = x_{t+1} - g_t(\hat{x}_{t-1}) + J_{g_t}\hat{x}_{t-1} = J_{g_t}x_t + w_t, \quad (4.25)$$

$$\tilde{y}_t = y_t - f_t(\hat{x}_{t-1}) + J_{f_t}\hat{x}_{t-1} = J_{f_t}x_t + \eta_t. \quad (4.26)$$

In this form, \tilde{x} and \tilde{y} are new *synthetic* state and observation variables, J_{g_t} plays the role of G , and J_{f_t} plays the role of F .

It is worth noting that the **EKF** iterations are essentially a form of weighted Newton iterations (i. e., an iterative nonlinear estimation method). As a result, it is often useful to iterate more than once *on the same observation* while holding the variance terms fixed. This allows the estimator to converge to a solution in the presence of large disturbances or significant nonlinearities. Only after convergence are the variance terms updated. This version of the Kalman filter is referred to as the *iterated extended Kalman filter* (IEKF).

4.3.2 Other Approaches to Estimation

In the previous section, we reviewed the most common and widely used estimation methods. However, there are several alternative methodologies for solving parameter estimation problems. Here we briefly introduce two: sequential importance sampling and graphical models.

Sequential Importance Sampling

Much of the discussion heretofore has centered around the notion of approximating everything known about the system state using an estimated mean and covariance. An alternative presents itself by simply going back to Bayes theorem which states, in general, that

$$p(x_n | y_1, y_2 \dots y_n) = \frac{p(y_1, y_2 \dots y_n | x_n)p(x_n)}{p(y_1, y_2 \dots y_n)}. \quad (4.27)$$

Assuming that y_n is independent of all prior observations and states given x_n , and that x_n is independent of x_{n-k}

for $k > 1$ given x_{n-1} , this expression simplifies to

$$p(x_n | x_{n-1}, y_n) = \frac{p(y_n | x_n)p(x_n | x_{n-1})}{p(y_n | x_{n-1})}. \quad (4.28)$$

Recall that the optimal mean-square estimate is given by the conditional mean which, in this case, is

$$\delta^*(y_n) = E[x_n | y_n]. \quad (4.29)$$

In fact, we essentially showed that the Kalman filter is a special case of this result for linear systems corrupted by Gaussian noise.

The difficulty in implementing this procedure in the general case ultimately comes down to the problem of representing and computing with the distributions that arise in the nonlinear, non-Gaussian case. However, suppose that the heretofore continuous variable x_n only took on a discrete set of values. In this case, computing Bayes theorem and other associated statistical quantities reduces to a straightforward set of computations on this discrete set of variables. This can be simply done for any distribution and any set of transformations.

Sequential important sampling (also known as particle filtering, condensation, and a variety of other names) is a way of taking this approach in a statistically sound manner. In order to perform sequential importance sampling, it is assumed that

1. it is possible to *sample from* the likelihood function $P(y_n | x_n)$, and
2. it is possible to *sample from* the dynamical model $P(x_n | x_{n-1})$.

Note the emphasis on sampling – there is no need to explicitly exhibit an analytical form of the likelihood function or of the dynamical model.

Given this, sequential important sampling, in its simplest form, can be written as follows.

1. Let $\pi_{n-1} = \{(x_{n-1}^k, w_{n-1}^k), k = 1, 2, \dots N\}$ represent a set of sample points x_{n-1}^k together with a set of weights w_{n-1}^k with $\sum w_{n-1}^k = 1$.
2. Compute a new set of N samples $\pi_n^- = \{(x_n^k, 1/N), k = 1, 2, \dots N\}$ as
 - a) choose a sample point x_{n-1}^{k-1} with probability proportional to its weight w^{k-1} ;
 - b) Sample from $P(x_n | x_{n-1}^k)$ given x_n^k with weight $1/N$;
3. Compute $\pi_n = \{(x_n^k, P(y_n | x_n^k)), k = 1, 2, \dots N\}$.

It is easy to see that this set of steps is now in the form of a recursive filter. Furthermore, at any time any statistic

of the associated distribution can be approximated from the set of samples and associated weights.

Sampling-based filters of this form have found wide applicability in a variety of challenging areas where linear estimation techniques do not suffice. These techniques have been particularly successful, for problems with low state dimension (typically $n \leq 3$) and well-constrained dynamics. For higher-dimensional problems or systems exhibiting high dynamic variability, the number of particles necessary to obtain good approximations can become prohibitively large. However, even in these cases, sampling-based systems can sometimes be engineered to produce acceptably good results.

Graphical Models

Graphical models are a class of models that represent dependence and independence relationships among a set of variables. Common examples of graphical models include Bayes nets, influence diagrams, and neural nets. Here, we focus on Bayes nets as a specific example.

A Bayesian network is a directed acyclic graph consisting of nodes representing random variables, and directed arcs representing probabilistic relationships between pairs of random variables. Let $\text{parents}(X)$ denote the set of nodes which have arcs terminating at X , and let X_1, X_2, \dots, X_N be the N random variables in the graph. Then we can write

$$P(X_1, X_2, \dots, X_N) = \prod_{i=1}^N P(X_i \mid \text{parents}(X_i)) \quad (4.30)$$

For example, a Bayesian network representing a mobile robot performing localization is shown in Fig. 4.12. This graphical model encodes the sequential form of the problem and is thus an example of a so-called *recurrent network*. More discussion of such models can be found in [4.31].

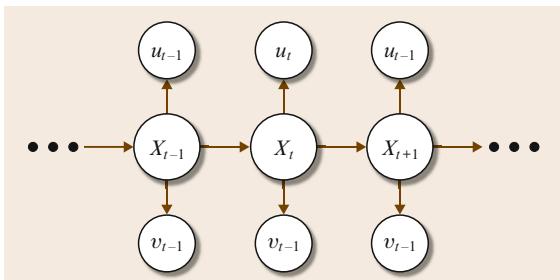

Fig. 4.12 An example of robot localization expressed as a graphical model

The structure of a Bayesian network encodes various independence relationships among variables. By exploiting these independence relationships, it is possible to design efficient inference algorithms. In particular, graphs which are acyclic even in their undirected form (referred to as *polytrees*) admit linear inference algorithms. More general graphs can be solved using various types of iterative methods. In particular, if the distributions in the network are of a continuous type, variations on sequential importance sampling can be used to solve problems in an approximate sense [4.32].

4.3.3 Robust Estimation Methods

In our previous discussions, we generally assumed that all of the data was *good*, meaning that it was perhaps corrupted by noise but ultimately carried information about the problem at hand. However, in many cases, the data may contain so-called *outliers* – data points that are either much more highly corrupted than *typical* data, or which are completely spurious. For example, in our mapping application we might occasionally obtain range data through multiple reflections. Thus, while scanning a straight wall, most of the points would lie on a straight line, but occasionally we would have a data point that has a completely inconsistent range value.

The problem is that many common estimation methods are quite sensitive to data outliers. Consider a very simple case: estimating a single scalar value x by averaging a series of observations X_1, X_2, \dots, X_N . Then we can write our estimate \hat{x} as

$$\hat{x} = \sum_{i=1}^N X_i / N. \quad (4.31)$$

Now, without loss of generality, suppose that X_N is an outlier. We can rewrite the above as

$$\hat{x} = \sum_{i=1}^{N-1} X_i / n + X_N / n. \quad (4.32)$$

It is now easy to see that we can produce *any* value of \hat{x} by manipulating X_n . In short, a single outlier can create an arbitrarily poor estimate. More generally, the solution to any least-squares problem, e.g., estimating a line from laser range data, takes the general form $\hat{x} = My$. By the same argument as above, it is easy to show that any least-squares solution is likewise susceptible to outliers.

The field of *robust statistics* studies the problem of estimation or decision making when the underlying data are contaminated by outliers. In robust statistics, there

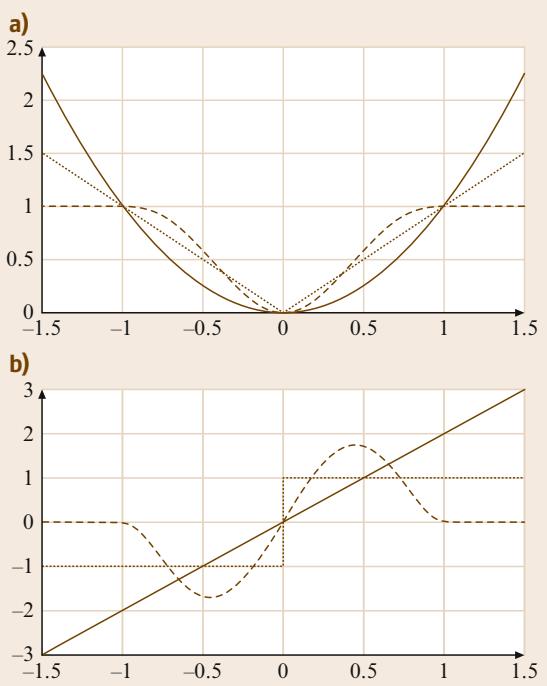

Fig. 4.13 (a) Three common robust M-estimation functions: the square function, the absolute value, and the Tukey biweight function. (b) The corresponding influence functions

are two important concepts: the *breakdown point* and *influence function*. The breakdown point is the proportion of outliers (i.e., data with arbitrarily large errors) that an estimator can tolerate before producing arbitrarily large errors in an estimate. We argued above that least-squares methods have a breakdown point of 0% since the estimate can be perturbed arbitrarily far by a single observation. By comparison, we might compute an estimate by taking the median of the data, which has a breakdown point of 50% – up to half of the data can be outliers and meaningful results may still be produced.

Whereas the breakdown point quantifies *how many* outliers can be tolerated, the influence function quantifies *how much* an outlier affects an estimate. In the case of least squares, the influence function is linear. One way of creating new estimators with better robustness is the method of *M-estimators* [4.19]. To produce an M-estimate, we consider the following minimization problem:

$$\min_{\hat{x}} \sum_{i=1}^N \rho(\hat{x}, y_i). \quad (4.33)$$

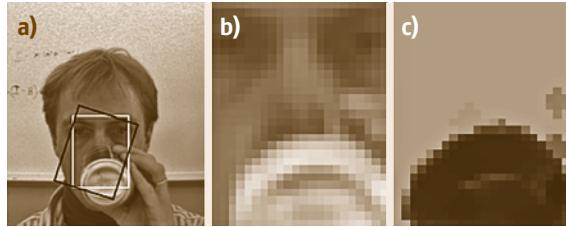

Fig. 4.14a–c An example of using an M-estimate implemented via IRLS for visual tracking (after [4.33]). (a) Results of a face tracker in a single frame of video. The black frame corresponds to a tracking algorithm without outlier rejection and the white frame corresponds to the algorithm with outlier rejection. (b) Magnified view of the region in the white frame; (c) the corresponding weighting matrix in which darker areas mark outliers

Note that defining $\rho(a, b) = (a - b)^2$ leads to a least-squares solution. However, we can now choose other functions with better resistance to outliers. Figure 4.13 shows three common examples.

Note that, in general, the optimization of (4.33) is nonlinear and the result will often not exist in closed form. Interestingly, it is often possible to solve this problem using the method of *iteratively reweighted least squares* (IRLS) [4.28, 34]. The idea behind IRLS is quite simple. Recall that in (4.7) we introduced a weighting matrix W . Suppose that, through some means, we knew which data points were outliers. In this case, we could simply set the weights for those points to zero, and the result would be the least-squares estimate on the remaining (good) data.

In IRLS, we alternate between hypothesizing outliers (through reweighting) and solving to produce a solution (through least squares). Typically, the weight for a point depends on the residual error of the estimate. That is, suppose we compute

$$r = y - F\hat{x}. \quad (4.34)$$

Let $\psi(y) = d\rho/dx|_x$; then we can set $W_{i,i} = \psi(y)/r_i$. It can be shown that in many cases this form of weighting will lead to convergence. An example of using IRLS techniques for video tracking is shown in Fig. 4.14.

Voting-Based Methods

Another common method for dealing with outliers is to choose a set of data and let it *vote* for a result. We discuss two common methods: **RANSAC** [4.9] and least median of squares (LMEDs) [4.35].

In both cases, we start with the idea that, amidst all of the data (including outliers), there is an estimate

that is consistent with the *good* data. The problem is to choose that estimate. Consider, however, our problem of estimating a line from laser data, and suppose we have 100 laser points. All we really need is to choose two points correctly, fit a line, and then count how many other points are consistent with this line. If we (conservatively) estimate that 3/4 of the data is good, then the odds of choosing two *good* points is 9/16, or equivalently, the odds of one or both points being outliers is 7/16. If we now repeat this process a few (e.g., ten) times, then the odds that *all* of our choices are bad is $(7/16)^{10} = 0.025\%$. To put it in other terms, there is a 99.975% chance we have chosen a *good* pair of points.

How do we decide to accept a sample? In RANSAC, we *vote* by counting the number of samples that are consistent with an estimate to within a given distance threshold. For example, we would choose points that are within a fixed distance to the line we estimated. We choose the candidate estimate with the largest number of votes. In LMedS, we instead compute the median distance of all of the samples to the line. We then choose the estimate with the least median value.

It is not hard to see that LMedS has a breakdown point of 50% of the data. RANSAC, on the other hand, can have a breakdown point that is potentially larger, but it requires the choice of a threshold. RANSAC also has the advantage that, once the inliers are identified, it is possible to compute a least-squares estimate from them, thus reducing the noise in the estimate.

Both RANSAC and LMedS can also provide good starting solutions for a robust iterative method such as IRLS.

4.3.4 Data Association Techniques

The previous section considered the case where there is a *known* relationship between observations and a quantity to be estimated. However, as was illustrated in our initial mobile robot mapping problem, it may be the case that we also have to compute this correspondence in conjunction with estimation. In this case, an essential step in estimation is the *data association* problem: producing a correspondence between the observed data and quantities to be estimated.

The literature on this problem is enormous; here we will focus on a few specific methods that have found wide use. We will also separate our discussion into *causal* (or sequential) association methods commonly used when filtering time-series data and *noncausal* (or batch) methods that can be used when the complete data

set is available for processing. The latter is typically treated with methods for data *clustering*.

In both cases, we can extend our previous models and notation to include uncertainty as to the underlying source of the data. To this end, we will use a superscript on quantities to denote the observation model. Thus, our observation model becomes

$$x_{t+1}^k = g^k(x_t^k) + w_t^k, \quad (4.35)$$

$$y_t^k = f_t^k(x_t^k) + \eta_t^k, \quad (4.36)$$

where $k = 1 \dots M$.

Clustering on Batch Data

Following the same course as our previous discussion on point estimation, let us first consider the case where we do not make any statistical assumptions about the data, and we have no system dynamics. Thus, we are simply given the observations y_1, y_2, \dots, y_M . We have unknown underlying parameters x^1, x^2, \dots, x^N (for the moment, we take N as known). Our goal is to compute an *association mapping* π such that $\pi(j) = k$ if and only if y_j arose from the model parameters x^k .

k-means Clustering

The *k*-means algorithm for clustering and data association is simple, well established, and forms a good starting point for our discussion. Here, we assume that $f(x) = x$ – that is, we are provided with noisy observations of the underlying state vectors. The *k*-means algorithm then proceeds as follows.

1. Pick N cluster centers $\{\hat{x}^i\}$.
2. For each observation y_j , associate it with the closest cluster center, that is, set $\pi(j) = i$, where

$$d(\hat{x}^i, y_j) = \min_k d(\hat{x}^k, y_j) \quad (4.37)$$

for some distance function d (typically the Euclidean distance).

3. Estimate the mean of the observation associated with each cluster center as

$$\hat{x}^i = \sum_{j, \pi(j)=i} y_j. \quad (4.38)$$

4. Repeat steps 2 and 3.

In many cases and with good initialization, *k*-means works quite well. However, it can also fail to produce good clusters, and there is no guarantee that it will even converge to a solution. It is common to repeat the algorithm several times from different initial conditions and take the result that has the *best* outcome. Note

also that the extension to linear observation models is straightforward by including F in (4.3) by defining

$$d(\hat{x}^i, y_j) = \|F\hat{x}^i - y_j\| \quad (4.39)$$

and replacing (4.38) with the corresponding least-squares estimator. Going a step further, if we have a statistical model for observed data, then we could make use of the likelihood function introduced earlier and define $d(\hat{x}^i, y_j) = p(y_j | \hat{x}^i)$ and make use of the **MLE** in (4.38).

One disadvantage of the k -means algorithm is that, even when we have known statistical models, it is not guaranteed to converge. However, a variation, known as *expectation maximization*, can be shown to converge.

Expectation Maximization for Data Association and Modeling

The expectation-maximization (**EM**) algorithm [4.36] is a general statistical technique for dealing with missing data. In previous discussion, we made use of maximum-likelihood estimation to maximize the conditional probability of observed data given a set of unknown parameters. However, our use of **MLE** presumed that we had complete knowledge of the data. In particular, we knew the association between the data elements and models.

Let us now assume that some of our data is missing. To this end, define \mathcal{Y}_O and \mathcal{Y}_U as the *observed* and *unobserved* data, respectively. We then note that we can write

$$p(\mathcal{Y}_O, \mathcal{Y}_U | x) = p(\mathcal{Y}_U | \mathcal{Y}_O, x)p(\mathcal{Y}_O | x). \quad (4.40)$$

Suppose now that we make a guess for \hat{x} , and we have a distribution over the unknown data \mathcal{Y}_U (where this comes from we will discuss in a minute). It follows that we could compute the *expected value* of the log-likelihood function (recall that maximizing the log likelihood is equivalent to maximizing the likelihood) as

$$Q(x, \hat{x}) = E_{\mathcal{Y}_U} [\log p(\mathcal{Y}_O, \mathcal{Y}_U | x) | \mathcal{Y}_O, \hat{x}]. \quad (4.41)$$

Note that we differentiate between the fixed value \hat{x} that is usually needed to define the distribution over the unknown data and the unknown x of the log-likelihood function.

Ideally, we would then like to choose values for x that make Q large. Thus, we can choose a new value according to the iterative rule

$$\hat{x}_i = \arg \max Q(x, \hat{x}_{i-1}). \quad (4.42)$$

What can be shown is that this iteration will converge to some local maximum of the objective function Q . It is

important to note that there is no guarantee that this is, however, the *global* maximum.

How do we connect this with clustering? We consider the observed data to be just that, the data we have observed. Let the unobserved data be the *association values* $\pi(j)$, $j = 1, 2, \dots, M$ that determine which model the observed data items originate from. Note that this is a discrete random variable. Let us further assume that N underlying clusters are distributed according to a Gaussian distribution with mean x_i and covariance Λ_i . Let the unconditional probability that a particular data item y_j comes from cluster i be α_i . The unknown parameters are then $\theta = \{x_1, x_2, \dots, x_N, \Lambda_1, \Lambda_2, \dots, \Lambda_N, \alpha_1, \alpha_2, \dots, \alpha_N\}$. We now use $^-$ and $^+$ to denote prior and updated parameter estimates, respectively. For conciseness, we also define $w_{i,j} = p(\pi(j) = i | y_j, \theta)$ and we use a subscript plus to denote updated parameter estimates. Then, after a series of calculations [4.36], the **EM** algorithm for data clustering becomes:

E-Step:

$$w_{i,j}^- = \frac{p(y_j | \pi(j) = i, \theta) \alpha_i}{\sum_i p(y_j | \pi(j) = i, \theta) \alpha_i}. \quad (4.43)$$

M-Step:

$$\hat{x}_i^+ = \sum_j y_j w_{i,j}^- / \sum_j w_{i,j}^-, \quad (4.44)$$

$$\Lambda_i^+ = \sum_j y_j (y_j)^t w_{i,j}^- / \sum_j w_{i,j}^-, \quad (4.45)$$

$$\alpha_i^+ = \sum_j w_{i,j}^- / \sum_i \sum_j w_{i,j}^-. \quad (4.46)$$

From this, we can see that **EM** produces a type of soft clustering, as opposed to k -means which produces specific decisions (in terms of $w_{i,j}$) as to which cluster an observation belongs. In fact, the result of estimation is the maximum-likelihood estimate of a *Gaussian mixture model* which has the form

$$p(y|\theta) = \sum_j \alpha_j N(y | \hat{x}_j, \Lambda_j), \quad (4.47)$$

where $N(\cdot)$ denotes a Gaussian density function. Figure 4.15 shows the results of executing the **EM** algorithm on data sampled from a Gaussian mixture model.

Recursive Filtering

In the batch methods described above, we do not have a priori information on state parameters. In the case of recursive filtering, we have the advantage that prior state

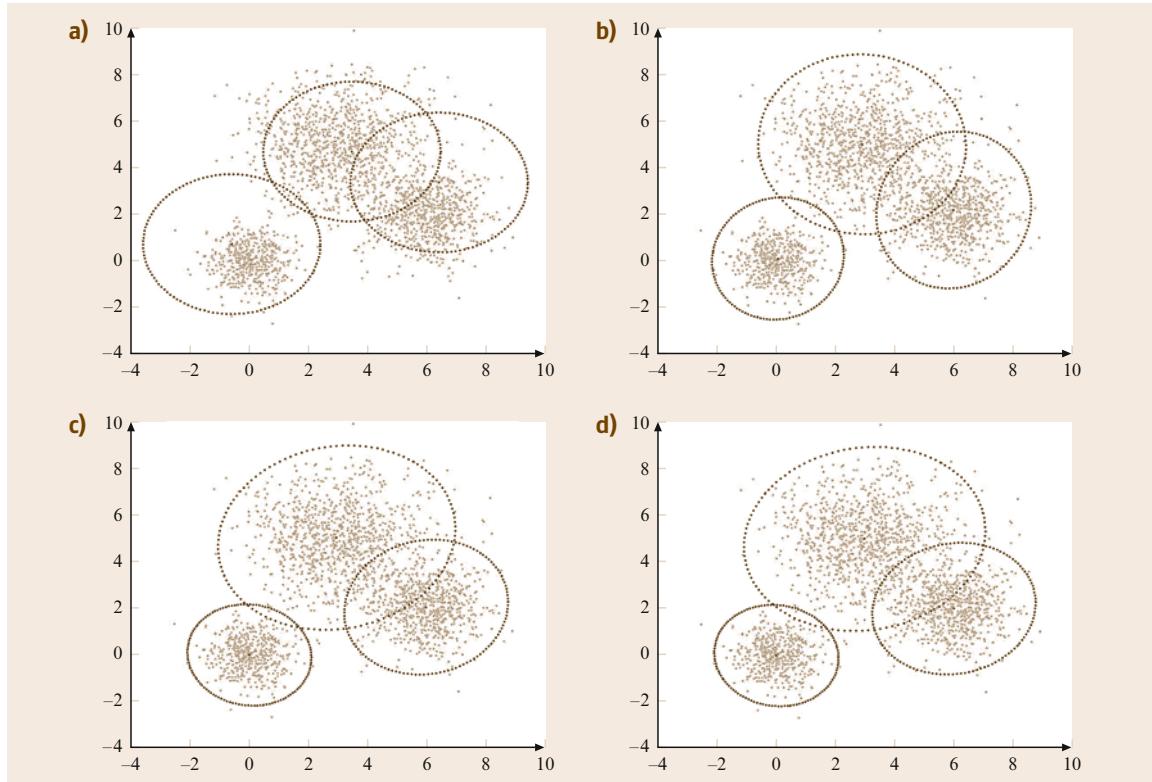

Fig. 4.15a–d An example of clustering using expectation maximization. The figures are the results at iterations 1, 2, 5, and 10

estimates, \hat{x}_t^k and Λ_t^k , are available for processing at time $t+1$. As before, for data y_t^i , $i = 1 \dots N$, the problem is to determine a mapping $\pi : \{1 \dots N\} \rightarrow \{1 \dots M\}$ which associates data element i to model $k = \pi(i)$. In some cases, it is also useful to include an *outlier process* to handle data that comes from no known model. For this purpose, we can include 0 in the range of the function, and use the mapping to zero as an outlier.

Nearest-Neighbor Association

Analogous to k -mean clustering, a simple way of producing a data association is to compute the data association value as

$$\pi(i) = \arg \min_j d(F^j \hat{x}^j, \hat{y}^i). \quad (4.48)$$

However, nearest-neighbor methods do not take into account what we know about either the sensor data or the estimate. That is, we may have a very very good estimate of some model i and a very very bad estimate for some other model j . If a sensor observation is equidistance

between them, does it make sense to flip a coin? Odds are that it is more likely to come from j (with a larger variance) than i (with a smaller variance).

A commonly used measure that can take this into account is the *Mahalanobis distance* [4.37]. The idea is to weight each value by its variance as

$$m(y_1, y_2) = (y_1 - y_2)(\Lambda_1 + \Lambda_2)^{-1}(y_1 - y_2)^\top. \quad (4.49)$$

Thus, distances are scaled inversely with uncertainty. In the case above, the observation with a higher variance would produce the smaller distance, as desired.

Even using this as a weighting method, it is still possible that we will make an error in data association. From an estimation point of view, this will introduce an outlier in the estimation process with, as discussed above, potentially disastrous results. Another approach, analogous to IRLS, is instead to weight the data based on the distance to a model. This leads naturally to the notion of a *data association filter*. We refer the reader to [4.18] for extensive discussions of these techniques.

4.3.5 Modeling Sensors

To this point, we have introduced several sensing modalities, and we have discussed several methods for estimation. However, the latter often rely on having statistical models for the former. Thus, no chapter on sensing and estimation would be complete without a short discussion of modeling sensors.

Developing a sensor model potentially involves four major elements: (1) creating a physical model, (2) determining a sensor calibration (3) determining an error model, and (4) identifying failure conditions.

The physical model is the relationship f between the underlying quantities of interest (x) and the available data (y). In many cases, this relationship is obvious, e.g., the distance from a laser sensor to a surface in the world. In others, it may be less so, e.g., what is the right model relating intensities in multiple camera images to the distance to an observed point? In some cases, it may be necessary to include computational processes, e.g., feature detection and correspondence, in the sensor model.

Once a physical model is determined, there is often a process of sensor calibration. Such procedures are typically specific to the sensor in question, for example, the imaging geometry of a perspective camera system requires identification of two scale parameters (governing image scale) and the location of the optical center (two additional parameters). There are also often lens distortion parameters. These parameters can only be determined by a careful calibration procedure [4.5].

Once a calibrated physical sensor model is available, determining an error model typically involves performing an identification of the statistical parameters. Ideally, the first step is to determine an empirical distribution on errors. However, this can often be difficult, as it requires knowing accurate *ground truth* for the underlying unknown parameters. This often requires the development of a laboratory setup that can simulate the expected sensing situation.

Given such an empirical distribution, there are several important questions, including: (1) Are observations statistically independent? (2) Is the error distribution unimodal? and (3) Can the essential aspects of the

empirical error be captured using common statistical quantities such as the data variance? We refer the reader to books on statistics and data modeling [4.38] for further information on this topic.

Finally, it is important to understand when sensors can and cannot provide reliable data, for example, a laser sensor may be less accurate on dark surfaces than on light ones, cameras do not produce meaningful data if the lighting is too bright or too dark, and so forth. In some cases, there are simple clues to these conditions (e.g., simply looking at the intensity histogram of a camera image can quickly determine if conditions are suitable for processing). In some cases it is only possible to detect conditions in context (e.g., two range sensors disagree on the distance to a surface). In some cases failure is only detectable in retrospect, e.g., after a 3-D surface model is built it is apparent that a hypothesized surface would be occluded by another and must therefore be a multiple reflection. In a truly robust sensing system, all available possibilities for verifying sensor operation should be exploited.

4.3.6 Other Uncertainty Management Methods

Due to the limitations of space, we have necessarily limited our discussion to cover the most commonly used sensing and estimation methods. It is important to note that many other alternative uncertainty management methods have been proposed and employed with success.

For example, if it is known that sensing error is bounded, constraint-based methods can be quite effective at performing point estimation [4.39, 40]. Alternatively, if only partial probability models can be identified, Dempster–Shafer methods can be employed to make judgments [4.41].

Fuzzy logic allows graded membership of a set. With fuzzy set theory it is possible to have partial membership. As an example in classification of data it might be difficult to select between two categories such as *average* and *tall* and gradual shifts may make sense. Such methods have for example been used for situation assessment and navigation as reported by [4.42] for the DAMN architecture.

4.4 Representations

Sensor data can be used directly for control but it is also used for estimation of the state of the robot and/or the world. The definition of *state* and the appropriate methods for estimation are closely related to the representation adopted for the application.

There are a rich variety of possible world representations including most typical geometric elements such as points, curves, surfaces, and volumes. A fundamental aspect in robotics is the concept of rigid-body *pose*. The pose of a robot or an entity in the world is characterized by position and orientation with respect to a reference frame.

In general, pose is represented by the pair (\mathbf{R}, \mathbf{T}) . Here \mathbf{R} is the orientation of the object represented by a rotation matrix with respect to a reference frame. Similarly, \mathbf{T} represents the translation of the object with respect to the reference frame. There is a rich set of potential representations for the transformation between reference frames as detailed in the chapter on Kinematics (Chap. 1) and in [4.43].

Sensory data is acquired in a local sensor reference frame, for example, a sonar transducer, a laser scanner, and a stereo imaging system would all measure distances to surfaces in the world relative to their own frame. However, if the goal is to combine this information into a common world model, the data must be transformed into a robot-centered reference frame, or possibly into a fixed world (inertial) reference frame. In particular, the world-centered reference frame enable simple transfer across robot motions and communication to other robots and/or users.

For the purposes of discussion, most representations for the integration of sensor data can be categorized into four general classes of models:

- raw sensor data models
- grid-based models
- feature-based models
- symbolic or graphical models

Naturally, it is also possible to combine elements of these four categories to achieve hybrid models of the environment.

4.4.1 Raw Sensor Representations

For simple feedback control [4.44] it is common to integrate raw sensory data directly into the control system, as in many cases it is unnecessary to have a *world model* for the control. For example, proprioceptive sensing is often

used in this manner: basic trajectory control makes direct use of encoder information from joints, and force control operates directly from force or torque information from force sensors.

Raw sensor models are less common with exteroceptive sensing, but there are cases where it can be useful. One example is mobile robot mapping from dense point data. This approach has in particular been made popular for laser range sensors, where scan alignment is used for the generation of point-based world models. The work by [4.45, 4.46] demonstrates how a number of laser range scans can be combined into a joint model of the environment. More formally a scan of the environment at time t is represented as a point set

$$\mathcal{P}_t = \{p_i = (\rho_i, \theta_i) | i \in 1 \dots N\}. \quad (4.50)$$

Two different scans \mathcal{P}_t and \mathcal{P}_{t+1} are then aligned through a standard SE(3) transformation. The estimation of the transformation is typically achieved through use of the ICP algorithm [4.13]; assume that $T^{[0]}$ is an initial estimate of the transformation between the two point sets and that $\|\mathbf{p}_t - \mathbf{p}_{t+1}\|$ is the Euclidean distance between a point from \mathcal{P}_t and a point from \mathcal{P}_{t+1} . If furthermore CP is a function to locate the closest point from one set in the other set, then let \mathcal{C} be the set of point correspondences between the two sets. Through iterations of the following algorithm:

1. compute $\mathcal{C}_k = \cup_{i=1}^N \{p_i, \text{CP}[T^{[k-1]}(p_i, \mathcal{P}_{t+1})]\}$,
2. estimate the $T^{[k]}$ that minimizes the LSQ error between the points in \mathcal{C}_k until the error has converged

an estimate of the scan alignment can be found and a joint model of the environment can be constructed.

The model is simple to construct and well suited for integration of sensor data from a single modality. Typically the model does not include information about uncertainty and, as the model grows the complexity, $O(\sum_t |\mathcal{P}_t|)$ becomes an issue.

4.4.2 Grid-Based Representations

In a grid-based representation the world is tessellated into a number cells. The cells can contain information about environmental features such as temperature, obstacles, force distribution, etc. The dimensionality of the grid is typically two or three, depending on the application. The tessellation can either be uniform or tree based using quad-tree or oct-trees [4.47]. The tree-based methods are in particular well suited for handling of in-

homogeneous and large-scale data sets. In a grid model each cell contains a probability over the parameter set. As an example, when using the grid model for representation of a physical environment, the cell specifies *occupied* or *free* and the cell encodes the probability $P(\text{occupied})$. Initially where there is no information the grid is initialized to $P(\text{occupied}) = 0.5$ to indicate unknown. It is further assumed that sensor models are available that specify $P(R|S_{ij})$, i.e., the probability of detection objects for a given sensor and location. Using Bayes theorem (4.10) it is now possible to update the grid model according to:

$$p_{ij}(t+1) = \frac{P(R|S_{ij} = O)p_{ij}(t)}{P(R|S_{ij} = 0)p_{ij}(t) + P(R|S_{ij} = F)(1 - p_{ij}(t))},$$

where p_{ij} is computed across the grid model whenever new data are acquired.

The grid-based model has been widely used in mobile robotics [4.48, 49] and in medical imaging where image volumes are quite common [4.50]. Volume models can be relative large. As an example a millimeter-resolution grid model of the human head requires 4 GB of storage, and thus demands significant computational resources for maintenance.

4.4.3 Discrete Feature Representations

Both the raw sensor representation and the grid-based models contain a minimum of abstraction for the sensory data. In many cases there is an interest in extracting features from the sensor data to reduce the storage requirement and only preserve data that are invariant across motion of the platform or external objects. Features span most standard geometric entities such as points (\mathbf{p}), lines (\mathcal{L}), planes (N, \mathbf{p}), curves ($\mathbf{p}(s)$), and more general surfaces. For estimation of properties of the external world there is a need for a hybrid model in which collections of features are integrated into a unified model of state.

In general a point is represented in $\mathcal{R}(3)$. Sensors have associated noise and, consequently, in most cases points have an associated uncertainty, typically modeled as Gaussian with mean μ and standard deviation σ . The estimation of the statistics is achieved using first- and second-order moments.

Line features are more difficult to represent. The mathematical line can be represented by the vector pair (\mathbf{p}, \mathbf{t}) , i.e., a point on the line and the tangent vector. In many practical applications the line has a finite extent, and there is a need to encode the length of the line,

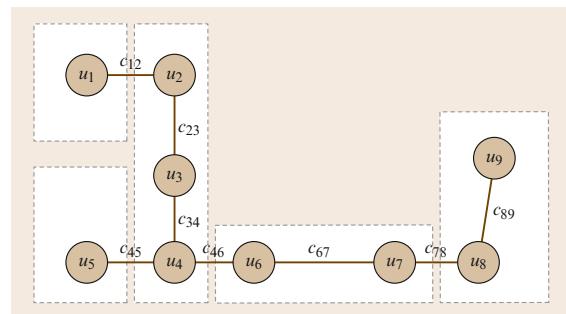

Fig. 4.16 A topological map of a spatial environment

which can be achieved using end points, start point, tangent, and length. In some cases it is advantageous to have a redundant representation of the line model to simplify updating and matching. The relation between end-point uncertainties and other line parameters can be derived analytically, as described in [4.51]. The estimation of line parameters is often based on the previously described RANSAC method through the use of the Hough transform [4.8], which is another voting-based method.

For more complex feature models such as curves or surfaces there is a corresponding need to utilize detection methods that facilitate robust segmentation of features, and estimation of the associated uncertainty. A comprehensive description of such methods is available from [4.36].

4.4.4 Symbolic/Graph-Based Models

All of the representations presented in Sects. 4.4.1–4.4.3 are parametric in nature with limited associated semantics. Methods for the recognition of structures, spaces, locations, and objects have seen major recent progress in particular due to advances in statistical learning theory [4.10, 52]. Consequently, today there exist a variety of methods for the recognition of complex structures in sensor data, such as landmarks, road surfaces, body structures, etc. Given the availability of recognized structures it is possible to represent the environment using the previously discussed graphical models. In general a graph is composed of a set of nodes N and a set of edges E that connect nodes. Both nodes and edges can have attributes associated such as labels and distances. One example of a graph structure is a topological map of the environment as shown in Fig. 4.16. The graph representation could also be a semantic model of the environment (objects and places) or a representation of the composition of an object to assembled.

In terms of model updating semantic/graph-based representations can take advantage of recent advances

in Bayesian reasoning as presented by *Pearl* [4.53], and exemplified in [4.54].

4.5 Conclusions and Further Readings

Sensing and estimation continues to be a challenging and very active area of robotics research. Several areas of sensing such as computer vision and medical imaging are themselves large and diverse research areas. At the same time, new fundamental and applied techniques in estimation continue to be developed. Indeed, it is fair to say that perception continues to be one of the most challenging areas of robotics research.

Given this wealth of activity, no single chapter can hope to cover all of the material that can be useful in the development of sensor-based robotics. However, the methods that have been presented here are representative of the most commonly used techniques in robotics. In particular, linear techniques such as the Kalman filter continue to form the backbone of perceptive robotics. Part C of the handbook provides more in-depth coverage of several of the key topics in sensing and estimation.

For the reader wishing to learn more, general discussion on the design, physics, and use of a rich variety of sensors can be found in the *Handbook of Modern Sensors* [4.3]. A discussion of sensors for mobile robots can be found in [4.55], though significant advances have been achieved since the book was published more than a decade ago. Sensing and estimation using computer vision is described in detail in [4.56] and [4.57].

The basic estimation theory is covered in a number of excellent text books. Much of the detection and linear estimation theory is covered in depth in [4.18] and [4.58]. General statistical estimation is covered in [4.10] and [4.11] and the more recently updated version [4.36]. Robust methods are described in detail in [4.19, 35]. In-depth coverage of estimation methods for mobile systems is also covered in [4.31].

5. Motion Planning

Motion Planning

Lydia E. Kavraki, Steven M. LaValle

This chapter first provides a formulation of the geometric path planning problem in Sect. 5.1 and then introduces sampling-based planning in Sect. 5.2. Sampling-based planners are general techniques applicable to a wide set of problems and have been successful in dealing with hard planning instances. For specific, often simpler, planning instances, alternative approaches exist and are presented in Sect. 5.3. These approaches provide theoretical guarantees and for simple planning instances they outperform sampling-based planners. Section 5.4 considers problems that involve differential constraints, while Sect. 5.5 overviews several other extensions of the basic problem formulation and proposed solutions. Finally, Sect. 5.7 addresses some important and more advanced topics related to motion planning.

A fundamental robotics task is to plan collision-free motions for complex bodies from a start to a goal position among a collection of static obstacles. Although relatively simple, this geometric path planning problem is computationally hard [5.1]. Extensions of this formulation take into account additional problems that are inherited from mechanical and sensor limitations of real robots such as uncertainties, feedback, and differential constraints, which further complicate the development of automated planners. Modern al-

gorithms have been fairly successful in addressing hard instances of the basic geometric problem and a lot of effort has been devoted to extend their capabilities to more challenging instances. These algorithms have had widespread success in applications beyond robotics, such as computer animation, virtual prototyping, and computational biology. There are many available surveys [5.2–4] and books [5.5–7] that cover modern motion planning techniques and applications.

5.1 Motion Planning Concepts

This section provides a description of the fundamental motion planning problem or the geometric path planning problem. Extensions of this basic formulation to more complicated instances will be discussed later in the chapter and will be revisited throughout this book.

5.1.1 Configuration Space

In path planning, a complete description of the geometry of a robot \mathcal{A} and of a workspace \mathcal{W} is provided. The workspace $\mathcal{W} = \mathbb{R}^N$, in which $N = 2$ or $N = 3$, is a static environment populated with obstacles. The goal is to find a collision-free path for \mathcal{A} to move from an initial position and orientation to a goal position and orientation.

To achieve this, a complete specification of the location of every point on the robot geometry, or a *configuration* \mathbf{q} , must be provided. The *configuration space*, or C-space ($\mathbf{q} \in \mathcal{C}$), is the space of all possible configurations. The C-space represents the set of all transformations that can be applied to a robot given its kinematics as described in Chap. 1 (Kinematics). It was recognized early on in motion planning research [5.8, 9] that the C-space is a useful way to abstract planning problems in a unified way. The advantage of this abstraction is that a robot with a complex geometric shape is mapped to a single point in the C-space. The number of degrees of freedom of a robot system is the dimension of the C-space, or the minimum number of parameters needed to specify a configuration.

Let the closed set $\mathcal{O} \subset \mathcal{W}$ represent the (*workspace*) *obstacle region*, which is usually expressed as a collection of polyhedra, three-dimensional (3-D) triangles, or piecewise-algebraic surfaces. Let the closed set $\mathcal{A}(\mathbf{q}) \subset \mathcal{W}$ denote the set of points occupied by the robot when at configuration $\mathbf{q} \in \mathcal{C}$; this set is usually modeled using the same primitives as used for \mathcal{O} . The *C-space obstacle region*, \mathcal{C}_{obs} , is defined as

$$\mathcal{C}_{\text{obs}} = \{\mathbf{q} \in \mathcal{C} \mid \mathcal{A}(\mathbf{q}) \cap \mathcal{O} \neq \emptyset\}. \quad (5.1)$$

Since \mathcal{O} and $\mathcal{A}(\mathbf{q})$ are closed sets in \mathcal{W} , the obstacle region is a closed set in \mathcal{C} . The set of configurations that avoid collision is $\mathcal{C}_{\text{free}} = \mathcal{C} \setminus \mathcal{C}_{\text{obs}}$, and is called the *free space*.

Simple Examples of C-spaces

Translating Planar Rigid Bodies. The robot's configuration can be specified by a reference point (x, y) on the planar rigid body relative to some fixed coordinate

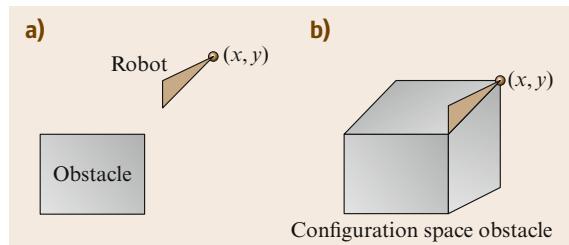

Fig. 5.1a,b A robot translating in the plane: (a) a triangular robot moves in a workspace with a single rectangular obstacle. (b) The C-space obstacle

frame. Therefore the C-space is equivalent to \mathbb{R}^2 . Figure 5.1 gives an example of a C-space for a triangular robot and a single polygonal obstacle. The obstacle region in the C-space can be traced by sliding the robot around the workspace obstacle to find the constraints on all $\mathbf{q} \in \mathcal{C}$. Motion planning for the robot is now equivalent to motion planning for a point in the C-space.

Planar Arms. Figure 5.2 gives an example of a two-joint planar arm. The bases of both links are pinned, so that they can only rotate around the joints, and there are no joint limits. For this arm, specifying the rotational parameters θ_1 and θ_2 provides the configuration. Each joint angle θ_i corresponds to a point on the unit circle \mathbb{S}^1 and the C-space is $\mathbb{S}^1 \times \mathbb{S}^1 = T^2$, the two-dimensional torus shown in Fig. 5.2. For a higher number of links without joint limits, the C-space can be similarly defined as:

$$\mathcal{C} = \mathbb{S}^1 \times \mathbb{S}^1 \times \dots \times \mathbb{S}^1. \quad (5.2)$$

If a joint has limits, then each corresponding \mathbb{S}^1 is often replaced with \mathbb{R} , even though it is a finite interval. If the base of the planar arm is mobile and not pinned,

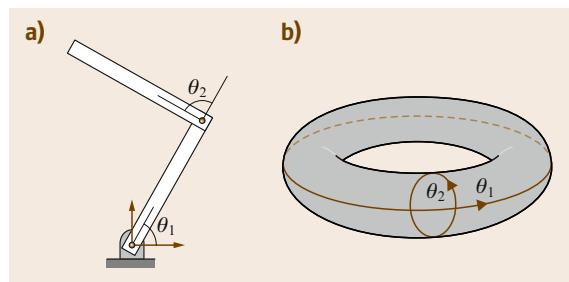

Fig. 5.2 (a) A two-joint planar arm in which the links are pinned and there are no joint limits. (b) The C-space

then the additional translation parameters must also be considered in the arm's configuration:

$$\mathcal{C} = \mathbb{R}^2 \times \mathbb{S}^1 \times \mathbb{S}^1 \times \dots \times \mathbb{S}^1. \quad (5.3)$$

Additional examples of C-spaces are provided in Sect. 5.6.1, where topological properties of configuration spaces are discussed.

5.1.2 Geometric Path Planning Problem

The basic motion planning problem, also known as the *piano mover's problem* [5.1], is defined as follows.

Given:

1. A *workspace* \mathcal{W} , where either $\mathcal{W} = \mathbb{R}^2$ or $\mathcal{W} = \mathbb{R}^3$.
2. An *obstacle region* $\mathcal{O} \subset \mathcal{W}$.
3. A *robot* defined in \mathcal{W} . Either a rigid body \mathcal{A} or a collection of m links: $\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_m$.
4. The *configuration space* \mathcal{C} (\mathcal{C}_{obs} and $\mathcal{C}_{\text{free}}$ are then defined).
5. An *initial configuration* $q_I \in \mathcal{C}_{\text{free}}$.
6. A *goal configuration* $q_G \in \mathcal{C}_{\text{free}}$. The initial and goal configuration are often called a *query* (q_I, q_G).

Compute a (continuous) path, $\tau : [0, 1] \rightarrow \mathcal{C}_{\text{free}}$, such that $\tau(0) = q_I$ and $\tau(1) = q_G$.

5.1.3 Complexity of Motion Planning

The main complications in motion planning are that it is not easy to directly compute \mathcal{C}_{obs} and $\mathcal{C}_{\text{free}}$, and the dimensionality of the C-space is often quite high. In terms of computational complexity, the piano mover's problem was studied early on and it was shown to be PSPACE-hard by Reif [5.1]. A series of polynomial-time algorithms for problems with fixed dimension suggested an exponential dependence on the problem dimensionality [5.10, 11]. A single exponential-time algorithm in the C-space dimensionality was proposed by Canny and

showed that the problem is PSPACE-complete [5.12]. Although impractical, the algorithm serves as an upper bound on the general version of the basic motion planning problem. It applies computational algebraic geometry techniques for modeling the C-space in order to construct a *roadmap*, a one-dimensional (1-D) subspace that captures the connectivity of $\mathcal{C}_{\text{free}}$. Additional details about such techniques can be found in Sect. 5.6.3.

The complexity of the problem motivated work in path planning research. One direction was to study subclasses of the general problem for which polynomial time algorithms exist [5.13]. Even some simpler, special cases of motion planning, however, are at least as challenging, for example, the case of a finite number of translating, axis-aligned rectangles in \mathbb{R}^2 is PSPACE-hard as well [5.14]. Some extensions of motion planning are even harder. For example, a certain form of planning under uncertainty in 3-D polyhedral environment is NEXPTIME-hard [5.15]. The hardest problems in NEXPTIME are believed to require doubly exponential time to solve.

A different direction was the development of alternative planning paradigms that were practical under realistic assumptions. Many combinatorial approaches can efficiently construct 1-D roadmaps for specific two-dimensional (2-D) or 3-D problems. Potential field-based approaches define vector fields which can be followed by a robot towards the goal. Both approaches, however, do not scale well in the general case. They will be described in Sect. 5.3. An alternative paradigm, sampling-based planning, is a general approach that has been shown to be successful in practice for many challenging problems. It avoids the exact geometric modeling of the C-space but it cannot provide the guarantees of a complete algorithm. Complete and exact algorithms are able to detect that no path can be found. Instead sampling-based planning offers a lower level of completeness guarantee. This paradigm is described in the following section.

5.2 Sampling-Based Planning

Sampling-based planners are described first because they are the method of choice for a very general class of problems. The following section will describe other planners, some of which were developed before the sampling-based framework. The key idea in sampling-based planning is to exploit advances in collision detection algorithms that compute whether

a single configuration is collision free. Given this simple primitive, a planner samples different configurations to construct a data structure that stores 1-D C-space curves, which represent collision-free paths. In this way, sampling-based planners do not access the C-space obstacles directly but only through the collision detector and the constructed data struc-

ture. Using this level of abstraction, the planners are applicable to a wide range of problems by tailoring the collision detector to specific robots and applications.

A standard for sampling-based planners is to provide a weaker, but still interesting, form of completeness: *if a solution path exists, the planner will eventually find it*. Giving up on the stronger form of completeness, which also requires failure to be reported in finite time, these techniques are able to solve in practice problems with more than three degrees of freedom that complete approaches cannot address. More details on this weaker form of completeness are provided in Sect. 5.6.2.

Different planners follow different approaches on how to sample configurations and what kind of data structures they construct. Section 5.6.2 provides a deeper insight on sampling issues. A typical classification of sampling-based planners is between multi-query and single-query approaches:

- In the first category, the planners construct a roadmap, an undirected graph G that is precomputed once so as to *map the connectivity properties of $\mathcal{C}_{\text{free}}$* . After this step, multiple queries in the same environment can be answered using only the constructed roadmap. Such planners are described in Sect. 5.2.1.
- Planners in the second category build tree data structures on the fly given a planning query. They attempt to focus on exploring the part of the C-space that will lead to solving a specific query as fast as possible. They are described in Sect. 5.2.2.

Both approaches, however, make similar use of a collision checking primitive. The objective of a collision detector is to report all geometric contacts between objects given their geometries and transformations [5.16–18]. The availability of packages that were able to answer collision queries in a fraction of a second was critical to the development of sampling-based planners. Modern planners use collision detectors as a *black box*. Initially the planner provides the geometries of all the involved objects and specifies which of them are mobile. Then, in order to validate a robot configuration, a planner provides the corresponding robot transformation and a collision detector responds on whether the objects collide or not. Many packages represent the geometric models hierarchically, avoid computing all-pairwise interactions, and conduct a binary search to evaluate collisions. Except from configurations, a planner must also validate

entire paths. Some collision detectors return distance-from-collision information, which can be used to infer that entire neighborhoods in \mathcal{C} are valid. It is often more expensive, however, to extract this information; instead paths are usually validated point by point using a small stepping size either incrementally or by employing binary search. Some collision detectors are incremental by design, which means that they can be faster by reusing information from a previous query [5.16].

5.2.1 Multi-Query Planners: Mapping the Connectivity of $\mathcal{C}_{\text{free}}$

Planners that aim to answer multiple queries for a certain static environment use a preprocessing phase during which they attempt to map the connectivity properties of $\mathcal{C}_{\text{free}}$ onto a roadmap. This roadmap has the form of a graph G , with vertices as configurations and edges as paths. A union of 1-D curves is a roadmap G if it satisfies the following properties:

1. *Accessibility*: From any $q \in \mathcal{C}_{\text{free}}$, it is simple and efficient to compute a path $\tau : [0, 1] \rightarrow \mathcal{C}_{\text{free}}$ such that $\tau(0) = q$ and $\tau(1) = s$, in which s may be any point in $S(G)$. $S(G)$ is the *swath* of G , the union of all configurations reached by all edges and vertices. This means that it is always possible to connect a planning query pair q_1 and q_G to some s_1 and s_G , respectively, in $S(G)$.
2. *Connectivity preserving*: The second condition requires that, if there exists a path $\tau : [0, 1] \rightarrow \mathcal{C}_{\text{free}}$ such that $\tau(0) = q_G$ and $\tau(1) = q_G$, then there also exists a path $\tau' : [0, 1] \rightarrow S(G)$, such that $\tau'(0) = s_1$ and $\tau'(1) = s_G$. Thus, solutions are not missed because G fails to capture the connectivity of $\mathcal{C}_{\text{free}}$.

The probabilistic roadmap method (**PRM**) approach [5.19] attempts to approximate such a roadmap G in a computationally efficient way. The preprocessing phase of **PRM**, which can be extended to sampling-based roadmaps in general, follows these steps:

1. *Initialization*: Let $G(V, E)$ represent an undirected graph, which is initially empty. Vertices of G will correspond to collision-free configurations, and edges to collision-free paths that connect vertices.
2. *Configuration sampling*: A configuration $\alpha(i)$ is sampled from $\mathcal{C}_{\text{free}}$ and added to the vertex set V . $\alpha(\cdot)$ is an infinite, dense sample sequence and $\alpha(i)$ is the i -th point in that sequence.

3. *Neighborhood computation*: Usually, a metric is defined in the C-space, $\rho : \mathcal{C} \times \mathcal{C} \rightarrow \mathbb{R}$. Vertices q already in V are then selected as part of $\alpha(i)$'s neighborhood if they have small distance according to ρ .
4. *Edge consideration*: For those vertices q that do not belong in the same connected component of G with $\alpha(i)$ the algorithm attempts to connect them with an edge.
5. *Local planning method*: Given $\alpha(i)$ and $q \in \mathcal{C}_{\text{free}}$ a module is used that attempts to construct a path $\tau_s : [0, 1] \rightarrow \mathcal{C}_{\text{free}}$ such that $\tau(0) = \alpha(i)$ and $\tau(1) = q$. Using collision detection, τ_s must be checked to ensure that it does not cause a collision.
6. *Edge insertion*: Insert τ_s into E , as an edge from $\alpha(i)$ to q .
7. *Termination*: The algorithm is typically terminated when a predefined number of collision-free vertices N has been added in the roadmap.

The algorithm is incremental in nature. Computation can be repeated by starting from an already existing graph. A general sampling-based roadmap is summarized in Algorithm 1.

Algorithm 5.1

SAMPLING-BASED ROADMAP

N : number of nodes to include in the roadmap

```

G.init(); i ← 0;
while i < N do
  if  $\alpha(i) \in \mathcal{C}_{\text{free}}$  then
    G.add_vertex( $\alpha(i)$ ); i ← i + 1;
    for  $q \in \text{NEIGHBORHOOD}(\alpha(i), G)$  do
      if CONNECT ( $\alpha(i)$ ,  $q$ ) then
        G.add_edge ( $\alpha(i)$ ,  $q$ );
    endif
  end for
endif
end while

```

An illustration of the algorithm's behavior is depicted in Fig. 5.3. To solve a query, q_1 and q_G are connected to the roadmap, and graph search is performed.

For the original PRM [5.19], the configuration $\alpha(i)$ was produced using random sampling. For the connection step between q and $\alpha(i)$, the algorithm used straight line paths in the C-space. In some cases a connection was not attempted if q and $\alpha(i)$ were in the same connected component. There have been many subsequent works that try to improve the roadmap

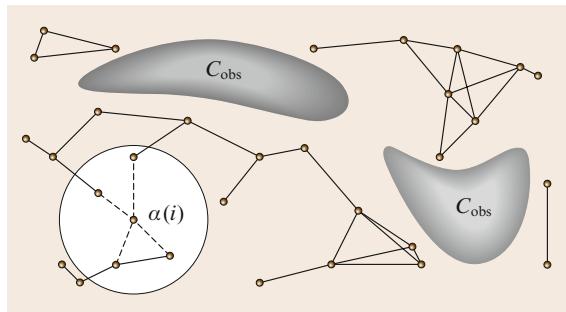

Fig. 5.3 The sampling-based roadmap is constructed incrementally by attempting to connect each new sample, $\alpha(i)$, to nearby vertices in the roadmap

quality while using fewer samples. Methods for concentrating samples at or near the boundary of $\mathcal{C}_{\text{free}}$ are presented in [5.20, 21]. Methods that move samples as far from the boundary as possible appear in [5.22, 23]. Deterministic sampling techniques, including grids, appear in [5.24]. A method of pruning vertices based on mutual visibility that leads to a dramatic reduction in the number of roadmap vertices appears in [5.25]. Theoretical analysis of sampling-based roadmaps appears in [5.24, 26, 27] and is briefly discussed in Sect. 5.6.2. An experimental comparison of sampling-based roadmap variants appears in [5.28]. One difficulty in these roadmap approaches is identifying narrow passages. One proposal is to use the *bridge test* for identifying these [5.29]. For other PRM-based works, see [5.30–34]. Extended discussion of the topic can be found in [5.5, 7].

5.2.2 Single-Query Planners: Incremental Search

Single-query planning methods focus on a single initial–goal configuration pair. They probe and search the continuous C-space by extending tree data structures initialized at these known configurations and eventually connecting them. Most single-query methods conform to the following template:

1. *Initialization*: Let $G(V, E)$ represent an undirected *search graph*, for which the vertex set V contains a vertex for one (usually q_1) or more configurations in $\mathcal{C}_{\text{free}}$, and the edge set E is empty. Vertices of G are collision-free configurations, and edges are collision-free paths that connect vertices.
2. *Vertex selection method*: Choose a vertex $q_{\text{cur}} \in V$ for expansion.

3. *Local planning method:* For some $\mathbf{q}_{\text{new}} \in \mathcal{C}_{\text{free}}$, which may correspond to an existing vertex in V but on a different tree or a sampled configuration, attempt to construct a path $\tau_s : [0, 1] \rightarrow \mathcal{C}_{\text{free}}$ such that $\tau(0) = \mathbf{q}_{\text{cur}}$ and $\tau(1) = \mathbf{q}_{\text{new}}$. Using collision detection, τ_s must be checked to ensure that it does not cause a collision. If this step fails to produce a collision-free path segment, then go to Step 2.
4. *Insert an edge in the graph:* Insert τ_s into E , as an edge from \mathbf{q}_{cur} to \mathbf{q}_{new} . If \mathbf{q}_{new} is not already in V , then it is inserted.
5. *Check for a solution:* Determine whether G encodes a solution path.
6. *Return to Step 2:* Iterate unless a solution has been found or some termination condition is satisfied, in which case the algorithm reports failure.

During execution, G may be organized into one or more trees. This leads to: (1) *unidirectional* methods, which involve a single tree, usually rooted at \mathbf{q}_I [5.35], (2) *bidirectional* methods, which involve two trees, typically rooted at \mathbf{q}_I and \mathbf{q}_G [5.35], and (3) *multidirectional* methods, which may have more than two trees [5.36, 37]. The motivation for using more than one tree is that a single tree may become trapped trying to find an exit through a narrow opening. Traveling in the opposite direction, however, may be easier. As more trees are considered it becomes more complicated to determine which connections should be made between trees.

Rapidly Exploring Dense Trees

The important idea with this family of techniques is that the algorithm must incrementally explore the properties of the C-space. An algorithm that achieves this objective is the rapidly exploring random tree (RRT) [5.35], which can be generalized to the rapidly exploring dense tree (RDT) for any dense sampling, deterministic or random [5.7]. The basic idea is to induce a *Voronoi bias* in the exploration process by selecting for expansion the point in the tree that is closest to $\alpha(i)$ in each iteration. Using random samples, the probability that a vertex is chosen is proportional to the volume of its Voronoi region. The tree construction is outlined as:

Algorithm 5.2

RAPIDLY EXPLORING DENSE TREES
 k : the exploration steps of the algorithm

```

 $G.\text{init}(\mathbf{q}_I);$ 
for  $i = 1$  to  $k$  do
     $G.\text{add\_vertex}(\alpha(i));$ 
     $\mathbf{q}_n \leftarrow \text{NEAREST}(S(G), \alpha(i));$ 
     $G.\text{add\_edge}(\mathbf{q}_n, \alpha(i));$ 
end for

```

The tree starts at \mathbf{q}_I , and in each iteration, an edge and vertex are added.

So far, the problem of reaching \mathbf{q}_G has not been explained. There are several ways to use RDTs in a planning algorithm. One approach is to bias $\alpha(i)$ so that \mathbf{q}_G is frequently chosen (perhaps once every 50 iterations). A more efficient approach is to develop a bidirectional search by growing two trees, one from each of \mathbf{q}_I and \mathbf{q}_G . Roughly half of the time is spent expanding each tree in the usual way, while the other half is spent attempting to connect the trees. The simplest way to connect trees is to let the newest vertex of one tree be a substitute for $\alpha(i)$ in extending the other. This tricks one RDT into attempting to connect to the other while using the basic expansion algorithm [5.38]. Several works have extended, adapted, or applied RDTs in various applications [5.37, 39–42]. Detailed descriptions can be found in [5.5, 7].

Other Tree Algorithms

Planners based on the idea of expansive spaces are presented in [5.43–45]. In this case, the algorithm forces exploration by choosing vertices for expansion that have fewer points in a neighborhood around them. In [5.46], additional performance is obtained by self-tuning random walks, which focus virtually all of their effort on exploration. Other successful tree-based algorithms include the path-directed subdivision tree algorithm [5.47] and some of its variants [5.48]. In the literature, it is sometimes hard to locate tree-based planners for ordinary path planning problems as many of them (including RRT) were designed and/or applied to more complex problems (see Sect. 5.4.4). Their performance is nevertheless excellent for a variety of path planning problems.

5.3 Alternative Approaches

Alternative approaches to the sampling-based paradigm include potential-field-based techniques and combinatorial methods that also produce roadmaps, such as cell decompositions. These algorithms are able to elegantly and efficiently solve a narrow class of problems, and are much preferred over the algorithms of Sect. 5.2 in these cases. Most of the combinatorial algorithms are of theoretical interest, whereas sampling-based algorithms are motivated primarily by performance issues in challenging applications. Nevertheless, given some abstractions, the combinatorial algorithms can be used to solve practical problems such as autonomous navigation of mobile planar robots.

5.3.1 Combinatorial Roadmaps

Several algorithms exist for the case in which $\mathcal{C} = \mathbb{R}^2$ and \mathcal{C}_{obs} is polygonal. Most of these cannot be directly extended to higher dimensions; however, some of the general principles remain the same. The *maximum clearance roadmap* (or *retraction method* [5.49]) constructs a roadmap that keeps paths as far from the obstacles as possible. Paths are contributed to the roadmap from the three cases shown in Fig. 5.5, which correspond to all ways to pair together polygon features. The roadmap can be made naively in time $O(n^4)$ by generating all curves

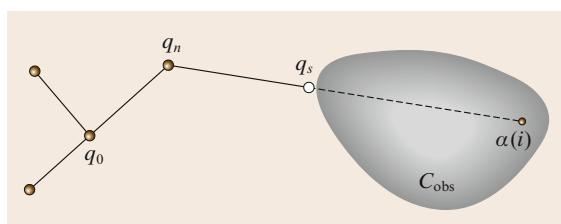

Fig. 5.4 If there is an obstacle, the edge travels up to the obstacle boundary, as far as allowed by the collision detection algorithm

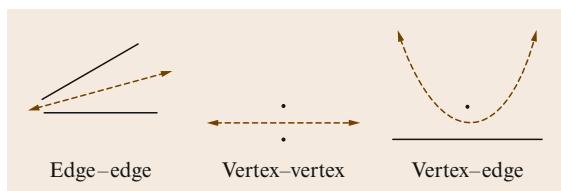

Fig. 5.5 Voronoi roadmap pieces are generated in one of three possible cases. The third case leads to a quadratic curve

shown in Fig. 5.5 for all possible pairs, computing their intersections, and tracing out the roadmap. Several algorithms exist that provide better asymptotic running time [5.50], but they are considerably more difficult to implement. The best-known algorithm runs in $O(n \lg n)$ time in which n is the number of roadmap curves [5.51].

An alternative is to compute a *shortest-path roadmap* [5.52], as shown in Fig. 5.6. This is different than the roadmap presented in the previous section because paths may actually touch the obstacles, which must be allowed for paths to be optimal. The roadmap vertices are the reflex vertices of \mathcal{C}_{obs} , which are vertices for which the interior angle is greater than π . An edge exists in the roadmap if and only if a pair of vertices is mutually visible and the line through them pokes into $\mathcal{C}_{\text{free}}$ when extended outward from each vertex (such lines are called *bitangents*). An $O(n^2 \lg n)$ -time construction algorithm can be formed by using a radial sweep algorithm from each reflex vertex. It can theoretically be computed in time $O(n^2 + m)$, in which m is the total number of edges in the roadmap [5.53].

Figure 5.7 illustrates the *vertical cell decomposition* approach. The idea is to decompose $\mathcal{C}_{\text{free}}$ into cells that are trapezoids or triangles. Planning in each cell is trivial because it is convex. A roadmap is made by placing a point in the center of each cell and each boundary between cells. Any graph search algorithm can be used to find a collision-free path quickly. The cell decomposition can be constructed in $O(n \lg n)$ time using the *plane-sweep principle* [5.54, 55]. Imagine that a vertical line sweeps from $x = -\infty$ to $x = \infty$, stopping at places where a polygon vertex is encountered. In these cases,

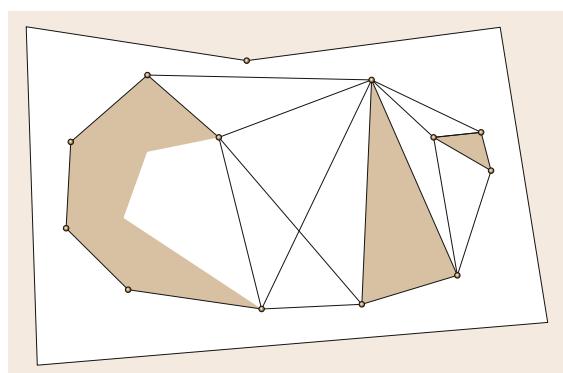

Fig. 5.6 The shortest-path roadmap includes edges between consecutive reflex vertices on \mathcal{C}_{obs} and also bitangent edges

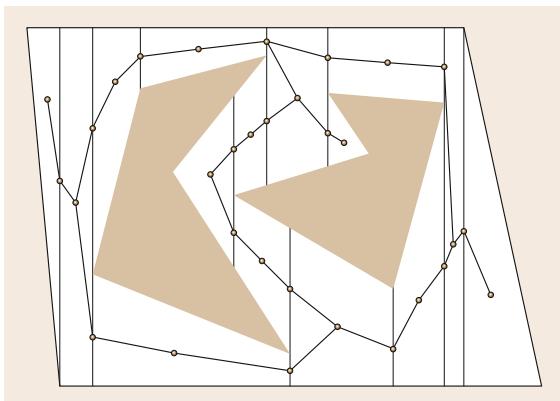

Fig. 5.7 The roadmap derived from the vertical cell decomposition

a cell boundary may be necessary above and/or below the vertex. The order in which segments stab the vertical line is maintained in a balanced search tree. This enables the determination of the vertical cell boundary limits in time $O(\lg n)$. The whole algorithm runs in time $O(n \lg n)$ because there are $O(n)$ vertices at which the sweep line can stop (also, the vertices need to be sorted at the outset, which requires time $O(n \lg n)$).

5.3.2 Roadmaps in Higher Dimensions

It would be convenient if the methods of Sect. 5.3.1 directly extend into higher dimensions. Although this unfortunately does not occur, some of the general ideas extend. To consider a cell decomposition in higher dimensions, there are two main requirements: (1) each cell should be simple enough that motion planning within a cell is trivial; (2) the cells should fit together nicely. A sufficient condition for the first requirement is that cells are convex; more general shapes may be allowed; however, the cells should not contain holes under any circumstances. For the second requirement, a sufficient condition is that the cells can be organized into a *singular complex*. This means that for any two d -dimensional cells for $d \leq n$, if the boundaries of the cells intersect, then the common boundary must itself be a complete cell (of lower dimension).

In two-dimensional polygonal C-spaces, triangulation methods define nice cell decompositions that are appropriate for motion planning. Finding good triangulations, which for example means trying to avoid thin triangles, is given considerable attention in computational geometry [5.55]. Determining the decomposition of a polygonal obstacle region with

holes that uses the smallest number of convex cells is NP -hard [5.56]. Therefore, we are willing to tolerate nonoptimal decompositions.

In three-dimensional C-spaces, if \mathcal{C}_{obs} is polyhedral, then the vertical decomposition method directly extends

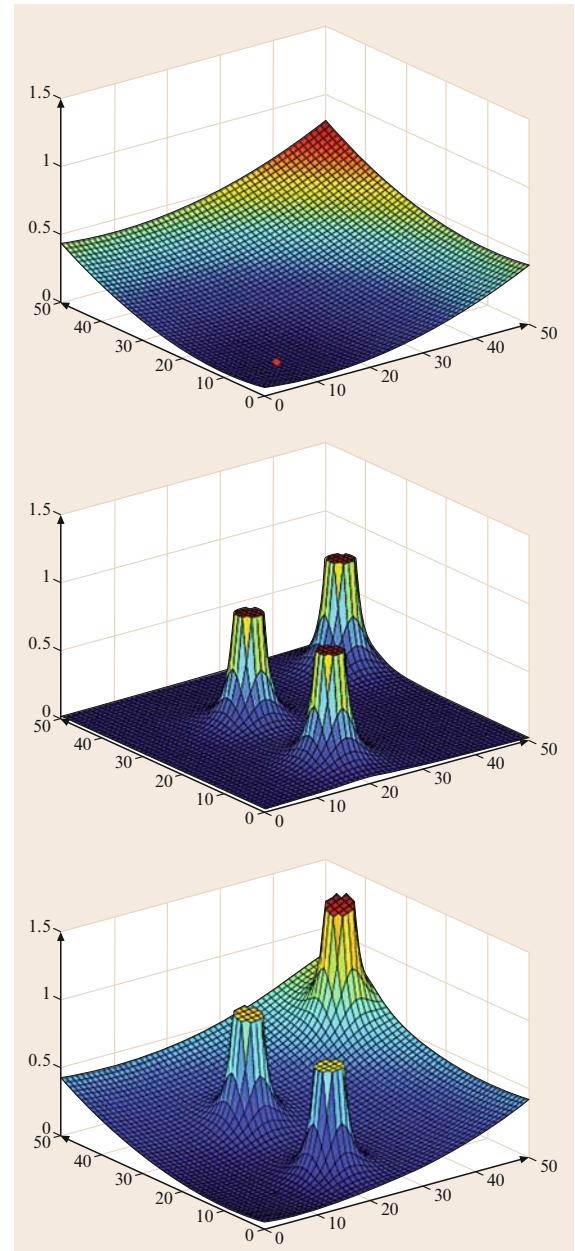

Fig. 5.8 An attractive and a repulsive component define a potential function

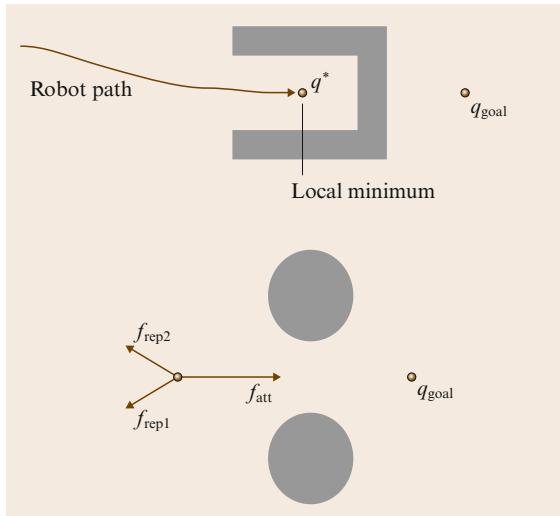

Fig. 5.9 Two examples of the local minimum problem with potential functions

by applying the plane sweep recursively, for example, the critical events may occur at each z coordinate, at which point changes a 2-D vertical decomposition over the x and y coordinates are maintained. The polyhedral case is obtained for a translating polyhedral robot among polyhedral obstacles in \mathbb{R}^3 ; however, for most interesting problems, \mathcal{C}_{obs} becomes nonlinear. Suppose $\mathcal{C} = \mathbb{R}^2 \times \mathbb{S}^1$, which corresponds to a robot that can translate and rotate in the plane. Suppose the robot and obstacles are polygonal. For the case of a line-segment robot, an $O(n^5)$ algorithm that is not too difficult to implement is given in [5.57]. The approaches for more general models and C-spaces are extremely difficult to use in practice; they are mainly of theoretical interest and are summarized in Sect. 5.6.3.

5.3.3 Potential Fields

A different approach for motion planning is inspired from obstacle avoidance techniques [5.58]. It does not explicitly construct a roadmap, but instead constructs a differentiable real-valued function $U : \mathbb{R}^m \rightarrow \mathbb{R}$, called a potential function, that guides the motion of the moving object. The potential is typically constructed so that it consists of an attractive component $U_a(\mathbf{q})$, which pulls the robot towards the goal, and a repulsive component $U_r(\mathbf{q})$, which pushes the robot away from the obstacles, as shown in Fig. 5.8. The gradient of the potential function is the vector $\nabla U(\mathbf{q}) = DU(\mathbf{q})^\top = \left[\frac{\partial U}{\partial q_1}(\mathbf{q}), \dots, \frac{\partial U}{\partial q_m}(\mathbf{q}) \right]^\top$, which

points in the direction that locally maximally increases U . After the definition of U , a path can be computed by starting from q_1 and applying *gradient descent*:

1. $\mathbf{q}(0) = q_1; i = 0;$
2. **while** $\nabla U(\mathbf{q}(i)) \neq 0$ **do**
3. $\mathbf{q}(i + 1) = \mathbf{q}(i) + \nabla U(\mathbf{q}(i))$
4. $i = i + 1$

However, this gradient-descent approach does not guarantee a solution to the problem. Gradient descent can only reach a local minimum of $U(\mathbf{q})$, which may not correspond to the goal state q_G , as shown in Fig. 5.9.

A planner that makes uses of potential functions and attempts to avoid the issue of local minima is the *randomized potential planner* [5.59]. The idea is to combine potential functions with random walks by employing multiple planning modes. In one mode, gradient descent is applied until a local minimum is reached. Another mode uses random walks to try to escape local minima. A third mode performs backtracking whenever several attempts to escape a local minimum have failed. In many ways, this approach can be considered as a sampling-based planner. It also provides the weaker

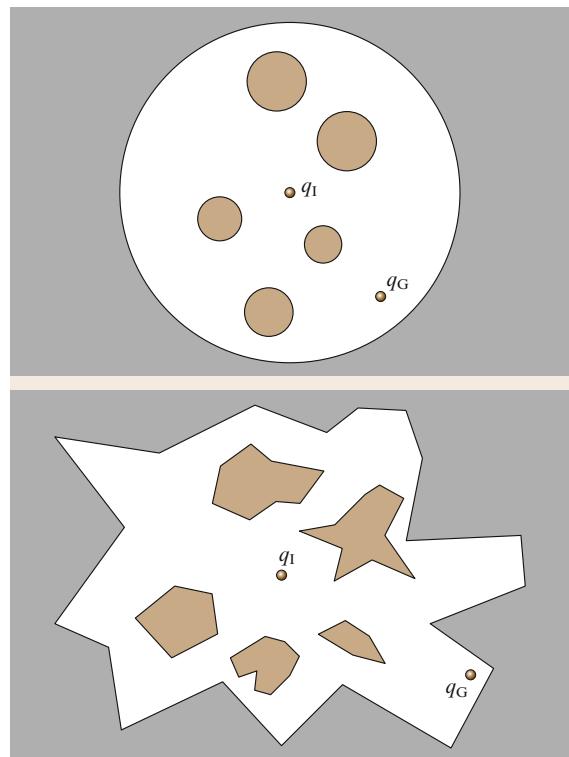

Fig. 5.10 Examples of sphere and star spaces

completeness guarantee but it requires parameter tuning. Recent sampling-based methods achieve better performance by spending more time exploring the space, rather than focusing heavily on a potential function.

The gradient of the potential function can be also used to define a *vector field*, which assigns a motion for the robot at any arbitrary configuration $\mathbf{q} \in \mathcal{C}$. This is an important advantage of the approach, beyond its computational efficiency, since it does not only compute a single path, but also a *feedback control* strategy. This makes the approach more robust against control and sensing errors. Most of the techniques in feedback motion planning are based on the idea of *navigation functions* [5.60], which are potential functions properly constructed so as to have a single minimum. A function $\phi : \mathcal{C}_{\text{free}} \rightarrow [0, 1]$ is called a navigation function if it:

- is smooth (or at least C^k for $k \geq 2$),
- has a unique minimum at \mathbf{q}_G in the connected component of the free space that contains \mathbf{q}_G ,

- is uniformly maximal on the free-space boundaries,
- and is Morse, which means that all its critical points, such as saddle points, are isolated and can be avoided with small random perturbations.

Navigation functions can be constructed for sphere boundary spaces centered at \mathbf{q}_I that contain only spherical obstacles, as illustrated in Fig. 5.10. Then they can be extended to a large family of C-spaces that are diffeomorphic to sphere spaces, such as star-shaped spaces, as shown in Fig. 5.10. A more elaborate description of strategies for feedback motion planning will be presented in Chaps. 35, 36, and 37.

Putting the issue of local minima aside, another major challenge for such potential function based approaches is constructing and representing the C-space in the first place. This issue makes the applications of these techniques too complicated for high-dimensional problems.

5.4 Differential Constraints

Robot motions must usually conform to both global and local constraints. Global constraints on \mathcal{C} have been considered in the form of obstacles and possibly joint limits. Local constraints are modeled with differential equations, and are therefore called *differential constraints*. These limit the velocities, and possibly accelerations, at every point due to kinematic considerations, such as wheels in contact, and dynamical considerations, such as the conservation of angular momentum.

5.4.1 Concepts and Terminology

Let $\dot{\mathbf{q}}$ denote a velocity vector. Differential constraints on \mathcal{C} can be expressed either *implicitly* in the form $g_i(\mathbf{q}, \dot{\mathbf{q}}) = 0$ or *parametrically* in the form $\dot{\mathbf{x}} = f(\mathbf{q}, \mathbf{u})$. The implicit form is more general but often more difficult to understand and utilize. In the parametric form, a vector-valued equation indicates the velocity that is obtained for a given \mathbf{q} and \mathbf{u} , in which \mathbf{u} is an *input*, chosen from some *input space*, U . Let T denote an interval of time, starting at $t = 0$.

To model dynamics, the concepts are extended into a *phase space* X of the C-space. Usually each point $\mathbf{x} \in X$ represents both a configuration and velocity, $\mathbf{x} = (\mathbf{q}, \dot{\mathbf{q}})$. Both implicit and parametric representations are possible, yielding $g_i(\mathbf{x}, \dot{\mathbf{x}}) = 0$ and $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$,

respectively. The latter is a common *control system* definition. Note that $\dot{\mathbf{x}} = (\dot{\mathbf{q}}, \ddot{\mathbf{q}})$, which implies that acceleration constraints and full system dynamics can be expressed.

Planning in the state space X could lead to a straightforward definition of X_{obs} by declaring $\mathbf{x} \in X_{\text{obs}}$ if and only if $\mathbf{q} \in \mathcal{C}_{\text{obs}}$ for $\mathbf{x} = (\mathbf{q}, \dot{\mathbf{q}})$. However, another interesting possibility exists which provides some intuition about the difficulty of planning with dynamics. This possibility is based on the notion of a *region of inevitable collision*, which is defined as:

$$X_{\text{ric}} = \left\{ \mathbf{x}(0) \in X \mid \text{for any } \tilde{u} \in \mathcal{U}_{\infty}, \exists t > 0 \text{ such that } \mathbf{x}(t) \in X_{\text{obs}} \right\}, \quad (5.4)$$

in which $\mathbf{x}(t)$ is the state at time t obtained by integrating the control function $\tilde{u} : T \rightarrow U$ from $\mathbf{x}(0)$. The set \mathcal{U}_{∞} is a predefined set of all possible control functions. X_{ric} denotes the set of states in which the robot is either in collision or, because of momentum, it cannot do anything to avoid collision. It can be considered as an invisible obstacle region that grows with speed.

Under the general heading of *planning under differential constraints*, there are many important categories of problems that have received considerable attention in research literature. The term *nonholonomic planning*

was introduced for wheeled mobile robots [5.61]. A simple example is that a car cannot move sideways, thereby making parallel parking more difficult. In general, a *nonholonomic constraint* is a differential equality constraint that cannot be integrated into a constraint that involves no derivatives. Typically, nonholonomic constraints that appear in robotics are *kinematic*, and arise from wheels in contact [5.62]. Nonholonomic constraints may also arise from dynamics.

If a planning problem involves constraints on at least velocity and acceleration, the problem is often referred to as *kinodynamic planning* [5.63]. Usually, the model expresses a *fully actuated system*, which means that it can be expressed as $\ddot{q} = h(q, \dot{q}, u)$, in which U contains an open set that includes the origin of \mathbb{R}^n (here, n is the dimension of both U and \mathcal{C}). It is possible for a problem to be nonholonomic, kinodynamic, both, or neither; however, in recent times, the terms are not used with much precision.

Trajectory planning is another important term, which has referred mainly to the problem of determining both a path and velocity function for a robot arm (e.g., PUMA 560). In the treatment below, all of these will be referred to as *planning under differential constraints*.

5.4.2 Discretization of Constraints

The only known methods for complete and optimal planning under differential constraints in the presence of obstacles are for the double integrator system with $X = \mathbb{R}$ [5.64] and $X = \mathbb{R}^2$ [5.65]. To develop planning algorithms in this context, several discretizations are often needed. For ordinary motion planning, only \mathcal{C} needed to be discretized; with differential constraints, T and possibly also U require discretization, in addition to \mathcal{C} (or X).

Discretization of the differential constraints is one of the most important issues. To solve challenging planning problems efficiently, it is often necessary to define *motion primitives* for the particular dynamical system [5.40, 66, 67]. One of the simplest ways to discretize the differential constraints is to construct a *discrete-time model*, which is characterized by three aspects:

1. The time interval T is partitioned into intervals of length Δt . This enables stages to be assigned, in which stage k indicates that $(k - 1)\Delta t$ time has elapsed.
2. A finite subset U_d of the action space U is chosen. If U is already finite, then this selection may be $U_d = U$.

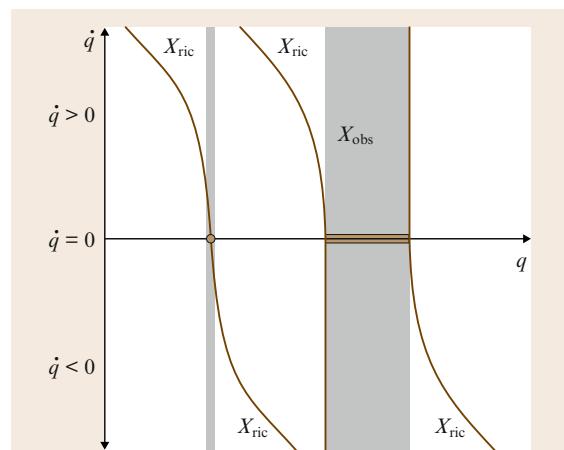

Fig. 5.11 The region of inevitable collision grows quadratically with the speed

3. The action $u(t)$ must remain constant over each time interval.

From an initial state, x , a *reachability tree* can be formed by applying all sequences of discretized actions. Figure 5.12 shows the path of this tree for the *Dubins car*, which is a kinematic model of a car that drives in the plane at unit speed and cannot move in reverse. The edges of the tree are circular arcs and line segments. For general systems, each trajectory segment in the tree is determined by numerical integration of $\dot{x} = f(x, u)$ for a given u . In general, this can be viewed as an *in-*

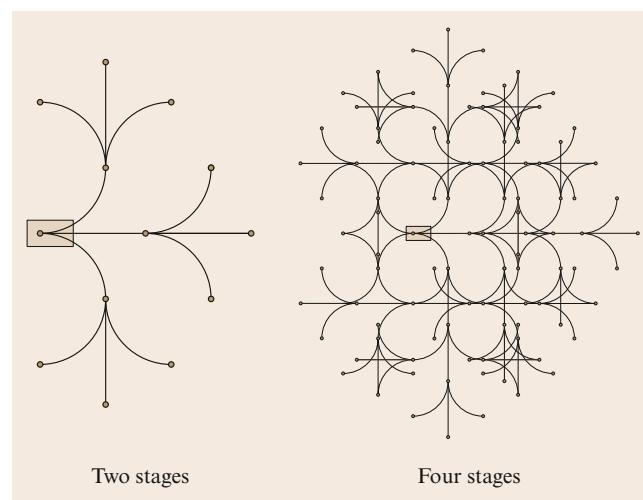

Fig. 5.12 A reachability tree for the Dubins car with three actions. The k -th stage produces 3^k new vertices

incremental simulator that takes an input and produces a trajectory segment according to $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$.

5.4.3 Decoupled Approach

A popular paradigm for trajectory planning and other problems that involve dynamics is to decouple the problem into first planning a path and then computing a timing function along the path by performing a search in the space spanned by (s, \dot{s}) , in which s is the path parameter and \dot{s} is its first derivative. This leads to a diagram such as the one shown in Fig. 5.13, in which the upper region S_{obs} must be avoided because the corresponding motion of the mechanical system violates the differential constraints. Most methods are based on early work in [5.68, 69], and determine a *bang-bang*-control, which means that they switch between accelerating and decelerating at full speed. This applies to determining

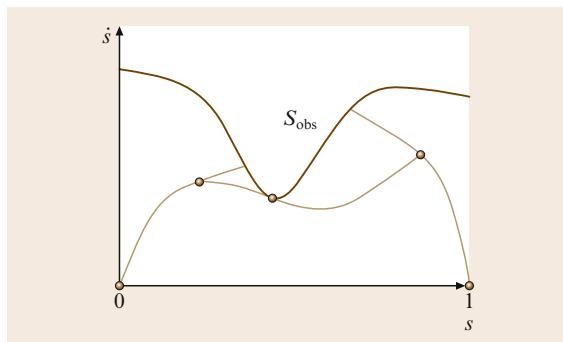

Fig. 5.13 An illustration of the bang–bang approach to computing a time-optimal trajectory. The solution trajectory is obtained by connecting the dots

time-optimal trajectories (optimal once constrained to the path). Dynamic programming can be used for more general problems [5.70].

For some problems and nonholonomic systems, *steering methods* have been developed to solve the two-point boundary value problem efficiently [5.62, 71]. This means that, for any pair of states, a trajectory that ignores obstacles but satisfies the differential constraints can be obtained. Moreover, for some systems, the complete set of optimal trajectories has been characterized [5.72, 73]. These control-based approaches enable straightforward adaptation of the sampling-based roadmap approach [5.74, 75]. One decoupled approach is to first plan a path that ignores differential constraints, and then incrementally transform it into one that obeys the constraints [5.62, 76].

5.4.4 Kinodynamic Planning

Due to the great difficulty of planning under differential constraints, many successful planning algorithms that address kinodynamic problems directly in the phase space X are sampling based.

Sampling-based planning algorithms proceed by exploring one or more reachability trees. Many parallels can be drawn with searching on a grid; however, reachability trees are more complicated because they do not necessarily involve a regular lattice structure. The vertex set of reachability trees is dense in most cases. It is therefore not clear how to search a bounded region exhaustively at a fixed resolution. It is also difficult to design approaches that behave like a multiresolution grid, in which refinements can be made arbitrarily to ensure resolution completeness.

Many algorithms attempt to convert the reachability tree into a lattice. This is the basis of the original kinodynamic planning work [5.63], in which the discrete-time approximation to the double integrator, $\ddot{\mathbf{q}} = \mathbf{u}$, is forced onto a lattice as shown in Fig. 5.14. This enables an approximation algorithm to be developed that solves the kinodynamic planning problem in time polynomial in the approximation quality $1/\epsilon$ and the number of primitives that define the obstacles. Generalizations of the methods to fully actuated systems are described in [5.7]. Surprisingly, it is even possible to obtain a lattice for some underactuated, nonholonomic systems [5.77].

If the reachability tree does not form a lattice, then one approach is to force it to behave as a lattice by imposing a regular cell decomposition over X (or \mathcal{C}), and allowing no more than one vertex per cell to be expanded in the reachability graph; see Fig. 5.15. This idea was

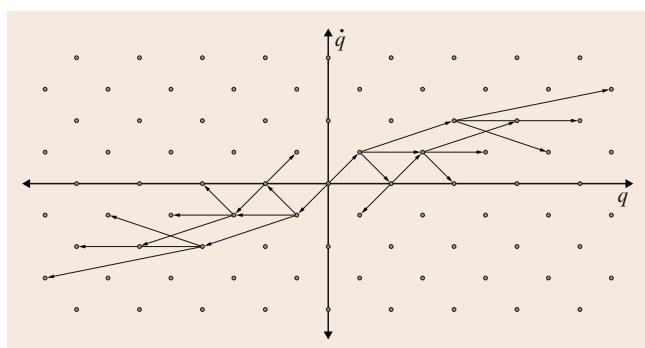

Fig. 5.14 Reachability graph from the origin, shown after three stages (the true edges are actually parabolic arcs when acceleration or deceleration occurs). Note that a lattice is obtained, but the distance traveled in one stage increases as $|\dot{\mathbf{q}}|$ increases

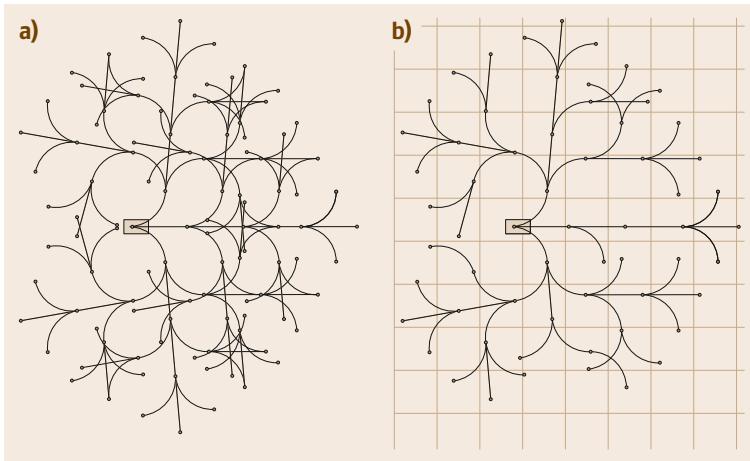

Fig. 5.15 (a) The first four stages of a dense reachability graph for the Dubins car; (b) one possible search graph, obtained by allowing at most one vertex per cell. Many branches are pruned away. In this simple example there are no cell divisions along the θ axis

introduced in [5.78]. In their version of this approach, the reachability graph is expanded by dynamic programming. Each cell is initially marked as being in collision or being collision free, but not yet visited. As cells are visited during the search, they become marked as such. If a potential new vertex lands in a visited cell, it is not saved. This has the effect of pruning the reachability tree.

Other related approaches do not try to force the reachability tree onto a lattice. RRTs were designed to expand the tree in a way that is biased toward

covering as much new territory as possible in each iteration [5.79]. Planners that are based on the concept of expansive trees attempt to control the density of vertices in the tree by analyzing neighborhoods [5.44]. The path-directed subdivision tree planner expands a tree, while building an adaptive subdivision of the state space, so as to avoid resampling the same regions of the space [5.47, 80]. Such approaches can be biased to accelerate the expansion of the tree towards a goal, while still providing the weaker probabilistic completeness guarantee [5.48].

5.5 Extensions and Variations

A brief overview of other important extensions to the basic motion planning problem are presented in this section.

5.5.1 Closed Kinematic Chains

In many cases, the robot may consist of links that form closed loops. This arises in many important applications, for example, if two arms grasp an object then a loop is formed and a humanoid robot forms a loop if both legs touch the ground. For *parallel robots*, loops are intentionally designed into the robot [5.81]; a classic example is the Stewart–Gough platform. To model closed-chain problems, the loops are broken so that a kinematic tree of links is obtained. The main complication is that constraints on \mathcal{C} of the form $h(\mathbf{q}) = 0$ are introduced, which require that the loops are maintained. This causes great trouble for most planning algorithms

because without loops a parameterization of \mathcal{C} was available. The closure constraints restrict the planning to a lower-dimensional subset of \mathcal{C} for which no parameterization is given. Computing a parameterization is generally difficult or impossible [5.82], although there has been recent progress for some special cases [5.83].

Sampling-based approaches can generally be adapted to handle closed chains. The main difficulty is that the samples $\alpha(i)$ over \mathcal{C} are unlikely to be configurations that satisfy closure. In [5.84], both RRTs and PRMs were adapted to closed chains. RRTs performed much better because a costly optimization was required in the PRM to move samples onto the closure subspace; RRTs on the other hand do not require samples to lie in this subspace. By decomposing chains into active and passive links, followed by inverse kinematics computations, performance was dramatically improved for PRMs in [5.85]. This idea was further improved by the introduction of

the *random loop generator (RLG)*. Based on this, some of the most challenging closed-chain planning problems ever solved appear in [5.86].

5.5.2 Manipulation Planning

In most forms of motion planning, the robot is not allowed to touch obstacles. Suppose instead that it is expected to interact with its environment by manipulating objects. The goal may be to bring an object from one place to another, or to rearrange a collection of objects. This leads to a kind of hybrid motion planning problem, which mixes discrete and continuous spaces. There are discrete modes that correspond to whether the robot is carrying a part [5.87]. In the *transit mode*, the robot moves toward a part. In the *transfer mode*, it carries the part. Transitions between modes require meeting specific grasping and stability requirement. One important variant of manipulation planning is *assembly planning*, in which the goal is to fit a collection of pieces together to make an assembled product [5.88]. Most motion planning work makes limiting assumptions on the kinds of interaction that can occur between the robot and the objects. For richer models of manipulation, see [5.89].

5.5.3 Time-Varying Problems

Suppose that the workspace contains moving obstacles whose trajectories are specified as a function of time. Let $T \subset \mathbb{R}$ denote the *time interval*, which may be *bounded*

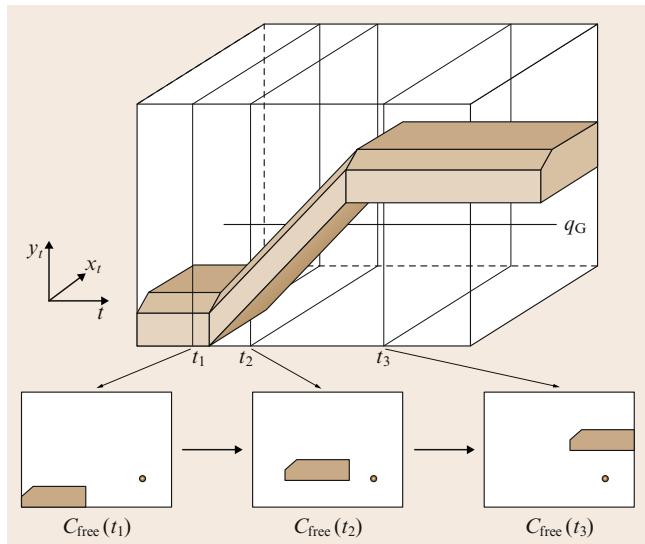

Fig. 5.16 A time-varying example with linear obstacle motion.

or *unbounded*. A state X is defined as $X = \mathcal{C} \times T$, in which \mathcal{C} is the usual C-space of the robot. The obstacle region in X is characterized as

$$X_{\text{obs}} = \{(\mathbf{q}, t) \in X \mid \mathcal{A}(\mathbf{q}) \cap \mathcal{O}(t) \neq \emptyset\}, \quad (5.5)$$

in which $\mathcal{O}(t)$ is a time-varying obstacle. Many planning algorithms can be adapted to X , which has only one more dimension than \mathcal{C} . The main complication is that time must always increase along a path through X .

For the easiest version of the problem, there is no bound on the robot speed. In this case, virtually any sampling-based algorithm can be adapted. Incremental searching and sampling methods apply with little modification, except that paths are directed so that forward time progress is made. Using bidirectional approaches is more difficult for time-varying problems because the goal is usually not a single point due to the time dependency. Sampling-based roadmaps can be adapted; however, a *directed roadmap* is needed, in which every edge must be directed to yield a time-monotonic path.

If the motion model is *algebraic* (i.e., expressed with polynomials) then X_{obs} is semi-algebraic. This enables cylindrical algebraic decomposition to apply. If X_{obs} is polyhedral, as depicted in Fig. 5.16, then vertical decomposition can be used. It is best to first sweep the plane along the T -axis, stopping at the critical times when the linear motion changes.

There has been no consideration so far of the speed at which the robot must move to avoid obstacles. It is obviously impractical in many applications if the solution requires the robot to move arbitrarily fast. One step towards making a realistic model is to enforce a bound on the speed of the robot. Unfortunately, the problem is considerably more difficult. Even for piecewise-linear motions of obstacles in the plane, the problem has been established to be PSPACE-hard [5.90]. A complete algorithm based on the shortest-path roadmap is presented in [5.91].

An alternative to defining the problem in $\mathcal{C} \times T$ is to decouple it into a *path planning* part and a *motion timing* part. A collision-free path in the absence of obstacles is first computed. A search in a two-dimensional space is then performed to determine the *timing function* (or *time scaling*) for the path.

5.5.4 Multiple Robots

A simple extension to the basic motion planning problem can be made to handle multibody robots by including robot self-intersections; however, it is important to specify the pairs of bodies for which collision is unac-

ceptable, for example, consecutive links in a robot arm are allowed to touch.

Substantial attention has been devoted to the problem of planning for multiple robots. Suppose there are m robots. A state space is defined that considers the configurations of all robots simultaneously,

$$X = \mathcal{C}^1 \times \mathcal{C}^2 \times \cdots \times \mathcal{C}^m. \quad (5.6)$$

A state $\mathbf{x} \in X$ specifies all robot configurations, and may be expressed as $\mathbf{x} = (\mathbf{q}^1, \mathbf{q}^2, \dots, \mathbf{q}^m)$. The dimension of X is N , which is $N = \sum_{i=1}^m \dim(\mathcal{C}^i)$.

There are two sources of obstacle regions in the state space: (1) *robot–obstacle* collisions, and (2) *robot–robot* collisions. For each i such that $1 \leq i \leq m$, the subset of X that corresponds to robot \mathcal{A}^i in collision with the obstacle region \mathcal{O} is

$$X_{\text{obs}}^i = \{\mathbf{x} \in X \mid \mathcal{A}^i(\mathbf{q}^i) \cap \mathcal{O} \neq \emptyset\}. \quad (5.7)$$

This models the robot–obstacle collisions.

For each pair, \mathcal{A}^i and \mathcal{A}^j , of robots, the subset of X that corresponds to \mathcal{A}^i in collision with \mathcal{A}^j is

$$X_{\text{obs}}^{ij} = \{\mathbf{x} \in X \mid \mathcal{A}^i(\mathbf{q}^i) \cap \mathcal{A}^j(\mathbf{q}^j) \neq \emptyset\}. \quad (5.8)$$

Both (5.7) and (5.8) will be combined in (5.9) to yield X_{obs} . The obstacle region in X is

$$X_{\text{obs}} = \left(\bigcup_{i=1}^m X_{\text{obs}}^i \right) \cup \left(\bigcup_{ij, i \neq j} X_{\text{obs}}^{ij} \right). \quad (5.9)$$

Once these definitions have been made, any general-purpose planning algorithm can be applied because X and X_{obs} appear no different from \mathcal{C} and \mathcal{C}_{obs} , except that the dimension N may be very high. Approaches that plan directly in X are called *centralized*. The high dimensionality of X motivates the development of *decoupled* approaches that handle some aspects of the planning independently for each robot. Decoupled approaches are usually more efficient, but this usually comes at the expense of sacrificing completeness. An early decoupled approach is *prioritized planning* [5.92, 93], in which a path and timing function is computed for the i -th robot while treating the first $i - 1$ robots as moving obstacles as they follow their paths. Another decoupled approach is *fixed-path coordination* [5.94], in which the paths are planned independently for each robot, and then their timing functions are determined by computing a collision-free path through an m -dimensional *coordination space*. Each axis in this space corresponds to the domain of the path of one robot. Figure 5.17 shows an example. The idea has been generalized to coordination on roadmaps [5.95, 96].

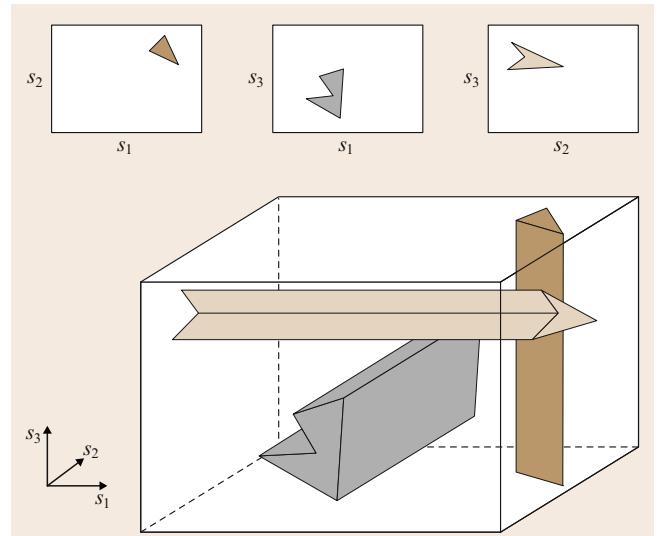

Fig. 5.17 The obstacles that arise from coordinating m robots are always cylindrical. The set of all $\frac{1}{2}m(m-1)$ axis-aligned 2-D projections completely characterizes X_{obs}

5.5.5 Uncertainty in Predictability

If the execution of the plan is not predictable, then feedback is needed. The uncertainty may be modeled either *implicitly*, which means that the plan is able to respond to unexpected future configurations, or *explicitly*, which means that the uncertainty is precisely characterized and analyzed in the development of a plan. Potential-function-based approaches are one way of achieving feedback motion planning.

A plan can be represented as a vector field over $\mathcal{C}_{\text{free}}$, in which each vector indicates the required velocity. The integral curves of the field should flow into the goal without leaving \mathcal{C}_{obs} . If dynamics are a concern, then the vector field can be tracked by an *acceleration-based control model*:

$$\mathbf{u} = K(f(\mathbf{q}) - \dot{\mathbf{q}}) + \nabla_{\dot{\mathbf{q}}} f(\mathbf{q}) \quad (5.10)$$

in which K is a scalar *gain constant*. Alternatively, a vector field may be designed directly on the phase space, X ; however, there are not methods to compute such fields efficiently under general conditions. This can also be considered as a feedback control problem with implicit, nonlinear constraints on X .

If the uncertainty is modeled explicitly, then a *game against nature* is obtained, in which the uncertainty is caused by a special decision maker called *nature*. The decisions of nature can either be modeled *non-*

deterministically, which means that a set of possible actions is specified, or *probabilistically*, which means that a probability distribution or density is specified over the nature actions. Under nondeterministic uncertainty, *worst-case analysis* is usually performed to select a plan; under probabilistic uncertainty, *expected-case analysis* is usually performed. Numerous approaches exist for such problems, including value iteration, Dijkstra-like algorithms, and reinforcement learning algorithms [5.7].

5.5.6 Sensing Uncertainty

Consider solving tasks such as localization, map building, manipulation, target tracking, and pursuit evasion (hide-and-seek) with limited sensing. If the current configuration or state is not known during execution, then the problem is substantially more difficult. Information is obtained from sensors, and the problem naturally

lives in an *information space* or *I-space* (see Chap. 11 of [5.7]). The state may include the configuration, velocities, or even the map of the environment (e.g., obstacles). The most basic I-space is the set of all histories that can be obtained during execution, based on all sensing observations, actions previously applied, and the initial conditions. The goal in developing efficient algorithms in this context is to determine information mappings that reduce the I-space size or complexity so that plans that use *information feedback* can be computed. The traditional way to use the information state is for estimating the state. This is sufficient for solving many tasks, but it is often not necessary. It may be possible to design and execute successful plans without ever knowing the current state. This can lead to more robust robot systems which may also be cheaper to manufacture due to weaker sensing requirements. For more material related to this topic, see any of the chapters in Part C of this book.

5.6 Advanced Issues

We cover here a series of more advanced issues, such as topics from topology and sampling theory, and how they influence the performance of motion planners. The last section is devoted to computational algebraic geometry techniques that achieve completeness in the general case. Rather than being a practical alternative, these techniques serve as an upper bound on the best asymptotic running time that could be obtained.

5.6.1 Topology of Configuration Spaces

Manifolds

One reason that the topology of a C-space is important is because it affects its representation. Another reason is that, if a path-planning algorithm can solve problems in a topological space, then that algorithm may carry over to topologically equivalent spaces.

The following definitions are important in order to describe the topology of C-space. A map $\phi : S \rightarrow T$ is called a *homeomorphism* if ϕ is a bijection and both ϕ and ϕ^{-1} are continuous. When such a map exists, S and T are said to be homeomorphic. A set S is an n -dimensional *manifold* if it is locally homeomorphic to \mathbb{R}^n , meaning that each point in S possesses a neighborhood that is homeomorphic to \mathbb{R}^n . For more details, see [5.97, 98].

In the vast majority of motion planning problems, the configuration space is a manifold. An example of a C-space that is not a manifold is the closed unit square: $[0, 1] \times [0, 1] \subset \mathbb{R}^2$, which is a manifold with boundary obtained by pasting the one-dimensional boundary on the two-dimensional open set $(0, 1) \times (0, 1)$. When a C-space is a manifold, then we can represent it with just n parameters, in which n is the dimension of the configuration space. Although an n -dimensional manifold can be represented using as few as n parameters, due to constraints it might be easier to use a representation that has higher number of parameters, e.g., the unit circle \mathbb{S}^1 can be represented as $\mathbb{S}^1 = \{(x, y) | x^2 + y^2 = 1\}$ by embedding \mathbb{S}^1 in \mathbb{R}^2 . Similarly, the torus T^2 can be embedded in \mathbb{R}^3 .

Representation

Embeddings into higher-dimensional spaces can facilitate many C-space operations. For example, the orientation of a rigid body in space can be represented by a $n \times n$ matrix of real numbers. The n^2 matrix entries must satisfy a number of smooth equality constraints, making the manifold of such matrices a *submanifold* of \mathbb{R}^{n^2} . One advantage is that these matrices can be multiplied to get another matrix in the manifold. For example, the orientation of a rigid-body in n -dimensional space ($n = 2$ or 3) is described by the set $SO(n)$, the set

of all $n \times n$ rotation matrices. The position and orientation of a rigid body is represented by the set $SE(n)$, the set of all $n \times n$ homogeneous transformation matrices. These matrix groups can be used to (1) represent rigid-body configurations, (2) change the reference frame for the representation of a configuration, and (3) displace a configuration.

There are numerous parameterizations of $SO(3)$ [5.99] but unit quaternions correctly preserve the C-space topology as \mathbb{S}^1 represents 2-D rotations. Quaternions were introduced in Chap. 1. There is, however, a two-to-one correspondence between unit quaternions and 3-D rotation matrices. This causes a topological issue that is similar to the equivalence of 0 and 2π for 2-D rotations. One way to account for this is to declare antipodal (opposite) points on \mathbb{S}^3 to be equivalent. In planning, only the upper hemisphere of \mathbb{S}^3 is needed, and paths that cross the equator instantly reappear on the opposite side of \mathbb{S}^3 , heading back into the northern hemisphere. In topology, this is called a real projective space: \mathbb{RP}^3 . Hence, the C-space of a 3-D body capable only of rotation is \mathbb{RP}^3 . If both translation and rotation are allowed, then $SE(3)$, the set of all 4×4 homogeneous transformation matrices, yields:

$$\mathcal{C} = \mathbb{R}^3 \times \mathbb{RP}^3, \quad (5.11)$$

which is six dimensional. A configuration $\mathbf{q} \in \mathcal{C}$ can be expressed using quaternions with seven coordinates, (x, y, z, a, b, c, d) , in which $a^2 + b^2 + c^2 + d^2 = 1$.

5.6.2 Sampling Theory

Since the most successful paradigm for motion planning today is the sampling-based framework, presented in Sect. 5.2, sampling theory becomes relevant to the motion planning problem.

Metrics in Configuration/State Spaces

Virtually all sampling-based methods require some notion of distance on \mathcal{C} . For example, the sampling-based roadmap method selects candidate vertices to connect a new configuration given a distance-defined neighborhood. Similarly, the rapidly exploring dense trees expands the tree from the nearest node of the tree to a newly sampled configuration. Usually, a metric, $\rho : \mathcal{C} \times \mathcal{C} \rightarrow \mathbb{R}$, is defined, which satisfies the standard axioms: nonnegativity, reflexivity, symmetry, and the triangle inequality.

Two difficult issues that arise in constructing a metric are: (1) the topology of \mathcal{C} must be respected, and (2) several different quantities, such as linear and angular

displacements, must be compared in some way. To illustrate the second issue, consider defining a metric ρ_z for a space constructed as $Z = X \times Y$ as

$$\begin{aligned} \rho_z(z, z') &= \rho_z(x, y, x', y') \\ &= c_1 \rho_x(x, x') + c_2 \rho_y(y, y'). \end{aligned} \quad (5.12)$$

Above, c_1 and c_2 are arbitrary positive constants that indicate the relative weights of the two components. For a 2-D rotation, θ_i , expressed as $a_i = \cos \theta_i$ and $b_i = \sin \theta_i$, a useful metric is:

$$\rho(a_1, b_1, a_2, b_2) = \cos^{-1}(a_1 a_2 + b_1 b_2). \quad (5.13)$$

The 3-D equivalent is obtained by defining

$$\rho_0(\mathbf{h}_1, \mathbf{h}_2) = \cos^{-1}(a_1 a_2 + b_1 b_2 + c_1 c_2 + d_1 d_2), \quad (5.14)$$

in which each $\mathbf{h}_i = (a_i, b_i, c_i, d_i)$ is a unit quaternion. The metric is defined as $\rho(\mathbf{h}_1, \mathbf{h}_2) = \min(\rho_0(\mathbf{h}_1, \mathbf{h}_2), \rho_0(\mathbf{h}_1, -\mathbf{h}_2))$, by respecting the required identification of antipodal points. This computes the shortest distance in \mathbb{R}^4 , for a path constrained to the unit sphere.

In some algorithms, defining volume on \mathcal{C} may also be important. In general, this leads to a *measure space*, for which the volume function (called the *measure*) must satisfy axioms that resemble the probability axioms, but without normalization. For transformation groups, one must be careful to define volumes in a way that is invariant with respect to transformations. Such volumes are called *Haar measures*. Defining volumes via balls using the metric definitions (5.13) and (5.14) actually satisfy this concern.

Probabilistic versus Deterministic Sampling

The C-space may be sampled *probabilistically* or *deterministically*. Either way, the requirement is usually that a dense sequence α of samples is obtained. This means that, in the limit as the number of samples tends to infinity, the samples become arbitrarily close to every point in \mathcal{C} . For probabilistic sampling, this denseness (with probability one) ensures *probabilistic completeness* of a planning algorithm. For deterministic sampling, it ensures *resolution completeness*, which means that, if a solution exists, the algorithm is guaranteed to find it; otherwise, it may run forever.

For probabilistic sampling, samples are selected randomly over \mathcal{C} , using a uniform probability density function. To obtain uniformity in a meaningful way, the Haar measure should be used. This is straightforward in many cases; $SO(3)$ however is tricky. A uniform

(with respect to Haar measure) random quaternion is selected as follows. Choose three points $u_1, u_2, u_3 \in [0, 1]$ uniformly at random, and let [5.100]

$$\mathbf{h} = \left(\sqrt{1-u_1} \sin 2\pi u_2, \sqrt{1-u_1} \cos 2\pi u_2, \sqrt{u_1} \sin 2\pi u_3, \sqrt{u_1} \cos 2\pi u_3 \right). \quad (5.15)$$

Even though random samples are uniform in some sense, they are also required to have some irregularity to satisfy statistical tests. This has motivated the development of deterministic sampling schemes that offer better performance [5.101]. Instead of being concerned with randomness, deterministic sampling techniques are designed to optimize criteria, such as *discrepancy* and *dispersion*. Discrepancy penalizes regularity in the sample, which frequently causes trouble in numerical integration. Dispersion gives the radius of the largest empty (not containing samples) ball. Thus, driving dispersion down quickly means that the whole space is explored quickly. Deterministic samples may be *irregular* neighborhood structure (appearing much like random samples), or *regular* neighborhood structure, which means that points are arranged along a grid or lattice. For more details in the context of motion planning, see [5.7].

5.6.3 Computational Algebraic Geometry Techniques

Sampling-based algorithms provide good practical performance at the expense of achieving only a weaker form of completeness. On the other hand, complete al-

gorithms, which are the focus of this section, are able to deduce that there is no solution to a planning problem.

Complete algorithms are able to solve virtually any motion planning problem as long as \mathcal{C}_{obs} is represented by patches of algebraic surfaces. Formally, the model must be *semi-algebraic*, which means that it is formed from unions and intersections of roots of multivariate polynomials in q , and for computability, the polynomials must have rational coefficients (otherwise roots may not have finite representations). The set of all roots to polynomials with rational coefficients is called *real algebraic numbers* and has many nice computational properties. See [5.12, 102–104] for more information on the exact representation and calculation with real algebraic numbers. For a gentle introduction to algebraic geometry, see [5.82].

To use techniques based on algebraic geometry, the first step is to convert the models into the required polynomials. Suppose that the models, the robot, \mathcal{A} , and the obstacles \mathcal{O} are semi-algebraic (this includes polyhedral models). For any number of attached 2-D or 3-D bodies, the kinematic transformations can be expressed using polynomials. Since polynomial transformations of polynomials yield polynomials, the transformed robot model is polynomial. The algebraic surfaces that comprise \mathcal{C}_{obs} are computed by carefully considering all contact types, which characterize all ways to pair a robot feature (faces, edges, vertices) with an obstacle feature [5.6, 7, 9, 105]. This step already produces too many model primitives to be useful in most applications.

Once the semi-algebraic representation has been obtained, powerful techniques from algebraic geometry can be exploited. One of the most widely known algorithms, *cylindrical algebraic decomposition* [5.102, 106, 107], provides the information needed to solve the motion planning problem. It was originally designed to determine whether *Tarski sentences*, which involve quantifiers and polynomials, are satisfiable, and to find an equivalent expression that does not involve quantifiers. The decomposition produces a finite set of cells over which the signs of the polynomials remain fixed. This enables a systematic approach to satisfiability and quantifier elimination. It was recognized by Schwartz and Sharir [5.104] that it also solves motion planning.

The method is conceptually simple, but there are many difficult technical details. The decomposition is called cylindrical because the cells are organized into vertical columns of cells, see Fig. 5.18 for a 2-D example. There are two kinds of critical events, shown in Fig. 5.19. At critical points, rays are extended indef-

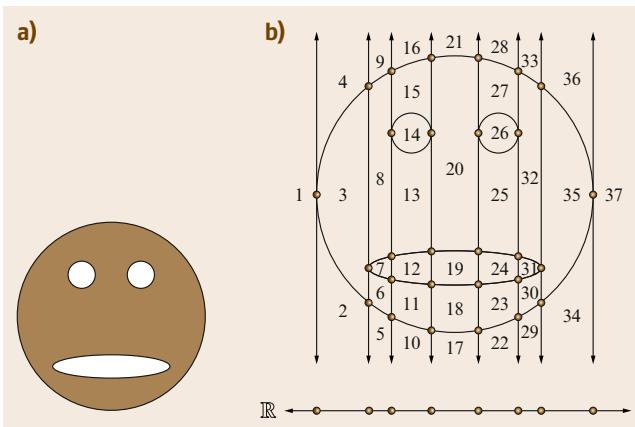

Fig. 5.18 (a) A face modeled with four algebraic primitives, and (b) a cylindrical algebraic decomposition of the face

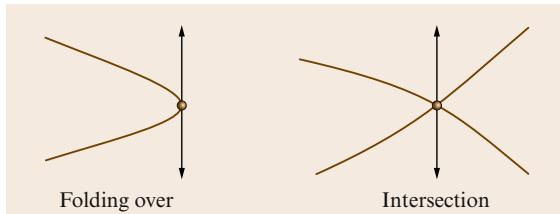

Fig. 5.19 Critical points occur either when the surface folds over in the vertical direction or when surfaces intersect

initely in both vertical directions. The decomposition differs from the vertical decomposition in Fig. 5.7 because there the rays were only extended until the next obstacle was hit. Here, columns of cells are obtained.

In n dimensions, each column represents a chain of cells. The first and last cells are n -dimensional and unbounded. The remaining cells are bounded and alternate between being $(n - 1)$ -dimensional and n dimensional. The bounded n -dimensional cells are bounded above and below by the roots of single multivariate polynomials. This makes it simple to describe the cells and their connectivity. To compute this cell decomposition, the algorithm constructs a cascading chain of projections. In the first step, \mathcal{C}_{obs} is projected from \mathbb{R}^n to \mathbb{R}^{n-1} . This is followed by a projection into \mathbb{R}^{n-2} . This repeats until \mathbb{R} is obtained with a univariate polynomial that encodes the places at which all critical boundaries need to be placed. In a second phase of the algorithm, a series of liftings is performed. Each lifting takes the polynomials and cell decomposition over \mathbb{R}^i and lifts them via columns of cells to \mathbb{R}^{i+1} . A single lifting is illustrated in Fig. 5.18b. The running time of the full algorithm depends on the particular methods used to perform the algebraic computations. The total running time required to use cylindrical algebraic decomposition for motion planning is bounded by $(md)^{O(1)^n}$, in which m is the number of polynomials to describe \mathcal{C}_{obs} (a huge number), and d is the maximum algebraic degree. [It may seem odd for $O(\cdot)$ to appear

in the middle of an expression. In this context, it means that there exists some $c \in [0, \infty)$ such that the running time is bounded by $(md)^{c^n}$. Note that another O is not necessary in the front of the whole formula.] The main point to remember is that the algorithm is doubly exponential in the dimension of \mathcal{C} (even the number of cells is doubly exponential).

Although performing the cylindrical decomposition is sufficient for solving motion planning, it computes more information than is necessary. This motivates Canny's roadmap algorithm [5.12], which produces a roadmap directly from the semi-algebraic set, rather than constructing a cell decomposition along the way. Since there are doubly exponentially many cells in the cylindrical algebraic decomposition, avoiding this construction pays off. The resulting roadmap method of Canny solves the motion planning problem in time that is again polynomial in the number of polynomials and polynomial in the algebraic degree, but is only singly exponential in dimension [5.12].

The basic idea is to find silhouette curves in \mathbb{R}^2 of \mathcal{C}_{obs} in \mathbb{R}^n . The method finds zero-dimensional critical points and one-dimensional critical curves. The critical curves become roadmap edges, and the critical points are places at which the algorithm recursively finds silhouettes of $(n - 1)$ -dimensional slices of \mathcal{C}_{obs} . These contribute more critical points and curves. The curves are added to the roadmap, and the algorithm recurses again on the critical points. The recursive iterations terminate at $n = 2$. Canny showed that the resulting union of critical curves preserves the connectivity of \mathcal{C}_{obs} (and hence, $\mathcal{C}_{\text{free}}$). Some of the technical issues are: the algorithm works with a stratification of \mathcal{C}_{obs} into manifolds; there are strong general position assumptions that are hard to meet; paths are actually considered along the boundary of $\mathcal{C}_{\text{free}}$; and the method does not produce a parameterized solution path. For improvements to Canny's algorithm and many other important details, see [5.102].

5.7 Conclusions and Further Reading

The brief survey given here hardly does justice to motion planning, which is a rich and active research field. For more details, we recommend consulting two recent textbooks [5.5, 7]. In addition, see the classic textbook

of Latombe [5.6], the classic papers in [5.4], and the recent surveys in [5.2, 3]. Furthermore, consult the related handbook chapters that were indicated throughout this chapter.

6. Motion Control

Motion Control

Wankyun Chung, Li-Chen Fu, Su-Hau Hsu[†]

This Chapter will focus on the motion control of robotic rigid manipulators. In other words, this Chapter does not treat the motion control of mobile robots, flexible manipulators, and manipulators with elastic joints. The main challenge in the motion control problem of rigid manipulators is the complexity of their dynamics and uncertainties. The former results from nonlinearity and coupling in the robot manipulators. The latter is twofold: structured and unstructured. Structured uncertainty means imprecise knowledge of the dynamic parameters and will be touched upon in this Chapter, whereas unstructured uncertainty results from joint and link flexibility, actuator dynamics, friction, sensor noise, and unknown environment dynamics, and will be treated in other Chapters.

In this Chapter, we begin with an introduction to motion control of robot manipulators from a fundamental viewpoint, followed by a survey and brief review of the relevant advanced materials. Specifically, the dynamic model and useful properties of robot manipulators are recalled in Sect. 6.1. The joint and operational space control approaches, two different viewpoints on control of robot manipulators, are compared in Sect. 6.2. Independent joint control and proportional–integral–derivative (PID) control, widely adopted in the field of industrial robots, are presented in Sections 6.3 and 6.4, respectively. Tracking control, based on feedback linearization, is introduced in Sect. 6.5. The computed-torque control and its variants are described in Sect. 6.6. Adaptive control is introduced in Sect. 6.7 to solve the problem of structural uncertainty, whereas the optimality and robustness issues are covered in Sect. 6.8. Since most controllers of robot manipulators are implemented by using microprocessors, the issues of digital implementation are discussed in Sect. 6.9. Finally, learning control, one popular approach to intelligent control, is illustrated in Sect. 6.10.

6.1 Introduction to Motion Control

The dynamical model of robot manipulators will be recalled in this section. Furthermore, important properties of this dynamical model, which is useful in controller design, will then be addressed. Finally, different control tasks of the robot manipulators will be defined.

6.1.1 Dynamical Model

For motion control, the dynamical model of rigid robot manipulators is conveniently described by Lagrange dynamics. Let the robot manipulator have n links and let the $(n \times 1)$ -vector \mathbf{q} of joint variables be $\mathbf{q} = [q_1, \dots, q_n]^\top$. The dynamic model of the robot manipulator is then described by Lagrange's equation [6.1–6]:

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) = \boldsymbol{\tau}, \quad (6.1)$$

where $\mathbf{H}(\mathbf{q})$ is the $(n \times n)$ inertia matrix, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}$ is the $(n \times 1)$ -vector of Coriolis and centrifugal forces, $\boldsymbol{\tau}_g(\mathbf{q})$ is the $(n \times 1)$ -vector of gravity force, and $\boldsymbol{\tau}$ is the $(n \times 1)$ -vector of joint control inputs to be designed. Friction and disturbance input have been neglected here.

Remark.

- Other contributions to the dynamic description of the robot manipulators may include the dynamics of the actuators, joint and link flexibility, friction, noise, and disturbances. Without loss of generality, the case of the rigid robot manipulators is stressed here.

The control schemes that we will introduce in this Chapter are based on some important properties of the dynamical model of robot manipulators. Before giving a detailed introduction to these different schemes, let us first give a list of those properties.

Property 6.1

The inertia matrix is a symmetric positive-definite matrix, which can be expressed

$$\lambda_h \mathbf{I}_n \leq \mathbf{H}(\mathbf{q}) \leq \lambda_H \mathbf{I}_n, \quad (6.2)$$

where λ_h and λ_H denote positive constants.

Property 6.2

The matrix $N(\mathbf{q}, \dot{\mathbf{q}}) = \dot{\mathbf{H}}(\mathbf{q}) - 2\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ is skew-symmetric for a particular choice of $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ (which is always possible), i. e.,

$$\mathbf{z}^\top N(\mathbf{q}, \dot{\mathbf{q}}) \mathbf{z} = 0 \quad (6.3)$$

for any $(n \times 1)$ -vector \mathbf{z} .

Property 6.3

The $(n \times n)$ -matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ satisfies

$$\| \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \| \leq c_0 \| \dot{\mathbf{q}} \| \quad (6.4)$$

for some bounded constant c_0 .

Property 6.4

The gravity force/torque vector satisfies

$$\| \boldsymbol{\tau}_g(\mathbf{q}) \| \leq g_0 \quad (6.5)$$

for some bounded constant g_0 .

Property 6.5

The equation of motion is linear in the inertia parameters. In other words, there is a $(r \times 1)$ constant vector \mathbf{a} and an $(n \times r)$ regressor matrix $\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ such that

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) = \mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})\mathbf{a}. \quad (6.6)$$

The vector \mathbf{a} is comprised of link masses, moments of inertia, and the link, in various combinations.

Property 6.6

The mapping $\tau \rightarrow \dot{\mathbf{q}}$ is passive; i.e., there exists $\alpha \geq 0$ such that

$$\int_0^t \dot{\mathbf{q}}^\top(\beta) \tau(\beta) d\beta \geq -\alpha, \quad \forall t < \infty. \quad (6.7)$$

Remarks.

- Properties 6.3 and 6.4 are very useful since they allow us to establish upper bounds on the nonlinear terms in the dynamical model. As we will see further, several control schemes require knowledge of such upper bounds.
- In Property 6.5, the parameter vector \mathbf{a} is comprised of several variables in various combinations. The dimensionality of the parameter space is not unique, and the search over the parameter space is an important problem.
- In this section, we assume that *the robot manipulator is fully actuated* and this indicates that there is an independent control input for each degree of freedom (DOF). In contrast, the robot manipulators with joint or link flexibility are no longer fully actuated and the control problems are more difficult in general.

6.1.2 Control Tasks

It is instructive for comparative purposes to classify control objectives into the following two classes:

- Trajectory tracking* is aimed at following a time-varying joint reference trajectory specified within the manipulator workspace. In general, this desired trajectory is assumed to comply with the actuators' capacity. In other words, the joint velocity and acceleration associated with the desired trajectory should

not violate, respectively, the velocity and acceleration limit of the manipulator. In practice, the capacity of actuators is set by torque limits, which result in bounds on the acceleration that are complex and state dependent.

- Regulation sometimes is also called point-to-point control. A fixed configuration in the joint space is specified; the objective is to bring to and keep the joint variable at the desired position in spite of torque disturbances and independently of the initial conditions. The behavior of transients and overshooting, are in general, not guaranteed.

The selection of the controller may depend on the type of task to be performed. For example, tasks only requiring the manipulator to move from one position to another without requiring significant precision during the motion between these two points can be solved by regulators, whereas such as welding, painting, and so on, require tracking controllers.

Remarks.

- The regulation problem may be seen as a special case of the tracking problem (for which the desired joint velocity and acceleration are zero).
- The task specification above is given in the joint space and results in joint space control, which is the main content of this Chapter. Sometimes, the task specification of the robot manipulators in terms of the desired trajectory of the end-effector (e.g., control with eye-in-hand) is carried out in the task space and gives rise to the operational space control, which will be introduced in Sect. 6.2.

6.1.3 Summary

In this section, we introduced the dynamical model of the robot manipulators and important properties of this dynamical model. Finally, we defined different control tasks of the robot manipulators.

6.2 Joint Space Versus Operational Space Control

In a motion control problem, the manipulator moves to a position to pick up an object, transports that object to another location, and deposits it. Such a task is an integral part of any higher-level manipulation tasks such as painting or spot-welding.

Tasks are usually specified in the task space in terms of a desired trajectory of the end-effector, while control actions are performed in the joint space to achieve the desired goals. This fact naturally leads to two kinds of general control methods, namely *joint space con-*

trol and *operational space control* (*task space control*) schemes.

6.2.1 Joint Space Control

The main goal of the joint space control is to design a feedback controller such that the joint coordinates $\mathbf{q}(t) \in R^n$ track the desired motion $\mathbf{q}_d(t)$ as closely as possible. To this end, consider the equations of motion (6.1) of an n -DOF manipulator expressed in the joint space [6.2, 4]. In this case, the control of robot manipulators is naturally achieved in the joint space, since the control inputs are the joint torques. Nevertheless, the user specifies a motion in terms of end-effector coordinates, and thus it is necessary to understand the following strategy.

Figure 6.1 shows the basic outline of the joint space control methods. Firstly, the desired motion, which is described in terms of end-effector coordinates, is converted to a corresponding joint trajectory using the inverse kinematics of the manipulator. Then the feedback controller determines the joint torque necessary to move the manipulator along the desired trajectory specified in joint coordinates starting from measurements of the current joint states [6.1, 4, 7, 8].

Since it is always assumed that the desired task is given in terms of the time sequence of the joint motion, joint space control schemes are quite adequate in situations where manipulator tasks can be accurately preplanned and little or no online trajectory adjustments are necessary [6.1, 4, 7, 9]. Typically, inverse kinematics is performed for some intermediate task points, and the joint trajectory is interpolated using the intermediate joint solutions. Although the command trajectory consists of straight-line motions in end-effector coordinates between interpolation points, the resulting joint motion consists of curvilinear segments that match

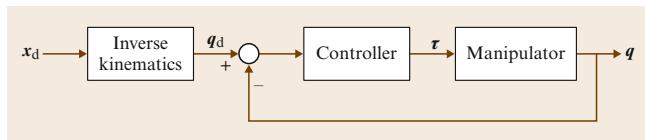

Fig. 6.1 Generic concept of joint space control

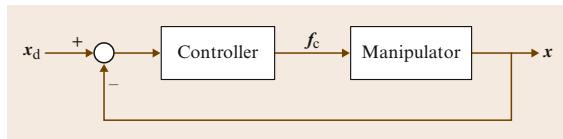

Fig. 6.2 Basic concept of operational space control

the desired end-effector trajectory at the interpolation points.

In fact, the joint space control includes simple PD control, PID control, inverse dynamic control, Lyapunov-based control, and passivity-based control, as explained in the following sections.

6.2.2 Operational Space Control

In more complicated and less certain environments, end-effector motion may be subject to online modifications in order to accommodate unexpected events or to respond to sensor inputs. There are a variety of tasks in manufacturing where these type of control problem arise. In particular, it is essential when controlling the interaction between the manipulator and environment is of concern.

Since the desired task is often specified in the operational space and requires precise control of the end-effector motion, joint space control schemes are not suitable in these situations. This motivated a different approach, which can develop control schemes directly based on the dynamics expressed in the operational space [6.10, 11].

Let us suppose that the Jacobian matrix, denoted by $J(\mathbf{q}) \in R^{n \times n}$, transforms the joint velocity $(\dot{\mathbf{q}} \in R^n)$ to the task velocity $(\dot{\mathbf{x}} \in R^n)$ according to

$$\dot{\mathbf{x}} = J(\mathbf{q})\dot{\mathbf{q}} . \quad (6.8)$$

Furthermore, assume that it is invertible. Then, the operational space dynamics is expressed as follows:

$$\mathbf{f}_c = \Lambda(\mathbf{q})\ddot{\mathbf{x}} + \Gamma(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \eta(\mathbf{q}) , \quad (6.9)$$

where $\mathbf{f}_c \in R^n$ denotes the command forces in the operational space; the *pseudo-inertia matrix* is defined by

$$\Lambda(\mathbf{q}) = J^{-\top}(\mathbf{q})H(\mathbf{q})J^{-1}(\mathbf{q}) , \quad (6.10)$$

and $\Gamma(\mathbf{q}, \dot{\mathbf{q}})$ and $\eta(\mathbf{q})$ are given by

$$\Gamma(\mathbf{q}, \dot{\mathbf{q}}) = J^{-\top}(\mathbf{q})C(\mathbf{q}, \dot{\mathbf{q}})J^{-1}(\mathbf{q}) - \Lambda(\mathbf{q})J(\mathbf{q})J^{-1}(\mathbf{q}) ,$$

$$\eta(\mathbf{q}) = J^{-\top}(\mathbf{q})\tau_g(\mathbf{q}) .$$

The task space variables are usually reconstructed from the joint space variables, via the kinematic mappings. In fact, it is quite rare to have sensors to directly measure end-effector positions and velocities. Also, it is worth remarking that an analytical Jacobian is utilized since the control schemes operate directly on task space quantities, i. e., the end-effector position and orientation.

The main goal of the operational space control is to design a feedback controller that allows execution of an end-effector motion $\mathbf{x}(t) \in R^n$ that tracks the de-

sired end-effector motion $\mathbf{x}_d(t)$ as closely as possible. To this end, consider the equations of motion (6.9) of the manipulator expressed in the operational space. For this case, Fig. 6.2 shows a schematic diagram of the operational space control methods. There are several advantages to such an approach because operational

space controllers employ a feedback loop that directly minimizes task errors. Inverse kinematics need not be calculated explicitly, since the control algorithm embeds the velocity-level forward kinematics (6.8), as shown in the figure. Now, motion between points can be a straight-line segment in the task space.

6.3 Independent-Joint Control

By independent-joint control (i.e., decentralized control), we mean that the control inputs of each joint only depends on the measurement of the corresponding joint displacement and velocity. Due to its simple structure, this kind of control schemes offers many advantages. For example, by using independent-joint control, communication among different joints is saved. Moreover, since the computational load of controllers may be reduced, only low-cost hardware is required in actual implementations. Finally, independent-joint control has the feature of scalability, since the controllers on all the joints have the same formulation. In this section, two kinds of design of independent-joint control will be introduced: one focused on the dynamical model of each joint (i.e., based on the single-joint model) and the other based on the analysis of the overall dynamical model (i.e., the multijoint model) of robot manipulators.

6.3.1 Controller Design Based on the Single-Joint Model

The simplest independent-joint control strategy is to control each joint axis as a single-input single-output (**SISO**) system. Coupling effects among joints due to varying configuration during motion are treated as disturbance inputs. Without loss of generality, the actuator is taken as a rotary electric direct-current (DC) motor. Hence, the block diagram of the control scheme of joint i can be represented in the domain of the complex variables as shown in Fig. 6.3. In this scheme, θ is the angular variable of the motor, J is the effective inertia viewed from the motor side, R_a is the armature resistance (auto-inductance being neglected), and k_t and k_v are, respectively, the torque and motor constants. Furthermore, G_v denotes the voltage gain of the power amplifier so that the reference input is the input voltage V_c of the amplifier instead of the armature voltage V_a . It has also been assumed that $F_m \ll k_v k_t / R_a$, i.e., the mechanical (viscous) friction coefficient has

been neglected with respect to the electrical coefficient. Now the input–output transfer function of the motor can be written as

$$M(s) = \frac{k_m}{s(1 + sT_m)}, \quad (6.11)$$

where $k_m = G_v/k_v$ and $T_m = R_a J/k_v k_t$ are, respectively, the voltage-to-velocity gain and the time constant of the motor.

To guide selection of the control structure, start by noticing that an effective rejection of the disturbance d on the output θ is ensured by

1. a large value of the amplifier before the point of intervention of the disturbance;
2. the presence of an integral action in the controller so as to cancel the effect of the gravitational component on the output at the steady state (i.e., constant θ).

In this case, as shown in Fig. 6.4, the types of control action with position and velocity feedback are characterized by [6.4]

$$G_p(s) = K_p, \quad G_v(s) = K_v \frac{1 + sT_V}{s}, \quad (6.12)$$

where $G_p(s)$ and $G_v(s)$ correspond to the position and velocity control actions, respectively. It is worth noting that the inner control action $G_v(s)$ is in a form of propositional-integral (PI) control to yield zero error in the steady state under a constant disturbance d . Furthermore, k_{Tp} and k_{Tv} are both transducer constants, and the amplifier gain K_V has been embedded in the gain

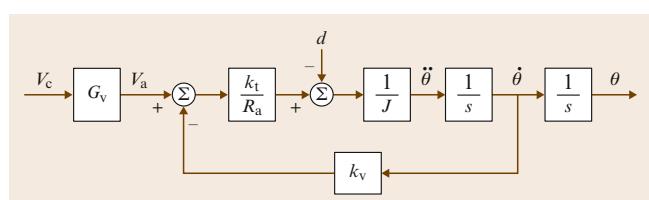

Fig. 6.3 Block scheme of a joint-driven system (after [6.4])

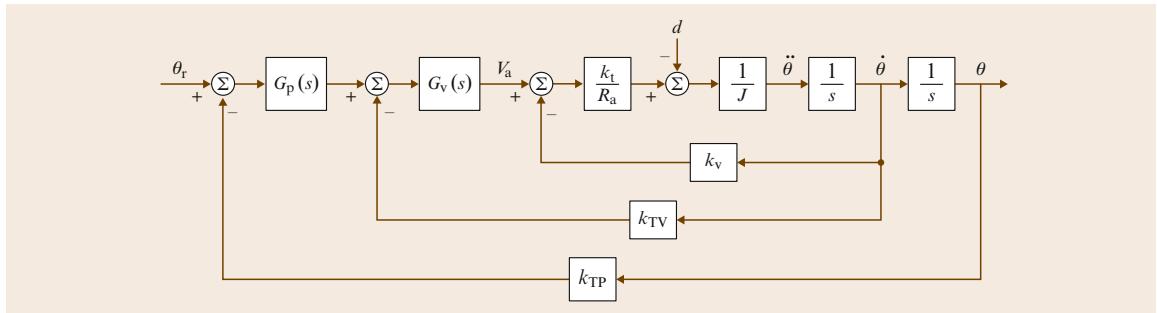

Fig. 6.4 Block scheme of position and velocity feedback (after [6.4])

of the inner controller. From the scheme of Fig. 6.4, the transfer function of the forward path is

$$P(s) = \frac{k_m K_p K_V (1 + s T_m)}{s (1 + s T_m)}, \quad (6.13)$$

while that of the return path is

$$H(s) = k_{TP} \left(1 + s \frac{k_{TV}}{K_p k_{TP}} \right). \quad (6.14)$$

The zero of the controller at $s = -1/T_V$ can be chosen so as to cancel the effects of the real pole of the motor at $s = -1/T_m$. Then, by setting $T_V = T_m$, the poles of the closed-loop system move on the root locus as a function of the loop gain, $k_m K_V k_{TV}$. By increasing the position feedback gain K_p , it is possible to confine the closed-loop poles to a region of the complex plane with large absolute real part. Then, the actual location can be established by a suitable choice of K_V .

The closed-loop input-output transfer function is

$$\frac{\Theta(s)}{\Theta_r(s)} = \frac{\frac{1}{k_{TP}}}{1 + \frac{s k_{TP}}{K_p k_{TP}} + \frac{s^2}{k_m K_p k_{TP} K_V}}, \quad (6.15)$$

which can be compared with the typical transfer function of a second-order system

$$W(s) = \frac{\frac{1}{k_{TP}}}{1 + \frac{2\zeta s}{\omega_n} + \frac{s^2}{\omega_n^2}}. \quad (6.16)$$

It can be recognized that, with a suitable choice of the gains, it is possible to obtain any value of natural frequency ω_n and damping ratio ζ . Hence, if ω_n and ζ are given as design specifications, the following relations can be found

$$K_V k_{TV} = \frac{2\zeta\omega_n}{k_m} \quad \text{and} \quad K_p k_{TP} K_V = \frac{\omega_n^2}{k_m}. \quad (6.17)$$

For given transducer constants k_{TP} and k_{TV} , K_V and K_p will be chosen to satisfy the two equations above, respectively. On the other hand, the closed-loop disturbance/output function is

$$\frac{\Theta(s)}{D(s)} = \frac{\frac{s R_a}{k_t K_p K_V (1 + s T_m)}}{1 + \frac{s k_{TV}}{K_p k_{TP}} + \frac{s^2}{k_m K_p k_{TP} K_V}}, \quad (6.18)$$

which shows that the disturbance rejection factor is $X_R(s) = K_p k_{TP} K_V$ and is fixed, provided that K_V and K_p have been chosen via the approach above. Concerning the disturbance dynamics, the zero at the origin introduced by the PI, a real pole at $s = -1/T_m$, and the pair of complex poles with real part $-\zeta\omega_n$ should be kept in mind. In this case, an estimate T_R of the output recovery time needed by the control system to recover from the effect of a disturbance on the joint position can be evaluated by analyzing models of the transfer function above. Such an estimate can reasonably be expressed as $T_R = \max\{T_m, 1/\zeta\omega_n\}$.

6.3.2 Controller Design Based on the Multijoint Model

In recent years, independent-joint control schemes based on the complete dynamic model of the robot manipulators (i.e., a multijoint model) have been proposed. For example, following the approach of computed-torque-like control, [6.12] dealt with the regulation task for horizontal motions, and [6.13] and [6.14] handled the tracking task for arbitrary smooth trajectories. Since the overall dynamic model is considered, the effects of coupling among joints are handled. These schemes will be introduced in detail in Sect. 6.6.

6.3.3 Summary

In this section, we have presented two independent-joint control schemes: one is based on the single-joint model and the other is based on the multijoint model. The former focuses on the dynamics of a single joint and regards the interaction among joints as a disturbance. This control scheme is simple but may not be suitable for high-speed tracking. Hence, we introduce the latter, which considers the overall dynamical model of robot manipulators such that the interaction among joints can be handled.

6.4 PID Control

Traditionally, control design in robot manipulators can be understood as the simple fact of tuning of a **PD** or **PID** compensator at the level of each motor driving the manipulator joints [6.1]. Fundamentally, a **PD** controller is a position and velocity feedback that has good closed-loop properties when applied to a double integrator system.

The **PID** control has a long history since Ziegler and Nichols' **PID** tuning rules were published in 1942 [6.15]. Actually, the strong point of **PID** control lies in its *simplicity* and clear physical meaning. Simple control is preferable to complex control, at least in industry, if the performance enhancement obtained by using complex control is not significant enough. The physical meanings of **PID** control [6.16] are as follows:

P-control means the present effort making a present state into desired state;

I-control means the accumulated effort using the experience information of previous states;

D-control means the predictive effort reflecting the information about trends in future states.

6.4.1 PD Control for Regulation

A simple design method for manipulator control is to utilize a linear control scheme based on the linearization of the system about an operating point. An example of this method is a **PD** control with a gravity compensation scheme [6.17, 18]. Gravity compensation acts as a bias correction, compensating only for the amount of forces that create overshooting and an asymmetric transient behavior. Formally, it has the following form

$$\tau = K_P(q_d - q) - K_V \dot{q} + \tau_g(q), \quad (6.19)$$

Further Reading

There are different types of feedback applied in the independent-joint control based on the single-joint model (such as pure position feedback or position, velocity, and acceleration feedback). A complete discussion is given in [6.4]. When the joint control servos are required to track reference trajectories with high speeds and accelerations, the tracking capabilities of the above schemes are inevitably degraded. A possible remedy is to adopt decentralized feed-forward compensation to reduce tracking errors [6.4, 5].

where K_P and $K_V \in R^{n \times n}$ are positive-definite gain matrices. This controller is very useful for set-point regulation, i.e., $q_d = \text{constant}$ [6.7, 18]. When this controller is applied to (6.1), the closed-loop equation becomes

$$H(q)\ddot{q} + C(q, \dot{q})\dot{q} + K_V \dot{q} - K_P e_q = \mathbf{0}, \quad (6.20)$$

where $e_q = q_d - q$, and the equilibrium point is $y = [e_q^\top, \dot{q}^\top]^\top = \mathbf{0}$. Now, the stability achieved by **PD** control with gravity compensation can be analyzed according to the closed-loop dynamic (6.20). Consider the positive-definite function

$$V = \frac{1}{2} \dot{q}^\top H(q) \dot{q} + \frac{1}{2} e_q^\top K_V e_q.$$

Then, the derivative of function becomes negative semidefinite for any value of \dot{q} by using Property 6.2 in Sect. 6.1, i.e.,

$$\dot{V} = -\dot{q}^\top K_V \dot{q} \leq -\lambda_{\min}(K_V) \|\dot{q}\|^2, \quad (6.21)$$

where $\lambda_{\min}(K_V)$ means the smallest eigenvalue of K_V . By invoking the Lyapunov stability theory and LaSalle's theorem [6.1], it can be shown that the regulation error will converge asymptotically to zero, while their high-order derivatives remain bounded. This controller requires knowledge of the gravity components (structure and parameters), though it is simple.

Now, consider simple **PD** control without gravity compensation

$$\tau = K_P(q_d - q) - K_V \dot{q}, \quad (6.22)$$

then the closed-loop dynamic equation becomes

$$H(q)\ddot{q} + C(q, \dot{q})\dot{q} + \tau_g(q) + K_V \dot{q} - K_P e_q = \mathbf{0}. \quad (6.23)$$

Consider the positive definite function

$$V = \frac{1}{2} \dot{\mathbf{q}}^\top \mathbf{H}(\mathbf{q}) \dot{\mathbf{q}} + \frac{1}{2} \mathbf{e}_q^\top \mathbf{K} \mathbf{v} \mathbf{e}_q + U(\mathbf{q}) + U_0,$$

where $U(\mathbf{q})$ denotes the potential energy with the relation of $\partial U(\mathbf{q})/\partial \mathbf{q} = \boldsymbol{\tau}_g(\mathbf{q})$ and U_0 is a suitable constant. Taking time derivative of V along the closed-loop dynamics (6.23) gives the same result (6.21) with previous one using gravity compensation. In this case, the control system must be stable in the sense of Lyapunov, but it can not conclude that the regulation error will converge to zero by LaSalle's theorem [6.1]. Actually, the system precision (the size of the regulation error vector) will depend on the size of the gain matrix \mathbf{K}_P in the following form:

$$\|\mathbf{e}_q\| \leq \|\mathbf{K}_P^{-1}\| g_0, \quad (6.24)$$

where g_0 is that in Property 6.4 in Sect. 6.1. Hence, the regulation error can be arbitrarily reduced by increasing \mathbf{K}_P ; nevertheless, measurement noise and other unmodeled dynamics, such as actuator friction, will limit the use of high gains in practice.

6.4.2 PID Control for Regulation

An integral action may be added to the previous PD control in order to deal with gravity forces, which to some extent can be considered as a constant disturbance (from the local point of view). The PID regulation controller can be written in the following general form:

$$\boldsymbol{\tau} = \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}) + \mathbf{K}_I \int f(\mathbf{q}_d - \mathbf{q}) dt - \mathbf{K}_V \dot{\mathbf{q}},$$

where $\mathbf{K}_I \in R^{n \times n}$ is a positive-definite gain matrix, and

- if $f(\mathbf{q}_d - \mathbf{q}) = \mathbf{q}_d - \mathbf{q}$, we have PID control,
- if $\mathbf{K}_I \int (-\dot{\mathbf{q}}) dt$ is added, we have PI²D control,
- if $f(\cdot) = \tanh(\cdot)$, we have PD + nonlinear integral control.

Global asymptotic stability (GAS) by PID control was proved in [6.12] for robotic motion control system including external disturbances, such as Coulomb friction. Also, Tomei proved the GAS of PD control in [6.19] by using an adaptation for gravity term. On the other hand, Ortega et al. showed in [6.20] that PI²D control could yield semiglobal asymptotic stability (SGAS) in the presence of gravity and bounded external disturbances. Also, Angelis proved in [6.21] that PD control could achieve the input-output-to-state stability (IOSS) for robotic systems. Also, Ramirez et al. proved the SGAS (with some conditions) for PID gains in [6.22].

Also, Kelly proved in [6.23] that PD plus nonlinear integral control could achieve GAS under gravity.

Actually, a large integral action in PID control can cause instability of the motion control system. In order to avoid this, the integral gain should be bounded by an upper limit of the following form [6.1]:

$$\frac{k_P k_V}{\lambda_H^2} > k_I,$$

where λ_H is that in Property 6.1 in Sect. 6.1, $\mathbf{K}_P = k_P \mathbf{I}$, $\mathbf{K}_I = k_I \mathbf{I}$, and $\mathbf{K}_V = k_V \mathbf{I}$. This relation gives the guidelines for gain selection implicitly. Also, PID control has generated a great variety of PID control plus something, e.g., PID plus friction compensator, PID plus gravity compensator, PID plus disturbance observer.

6.4.3 PID Gain Tuning

The PID control can be utilized for trajectory tracking as well as set-point regulation. True tracking control will be treated after Sect. 6.5. In this section, the simple but useful PID gain tuning method will be introduced for practical use. The general PID controller can be written in the following general form:

$$\boldsymbol{\tau} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \mathbf{K}_I \int \mathbf{e}_q dt,$$

or, in another form,

$$\boldsymbol{\tau} = \left(\mathbf{K} + \frac{1}{\gamma^2} \mathbf{I} \right) \left(\dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \mathbf{K}_I \int \mathbf{e}_q dt \right). \quad (6.25)$$

In a fundamental stability analysis of tracking control systems, Qu et al. proved in [6.24] that PD control could satisfy uniform ultimate boundedness (UUB). Also, Berghuis et al. proposed output feedback PD control, which satisfies semiglobal uniform ultimate boundedness (SGUUB) in [6.25] under gravity and a bounded disturbance. Recently, Choi et al. suggested inverse optimal PID control [6.26], assuring extended disturbance input-to-state stability (ISS).

Actually, if a PID controller (6.25) is repeatedly applied to the same set point or desired trajectory, then the maximum error will be proportional to the gains in the following form:

$$\max_{0 \leq t \leq t_f} \|\mathbf{e}_q(t)\| \propto \frac{\gamma^2}{\sqrt{2k\gamma^2 + 1}}, \quad (6.26)$$

where t_f denotes the final execution time of a given task and $\mathbf{K} = k \mathbf{I}$. This relation can be utilized to tune the gain of a PID controller and is referred to as the compound

tuning rule [6.16]. The compound tuning rule implicitly includes simple tuning rules as follows:

$$\text{Square tuning: } \max \|e_q\| \propto \gamma^2, \quad \text{for a small } k,$$

$$\text{Linear tuning: } \max \|e_q\| \propto \gamma, \quad \text{for a large } k.$$

For example, suppose we select positive constant diagonal matrices $\mathbf{K}_P = k_P \mathbf{I}$, $\mathbf{K}_I = k_I \mathbf{I}$, while satisfying $k_P^2 > 2k_I$. For small k , the maximum error will be reduced by $\frac{1}{4}$ according to the square tuning rule, if we reduce the value γ by $\frac{1}{2}$. For large k , the maximum error will be proportionally reduced as γ according to the linear tuning rule. This means that we can tune the **PID** controller using only one parameter γ when the other gain parameters are fixed [6.16]. Although these rules

are very useful in tuning the control performance, they can be utilized only for repetitive experiments for the same set point or desired trajectory because the tuning rules consist of proportional relations.

Further Reading

PID-type controllers were designed to solve the regulation control problem. They have the advantage of requiring knowledge of neither the model structure nor the model parameters. Also, the stability achieved by **PID**-type controllers was presented in this section. A range of books and papers [6.1, 15, 16, 22, 27, 28] are available to the robotics audience, detailing the individual tuning methods used in **PID** control and their concrete proofs.

6.5 Tracking Control

While independent **PID** controls are adequate in most set-point regulation problems, there are many tasks that require effective trajectory tracking capabilities such as plasma-welding, laser-cutting or high-speed operations in the presence of obstacles. In this case, employing local schemes requires moving slowly through a number of intermediate set points, thus considerably delaying the completion of the task. Therefore, to improve the trajectory tracking performance, controllers should take account of the manipulator dynamic model via a computed-torque-like technique.

The tracking control problem in the joint or task space consists of following a given time-varying trajectory $\mathbf{q}_d(t)$ or $\mathbf{x}_d(t)$ and its successive derivatives $\dot{\mathbf{q}}_d(t)$ or $\dot{\mathbf{x}}_d(t)$ and $\ddot{\mathbf{q}}_d(t)$ or $\ddot{\mathbf{x}}_d(t)$, which describe the desired velocity and acceleration, respectively. To obtain successful performance, significant effort has been devoted to the development of model-based control strategies [6.1, 2, 7]. Among the control approaches reported in the literature, typical methods include inverse dynamic control, the feedback linearization technique, and the passivity-based control method.

6.5.1 Inverse Dynamics Control

Though the inverse dynamics control has a theoretical background, such as the theory of feedback linearization discussed later, its starting point is mechanical engineering intuition based on cancelling nonlinear terms and decoupling the dynamics of each link. Inverse dynamics control in joint space has the

form

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\mathbf{v} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}) \quad (6.27)$$

which, applied to (6.1), yields a set of n decoupled linear systems, e.g., $\ddot{\mathbf{q}} = \mathbf{v}$, where \mathbf{v} is an auxiliary control input to be designed. Typical choices for \mathbf{v} are

$$\mathbf{v} = \ddot{\mathbf{q}}_d + \mathbf{K}_V(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}) \quad (6.28)$$

or with an integral component

$$\begin{aligned} \mathbf{v} = & \ddot{\mathbf{q}}_d + \mathbf{K}_V(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_P(\mathbf{q}_d - \mathbf{q}) \\ & + \mathbf{K}_I \int (\mathbf{q}_d - \mathbf{q}) dt, \end{aligned} \quad (6.29)$$

leading to the error dynamics equation

$$\ddot{\mathbf{e}}_q + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q = \mathbf{0}$$

for an auxiliary control input (6.28), and

$$\mathbf{e}_q^{(3)} + \mathbf{K}_V \ddot{\mathbf{e}}_q + \mathbf{K}_P \dot{\mathbf{e}}_q + \mathbf{K}_I \mathbf{e}_q = \mathbf{0}$$

if an auxiliary control input (6.29) is used. Both error dynamics are exponentially stable by a suitable choice of the gain matrices \mathbf{K}_V and \mathbf{K}_P (and \mathbf{K}_I).

Alternatively, inverse dynamics control can be described in the operational space. Consider the operational space dynamics (6.9). If the following inverse dynamics control is used in the operational space,

$$\mathbf{f}_c = \boldsymbol{\Lambda}(\mathbf{q})(\ddot{\mathbf{x}}_d + \mathbf{K}_V \dot{\mathbf{e}}_x + \mathbf{K}_P \mathbf{e}_x) + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}),$$

where $\mathbf{e}_x = \mathbf{x}_d - \mathbf{x}$, the resulting error dynamics is

$$\ddot{\mathbf{e}}_x + \mathbf{K}_V \dot{\mathbf{e}}_x + \mathbf{K}_P \mathbf{e}_x = \mathbf{0}, \quad (6.30)$$

and it is also exponentially stable. One apparent advantage of using this controller is that K_P and K_V can be selected with a clear physical meaning in operational space. However, as can be seen in (6.10), $\Lambda(\mathbf{q})$ becomes very large when the robot approaches singular configurations [6.8]. This means that large forces in some direction are needed to move the arm.

6.5.2 Feedback Linearization

This approach generalizes the concept of inverse dynamics of rigid manipulators. The basic idea of feedback linearization is to construct a transformation as a so-called *inner-loop control*, which exactly linearizes the nonlinear system after a suitable state space change of coordinates. One can then design a second stage or *outer-loop control* in the new coordinates to satisfy the traditional control design specifications such as tracking, disturbance rejection, etc. [6.5, 29]. The full power of the feedback linearization scheme for manipulator control becomes apparent if one includes in the dynamic description of the manipulator the transmission dynamics, such as the elasticity resulting from shaft windup, gear elasticity, etc. [6.5].

In recent years, an impressive volume of literature has emerged in the area of differential-geometric methods for nonlinear systems. Most of the results in this area are intended to give abstract coordinate-free descriptions of various geometric properties of nonlinear systems and as such are difficult for the non-mathematician to follow. It is our intention here to give only the basic idea of the feedback linearization scheme and to introduce a simple version of this technique that finds an immediate application to the manipulator control problem. The reader is referred to [6.30] for a comprehensive treatment of the feedback linearization technique using differential-geometric methods.

Let us now develop a simple approach to the determination of linear state-space representations of the manipulator dynamics (6.1) by considering a general sort of output $\xi \in R^p$:

$$\xi = \mathbf{h}(\mathbf{q}) + \mathbf{r}(t), \quad (6.31)$$

where $\mathbf{h}(\mathbf{q})$ is a general predetermined function of the joint coordinate $\mathbf{q} \in R^n$ and $\mathbf{r}(t)$ is a general predetermined time function. The control objective will be to select the joint torque inputs $\boldsymbol{\tau}$ in order to make the output $\xi(t)$ go to zero.

The choice of $\mathbf{h}(\mathbf{q})$ and $\mathbf{r}(t)$ is based on the control purpose. For example, if $\mathbf{h}(\mathbf{q}) = -\mathbf{q}$ and $\mathbf{r}(t) = \mathbf{q}_d(t)$, the desired joint space trajectory we would like the

manipulator to follow, then $\xi(t) = \mathbf{q}_d(t) - \mathbf{q}(t) \equiv \mathbf{e}_q(t)$ is the joint space tracking error. Forcing $\xi(t)$ to zero in this case would cause the joint variables $\mathbf{q}(t)$ to track their desired values $\mathbf{q}_d(t)$, resulting in a manipulator trajectory-following problem. As another example, $\xi(t)$ could represent the operational space tracking error $\xi(t) = \mathbf{x}_d(t) - \mathbf{x}(t) \equiv \mathbf{e}_x(t)$. Then, controlling $\xi(t)$ to zero would result in trajectory following directly in operational space where the desired motion is usually specified.

To determine a linear state-variable model for manipulator controller design, let us simply differentiate the output $\xi(t)$ twice to obtain

$$\dot{\xi} = \frac{\partial \mathbf{h}}{\partial \mathbf{q}} \dot{\mathbf{q}} + \dot{\mathbf{r}} = \mathbf{T}\dot{\mathbf{q}} + \dot{\mathbf{r}}, \quad (6.32)$$

$$\ddot{\xi} = \mathbf{T}\ddot{\mathbf{q}} + \dot{\mathbf{T}}\dot{\mathbf{q}} + \ddot{\mathbf{r}}, \quad (6.33)$$

where we defined a $(p \times n)$ transformation matrix of the form

$$\mathbf{T}(\mathbf{q}) = \frac{\partial \mathbf{h}(\mathbf{q})}{\partial \mathbf{q}} = \begin{pmatrix} \frac{\partial \mathbf{h}}{\partial q_1} & \frac{\partial \mathbf{h}}{\partial q_2} & \cdots & \frac{\partial \mathbf{h}}{\partial q_n} \end{pmatrix}. \quad (6.34)$$

Given the output $\mathbf{h}(\mathbf{q})$, it is straightforward to compute the transformation $\mathbf{T}(\mathbf{q})$ associated with $\mathbf{h}(\mathbf{q})$. In the special case where $\dot{\xi}$ represents the operational space velocity error, then $\mathbf{T}(\mathbf{q})$ denotes the Jacobian matrix $\mathbf{J}(\mathbf{q})$.

According to (6.1),

$$\dot{\mathbf{q}} = \mathbf{H}^{-1}(\mathbf{q})[\boldsymbol{\tau} - \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})] \quad (6.35)$$

with the nonlinear terms represented by

$$\mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\tau}_g(\mathbf{q}). \quad (6.36)$$

Then (6.33) yields

$$\ddot{\xi} = \ddot{\mathbf{r}} + \dot{\mathbf{T}}\dot{\mathbf{q}} + \mathbf{T}(\mathbf{q})\mathbf{H}^{-1}(\mathbf{q})[\boldsymbol{\tau} - \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})]. \quad (6.37)$$

Define the *control input* function

$$\mathbf{u} = \ddot{\mathbf{r}} + \dot{\mathbf{T}}\dot{\mathbf{q}} + \mathbf{T}(\mathbf{q})\mathbf{H}^{-1}(\mathbf{q})[\boldsymbol{\tau} - \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})]. \quad (6.38)$$

Now we may define a state $\mathbf{y}(t) \in R^{2p}$ by $\mathbf{y} = (\xi \ \dot{\xi})$ and write the manipulator dynamics as

$$\dot{\mathbf{y}} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_p \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \mathbf{y} + \begin{pmatrix} \mathbf{0} \\ \mathbf{I}_p \end{pmatrix} \mathbf{u}. \quad (6.39)$$

This is a linear state-space system of the form

$$\dot{\mathbf{y}} = \mathbf{A}\mathbf{y} + \mathbf{B}\mathbf{u}, \quad (6.40)$$

driven by the control input \mathbf{u} . Due to the special form of \mathbf{A} and \mathbf{B} , this system is called the *Brunovsky canonical form* and it is always controllable from $\mathbf{u}(t)$.

Since (6.38) is said to be a *linearizing transformation* for the manipulator dynamic equation, one may invert this transformation to obtain the joint torque

$$\tau = \mathbf{H}(\mathbf{q})\mathbf{T}^+(\mathbf{q})(\mathbf{u} - \ddot{\mathbf{r}} - \dot{\mathbf{T}}\dot{\mathbf{q}}) + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}), \quad (6.41)$$

where \mathbf{T}^+ denotes the *Moore–Penrose inverse* of the transformation matrix $\mathbf{T}(\mathbf{q})$.

In the special case $\xi = \mathbf{e}_q(t)$, and if we select $\mathbf{u}(t)$ so that (6.39) is stable by the PD feedback $\mathbf{u} = -\mathbf{K}_P\xi - \mathbf{K}_V\dot{\xi}$, then $\mathbf{T} = -\mathbf{I}_n$ and the control input torque $\tau(t)$ defined by (6.41) makes the manipulator move in such a way that $\mathbf{y}(t)$ goes to zero. In this case, the feedback linearizing control and the inverse dynamics control become the same.

6.5.3 Passivity-Based Control

This method explicitly uses the passivity properties of the Lagrangian system [6.31,32]. In comparison with the inverse dynamics method, passivity-based controllers are expected to have better robust properties because they do not rely on the exact cancellation of the manipulator nonlinearities. The passivity-based control input is given by

$$\begin{aligned} \dot{\mathbf{q}}_r &= \dot{\mathbf{q}}_d + \alpha \mathbf{e}_q, \quad \alpha > 0, \\ \tau &= \mathbf{H}(\mathbf{q})\ddot{\mathbf{q}}_r + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_r + \tau_g(\mathbf{q}) + \mathbf{K}_V\dot{\mathbf{e}}_q + \mathbf{K}_P\mathbf{e}_q. \end{aligned} \quad (6.42)$$

With (6.42), we obtain the following closed-loop system

$$\mathbf{H}(\mathbf{q})\dot{s}_q + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})s_q + \mathbf{K}_V\dot{\mathbf{e}}_q + \mathbf{K}_P\mathbf{e}_q = \mathbf{0}, \quad (6.43)$$

where $s_q = \dot{\mathbf{e}}_q + \alpha \mathbf{e}_q$. Let us choose a Lyapunov function $V(\mathbf{y}, t)$ as follows:

$$\begin{aligned} V &= \frac{1}{2}\mathbf{y}^\top \begin{pmatrix} \alpha\mathbf{K}_V + \mathbf{K}_P + \alpha^2\mathbf{H} & \alpha\mathbf{H} \\ \alpha\mathbf{H} & \mathbf{H} \end{pmatrix} \mathbf{y} \\ &= \frac{1}{2}\mathbf{y}^\top \mathbf{P}\mathbf{y}. \end{aligned} \quad (6.44)$$

Since the above equation is positive definite, it has a unique equilibrium at the origin, i.e., $\mathbf{y} = (\mathbf{e}_q^\top, \dot{\mathbf{e}}_q^\top)^\top$

$= \mathbf{0}$. Moreover, V can be bounded by

$$\sigma_m \|\mathbf{y}\|^2 \leq \mathbf{y}^\top \mathbf{P}\mathbf{y} \leq \sigma_M \|\mathbf{y}\|^2, \quad \sigma_M \geq \sigma_m > 0. \quad (6.45)$$

The time derivative of V gives

$$\dot{V} = -\dot{\mathbf{e}}_q^\top \mathbf{K}_V \dot{\mathbf{e}}_q - \alpha \mathbf{e}_q^\top \mathbf{K}_P \mathbf{e}_q = -\mathbf{y}^\top \mathbf{Q} \mathbf{y} < 0, \quad (6.46)$$

where $\mathbf{Q} = \text{diag}[\alpha \mathbf{K}_P, \mathbf{K}_V]$. Since \mathbf{Q} is positive definite and quadratic in \mathbf{y} , it can be also bounded by

$$\kappa_m \|\mathbf{y}\|^2 \leq \mathbf{y}^\top \mathbf{Q} \mathbf{y} \leq \kappa_M \|\mathbf{y}\|^2, \quad \kappa_M \geq \kappa_m > 0. \quad (6.47)$$

Then, from the bound of the Lyapunov function V , we get

$$\dot{V} \leq -\kappa_m \|\mathbf{y}\|^2 = -2\eta V, \quad \eta = \frac{\kappa_m}{\sigma_M} \quad (6.48)$$

which finally yields

$$V(t) \leq V(0) e^{-2\eta t}. \quad (6.49)$$

It has been shown that the value of α affects the tracking result dramatically [6.33]. The manipulator tends to vibrate for small values of α . Larger values of α allow better tracking performance and protect s_q from being spoiled by the velocity measurement noise when the position error is small. In [6.34], it was suggested that

$$\mathbf{K}_P = \alpha \mathbf{K}_V \quad (6.50)$$

be used for quadratic optimization.

6.5.4 Summary

In this section, we have reviewed some of the model-based motion control methods proposed to date. Under some control approaches, the closed-loop system theoretically, gives either asymptotic stability or globally exponential stability. However, such ideal performance cannot be obtained in practical implementation because factors such as sampling rate, measurement noise, disturbances, and unmodeled dynamics will limit the achievable gain and the performance of the control algorithms [6.33, 35, 36].

6.6 Computed-Torque Control

Through the years many kinds of robot control schemes have been proposed. Most of these can be considered as special cases of the class of computed-torque control (Fig. 6.5) which is the technique of applying feedback

linearization to nonlinear systems in general [6.37, 38]. In the section, computed-torque control will be first introduced, and its variant, so-called computed-torque-like control, will be introduced later.

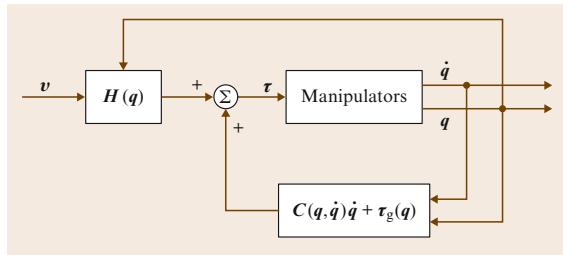

Fig. 6.5 Computed-torque control

6.6.1 Computed-Torque Control

Consider the control input (6.27)

$$\tau = \mathbf{H}(q)\mathbf{v} + \mathbf{C}(q, \dot{q})\dot{q} + \tau_g(q),$$

which is also known as computed-torque control; it consists of an inner nonlinear compensation loop and an outer loop with an exogenous control signal v . Substituting this control law into the dynamical model of the robot manipulator, it follows that

$$\ddot{q} = v. \quad (6.51)$$

It is important to note that this control input converts a complicated nonlinear controller design problem into a simple design problem for a linear system consisting of n decoupled subsystems. One approach to the outer-loop control v is propositional-derivative (PD) feedback, as in (6.28):

$$v = \ddot{q}_d + K_V \dot{e}_q + K_P e_q,$$

in which case the overall control input becomes

$$\tau = \mathbf{H}(q)(\ddot{q}_d + K_V \dot{e}_q + K_P e_q) + \mathbf{C}(q, \dot{q})\dot{q} + \tau_g(q),$$

and the resulting linear error dynamics are

$$\ddot{e}_q + K_V \dot{e}_q + K_P e_q = \mathbf{0}. \quad (6.52)$$

According to linear system theory, convergence of the tracking error to zero is guaranteed [6.29, 39].

Remark.

- One usually lets K_V and K_P be $(n \times n)$ diagonal positive-definite gain matrices (i.e., $K_V = \text{diag}(k_{V,1}, \dots, k_{V,n}) > \mathbf{0}$, $K_P = \text{diag}(k_{P,1}, \dots, k_{P,n}) > \mathbf{0}$) to guarantee the stability of the error system. However, the format of the foregoing control never leads to *independent joint control* because the outer-loop multiplier $\mathbf{H}(q)$ and the full nonlinear compensation term $\mathbf{C}(q, \dot{q})\dot{q} + \tau_g(q)$ in the

inner loop scramble all joint signals among different control channels.

6.6.2 Computed-Torque-Like Control

It is worth noting that the implementation of computed-torque control requires that parameters of the dynamical model are accurately known and the control input is computed in real time. In order to avoid those problems, several variations of this control scheme have been proposed, for example, computed-torque-like control. An entire class of computed-torque-like controllers can be obtained by modifying the computed-torque control as

$$\tau = \hat{\mathbf{H}}(q)v + \hat{\mathbf{C}}(q, \dot{q})\dot{q} + \hat{\tau}(q), \quad (6.53)$$

where $\hat{\cdot}$ represents the computed or nominal value and indicates that the theoretically exact feedback linearization cannot be achieved in practice due to the uncertainty in the systems. The overall control scheme is depicted in Fig. 6.6.

Computed-Torque-Like Control with Variable-Structure Compensation

Since there is parametric uncertainty, compensation is required in the outer-loop design to achieve trajectory tracking. The following shows a computed-torque-like control with variable-structure compensation

$$v = \ddot{q}_d + K_V \dot{e}_q + K_P e_q + \Delta v, \quad (6.54)$$

where the variable-structure compensation Δv is devised as

$$\Delta v = \begin{cases} -\rho(x, t) \frac{\mathbf{B}^\top \mathbf{P} x}{\|\mathbf{B}^\top \mathbf{P} x\|} & \text{if } \|\mathbf{B}^\top \mathbf{P} x\| \neq 0 \\ 0 & \text{if } \|\mathbf{B}^\top \mathbf{P} x\| = 0, \end{cases} \quad (6.55)$$

where $x = (e_q^\top, \dot{e}_q^\top)^\top$, $\mathbf{B} = (\mathbf{0}, \mathbf{I}_n)^\top$, \mathbf{P} is a $(2n \times 2n)$ symmetric positive-definite matrix satisfying

$$\mathbf{P}\mathbf{A} + \mathbf{A}^\top \mathbf{P} = -\mathbf{Q} \quad (6.56)$$

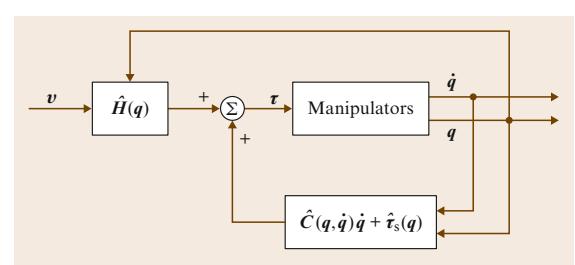

Fig. 6.6 Computed-torque-like control

with \mathbf{A} being defined as

$$\mathbf{A} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_n \\ -\mathbf{K}_P & -\mathbf{K}_V \end{pmatrix}, \quad (6.57)$$

\mathbf{Q} being any appropriate $(2n \times 2n)$ symmetric positive-definite matrix,

$$\rho(\mathbf{x}, t) = \frac{1}{1-\alpha} [\alpha\beta + \|\mathbf{K}\| \|\mathbf{x}\| + \bar{\mathbf{H}}\phi(\mathbf{x}, t)], \quad (6.58)$$

where α and β are positive constants such that $\|\mathbf{H}^{-1}(\mathbf{q})\hat{\mathbf{H}}(\mathbf{q}) - \mathbf{I}_n\| \leq \alpha < 1$ for all $\mathbf{q} \in R^n$ and $\sup_{t \in [0, \infty)} \|\ddot{\mathbf{q}}_d(t)\| < \beta$, respectively, \mathbf{K} is the $(n \times 2n)$ matrix defined as $\mathbf{K} = [\mathbf{K}_P \ \mathbf{K}_V]$, $\bar{\lambda}_H$ being a positive constant such that $\|\mathbf{H}^{-1}(\mathbf{q})\| \leq \bar{\lambda}_H$ for all $\mathbf{q} \in R^n$, and the function ϕ being defined as

$$\begin{aligned} & \|[\hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) - \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})]\dot{\mathbf{q}} + [\hat{\boldsymbol{\tau}}_g(\mathbf{q}) - \boldsymbol{\tau}_g(\mathbf{q})]\| \\ & \leq \phi(\mathbf{x}, t). \end{aligned} \quad (6.59)$$

Convergence of the tracking error to zero can be shown using the Lyapunov function

$$V = \mathbf{x}^\top \mathbf{P} \mathbf{x}, \quad (6.60)$$

following the stability analysis in [6.5, 40].

Remarks.

- By Property 6.1 in Sect. 6.1, there exist positive constants $\bar{\lambda}_H$ and $\bar{\lambda}_h$ such that $\bar{\lambda}_h \leq \|\mathbf{H}^{-1}(\mathbf{q})\| \leq \bar{\lambda}_H$ for all $\mathbf{q} \in R^n$. If we choose

$$\hat{\mathbf{H}} = \frac{1}{c} \mathbf{I}_n, \quad \text{where } c = \frac{\bar{\lambda}_H + \bar{\lambda}_h}{2}, \quad (6.61)$$

it can be shown that

$$\|\mathbf{H}^{-1}(\mathbf{q})\hat{\mathbf{H}}(\mathbf{q}) - \mathbf{I}_n\| \leq \frac{\bar{\lambda}_H - \bar{\lambda}_h}{\bar{\lambda}_H + \bar{\lambda}_h} \equiv \alpha < 1, \quad (6.62)$$

which indicates that there is always at least one choice of $\hat{\mathbf{H}}$ for some $\alpha < 1$.

- Due to the discontinuity in $\Delta \mathbf{v}$, chattering phenomenon may occur when the control scheme is applied. It is worth noting that chattering is often undesirable since the high-frequency component in the control can excite unmodeled dynamic effect (such as joint flexibility) [6.6, 29, 38]. In order to avoid chattering, the variable-structure compensation can be modified to become smooth, i.e.,

$$\Delta \mathbf{v} = \begin{cases} -\rho(\mathbf{x}, t) \frac{\mathbf{B}^\top \mathbf{P} \mathbf{x}}{\|\mathbf{B}^\top \mathbf{P} \mathbf{x}\|} & \text{if } \|\mathbf{B}^\top \mathbf{P} \mathbf{x}\| > \varepsilon, \\ \frac{-\rho(\mathbf{x}, t)}{\varepsilon} \mathbf{B}^\top \mathbf{P} \mathbf{x} & \text{if } \|\mathbf{B}^\top \mathbf{P} \mathbf{x}\| \leq \varepsilon, \end{cases} \quad (6.63)$$

where ε is a positive constant and is used as the boundary layer. Following this modification, convergence of tracking errors to a residual set can be ensured, and the size of this residual set can be made smaller by use of a smaller value of ε .

Computed-Torque-Like Control with Independent-Joint Compensation

Obviously, the previous compensation scheme is centralized, which implies that the online computation load is heavy and high-cost hardware is required for practical implementation. In order to solve this problem, a scheme with independent-joint compensation is introduced below. In this scheme, a computed-torque-like control is designed with estimates as

$$\hat{\mathbf{H}}(\mathbf{q}) = \mathbf{I}, \quad \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) = 0, \quad \hat{\boldsymbol{\tau}}(\mathbf{q}) = \mathbf{0}. \quad (6.64)$$

Then, we use the outer-loop \mathbf{v} as

$$\mathbf{v} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P e_q + \Delta \mathbf{v}, \quad (6.65)$$

where the positive constants \mathbf{K}_P and \mathbf{K}_V are selected to be sufficiently large, and the i -th component Δv_i of $\Delta \mathbf{v} = (v_1, \dots, v_n)^\top$ is

$$\Delta v_i = \begin{cases} -[\boldsymbol{\beta}^\top \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)]^2 \frac{s_i}{\varepsilon_i} & \text{if } |s_i| \leq \frac{\varepsilon_i}{\boldsymbol{\beta}^\top \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)}, \\ -\boldsymbol{\beta}^\top \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \frac{s_i}{|s_i|} & \text{if } |s_i| > \frac{\varepsilon_i}{\boldsymbol{\beta}^\top \mathbf{w}(\mathbf{q}_d, \dot{\mathbf{q}}_d)}. \end{cases} \quad (6.66)$$

In this compensation, $s_i = \dot{e}_{q,i} + \lambda_i e_{q,i}$, $i \in \{1, \dots, n\}$, and λ_i , $i \in \{1, \dots, n\}$ are positive constants. Furthermore, following the properties of robot manipulators, we have

$$\begin{aligned} & \|\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}}_d + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_d + \boldsymbol{\tau}_g(\mathbf{q})\| \\ & \leq \beta_1 + \beta_2 \|\mathbf{q}\| + \|\dot{\mathbf{q}}\| = \boldsymbol{\beta}^\top \mathbf{w}(\mathbf{q}, \dot{\mathbf{q}}) \end{aligned}$$

for some suitable positive constants β_1 , β_2 , and β_3 , where $\boldsymbol{\beta} = (\beta_1, \beta_2, \beta_3)^\top$ and

$$\mathbf{w}(\mathbf{q}, \dot{\mathbf{q}}) = [1, \|\mathbf{q}\|, \|\dot{\mathbf{q}}\|]^\top. \quad (6.67)$$

Finally, ε_i , $i \in \{1, \dots, n\}$, is the variable length of the boundary layer, satisfying

$$\dot{\varepsilon}_i = -g_i \varepsilon_i, \quad \varepsilon(0) > 0, \quad g_i > 0. \quad (6.68)$$

It is worth pointing out that the term \mathbf{w} in this control scheme is devised as the desired compensation rather than feedback. Furthermore, this scheme is in a form of independent-joint control and hence has the advantages introduced before. The convergence of the tracking error to zero can be shown using the Lyapunov function

$$V = \frac{1}{2}(\mathbf{e}_q^\top \dot{\mathbf{e}}_q^\top) \begin{pmatrix} \lambda \mathbf{K}_P & \mathbf{H} \\ \mathbf{H} & \lambda \mathbf{H} \end{pmatrix} \begin{pmatrix} \mathbf{e}_q \\ \dot{\mathbf{e}}_q \end{pmatrix} + \sum_{i=1}^n g_i^{-1} \varepsilon_i, \quad (6.69)$$

whose time derivative along the trajectory of the closed-loop systems follows

$$\dot{V} = -\alpha \left| \begin{pmatrix} \mathbf{e}_q \\ \dot{\mathbf{e}}_q \end{pmatrix} \right|^2 \quad (6.70)$$

with α being some positive constant, if sufficiently large \mathbf{K}_P and γ are used. The detailed analysis of stability, which requires Properties 6.3 and 6.4, can be found in [6.13].

Remark.

- Similar to computed-torque-like control with variable-structure compensation, we can consider the nonzero boundary layer as

$$\dot{\varepsilon}_i = -g_i \varepsilon_i, \quad \varepsilon(0) > 0, \quad g_i, \alpha_i > 0. \quad (6.71)$$

Following this modification, tracking errors converge to a residual set. The size of this residual set can be made smaller by the use of a smaller value of ε (i.e., smaller α_i).

For the task of point-to-point control, one PD controller with gravity compensation is designed with the estimates

$$\hat{\mathbf{H}}(\mathbf{q}) = \mathbf{I}, \quad \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{0}, \quad \hat{\boldsymbol{\tau}}_g(\mathbf{q}) = \boldsymbol{\tau}_g(\mathbf{q}) \quad (6.72)$$

with $\boldsymbol{\tau}_g(\mathbf{q})$ being the *gravity term* of the dynamical model of the robot manipulators. Then, we use the outer-loop \mathbf{v} as

$$\mathbf{v} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \quad (6.73)$$

such that the control input becomes

$$\boldsymbol{\tau} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q + \boldsymbol{\tau}_g(\mathbf{q}). \quad (6.74)$$

This scheme is much simpler to implement than the exact computed-torque controller. The convergence

of the tracking error to zero can be shown using the Lyapunov function

$$V = \frac{1}{2} \dot{\mathbf{e}}_q^\top \mathbf{H}(\mathbf{q}) \dot{\mathbf{e}}_q + \frac{1}{2} \mathbf{e}_q^\top \mathbf{K}_P \mathbf{e}_q, \quad (6.75)$$

whose time derivative along the solution trajectories of the closed-loop system is

$$\dot{V} = -\dot{\mathbf{e}}_q^\top \mathbf{K}_V \dot{\mathbf{e}}_q. \quad (6.76)$$

The detailed analysis of stability is given in [6.12]. It is necessary to note that this result is for the case of regulation, rather than for the case of tracking, since the former theoretical base, which relies on LaSalle's lemma, requires the system be autonomous (time invariant) [6.38, 41, 42].

Remark.

- If we neglect gravity in the dynamical model of the robot manipulators, then the gravity estimation can be omitted here, i.e., $\hat{\boldsymbol{\tau}}_g(\mathbf{q}) = \mathbf{0}$, so that the control law becomes

$$\boldsymbol{\tau} = \mathbf{v} = \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \quad (6.77)$$

which leads to pure PD control. The gain matrices, \mathbf{K}_P and \mathbf{K}_V , can be selected to be diagonal so that this PD control is in a form of independent-joint control developed based on the multijoint dynamic model.

6.6.3 Summary

In this section, we have presented two control schemes: the computed-torque and computed-torque-like control. The former transforms a multi-input multi-output (MIMO) nonlinear robotic system into a very simple decoupled linear closed-loop system whose control design is a well-established problem. Since the practical implementation of the former control requires preknowledge of all the manipulator parameters and its payload, which may not be realistic, the latter was introduced to relax the foregoing requirement and still to achieve the objective of tracking subject to system's uncertainty.

Further Reading

The PD control with different feedforward compensation for tracking control is investigated in [6.43]. An adaptive control scheme based on PD control is presented in [6.19].

6.7 Adaptive Control

An adaptive controller differs from an ordinary controller in that the controller parameters are time varying, and there is a mechanism for adjusting these parameters online based on some signals in the closed-loop systems. By the use of such control scheme, the control goal can be achieved even if there is parametric uncertainty in the plant. In this section, we will introduce several adaptive control schemes to deal with the case of imperfect knowledge of dynamical parameters of the robot manipulators. The control performance of those adaptive control schemes, including adaptive computed-torque control, adaptive inertia-related control, adaptive control based on passivity, and adaptive control with desired compensation, are basically derived from Property 6.5. Finally, the condition of persistent excitation, which is important in parameter convergence, will be addressed.

6.7.1 Adaptive Computed-Torque Control

The computed-torque control scheme is appealing, since it allows the designer to transform a **MIMO** highly coupled nonlinear system into a very simple decoupled linear system, whose control design is a well-established problem. However, this method of feedback linearization relies on perfect knowledge of the system parameters, and failure to have this will cause erroneous parametric estimates, resulting in a mismatch term in the closed-loop model of the error system. That term can be interpreted as a nonlinear perturbation acting at the input of the closed-loop system. In order to solve the problem due to parametric uncertainty, we instead consider the inverse dynamics method with parameter estimates of

$$\tau = \hat{H}(q)(\ddot{q}_d + K_v \dot{e}_q + K_p e_q) + \hat{C}(q, \dot{q})\dot{q} + \hat{\tau}_g(q), \quad (6.78)$$

where \hat{H} , \hat{C} , $\hat{\tau}_g$ have the same functional form as H , C , τ_g . From Property 6.5 of the dynamics model, we have

$$\hat{H}(q)\ddot{q} + \hat{C}(q, \dot{q})\dot{q} + \hat{\tau}_g(q) = Y(q, \dot{q}, \ddot{q})\hat{a}, \quad (6.79)$$

where $Y(q, \dot{q}, \ddot{q})$, called the regressor, is a known $(n \times r)$ function matrix and \hat{a} is the $(r \times 1)$ vector that summarizes all the estimated parameters. Substituting this control input τ into the manipulator dynamics gives the following closed-loop error model

$$\hat{H}(q)(\ddot{e}_q + K_v \dot{e}_q + K_p e_q) = Y(q, \dot{q}, \ddot{q})\tilde{a}, \quad (6.80)$$

where $\tilde{a} = \hat{a} - a$. In order to acquire an appropriate adaptive law, we first assume that the acceleration term \ddot{q} is

measurable, and that the estimated inertia matrix $\hat{H}(q)$ is never singular. Now, for convenience, the error equation is rewritten as

$$\dot{x} = Ax + B\hat{H}^{-1}(q)Y(q, \dot{q}, \ddot{q})\tilde{a} \quad (6.81)$$

with $x = (e_q^\top, \dot{e}_q^\top)^\top$,

$$A = \begin{pmatrix} \mathbf{0}_n & I_n \\ -K_P & -K_V \end{pmatrix}, \quad B = \begin{pmatrix} \mathbf{0}_n \\ I_n \end{pmatrix}. \quad (6.82)$$

The adaptive law is considered as

$$\dot{\tilde{a}} = -\Gamma^{-1}Y^\top(q, \dot{q}, \ddot{q})\hat{H}^{-1}(q)B^\top Px, \quad (6.83)$$

where Γ is an $(r \times r)$ positive-definite constant matrix, and P is a $(2n \times 2n)$ symmetric positive-definite constant matrix satisfying

$$PA + A^\top P = -Q, \quad (6.84)$$

with Q being a symmetric positive-definite constant matrix with coherent dimension. In this adaptive law, we made two assumptions:

- the joint acceleration \ddot{q} is measurable, and
- the bounded range of the unknown parameter is available.

The first assumption is to ensure that the regressor $Y(q, \dot{q}, \ddot{q})$ is known a priori, whereas the second assumption is to allow one to keep the estimate $\hat{H}(q)$ nonsingular by restricting the estimated parameter \hat{a} to lie within a range about the true parameter value.

Convergence of the tracking error and maintaining boundedness of all internal signals can actually be guaranteed by Lyapunov stability theory with the Lyapunov function

$$\dot{V} = -x^\top Q x. \quad (6.85)$$

Detailed stability analysis is given in [6.2].

Remark.

- For practical and theoretical reasons, the first assumption above is hardly acceptable. In most cases, it is not easy to obtain an accurate measure of acceleration; the robustness of the above adaptive control scheme with respect to such a disturbance has to be established. Moreover, from a pure theoretical viewpoint, measuring q, \dot{q}, \ddot{q} means that not only do we

need the whole system state vector, but we also need its derivative.

6.7.2 Adaptive Inertia-Related Control

Another adaptive control scheme is now introduced. This proposed scheme does not require the measurement of the manipulator's acceleration nor does it require inversion of the estimated inertia matrix. Hence, the drawbacks of the adaptive computed-torque control scheme are avoided. Let us consider the control input

$$\tau = \hat{H}(\mathbf{q})\dot{\mathbf{v}} + \hat{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \hat{\tau}_g(\mathbf{q}) + \mathbf{K}_{Ds}, \quad (6.86)$$

where the auxiliary signals \mathbf{v} and s are defined as $\mathbf{v} = \dot{\mathbf{q}}_d + \Lambda \mathbf{e}_q$ and $s = \mathbf{v} - \dot{\mathbf{q}} = \dot{\mathbf{e}}_q + \Lambda \mathbf{e}_q$, with Λ being an $(n \times n)$ positive-definite matrix. Following Property 6.5 of the dynamic model, we have

$$\mathbf{H}(\mathbf{q})\dot{\mathbf{v}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \tau_g(\mathbf{q}) = \bar{Y}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \dot{\mathbf{v}})\mathbf{a}, \quad (6.87)$$

where $\bar{Y}(\cdot, \cdot, \cdot, \cdot)$ is an $(n \times r)$ matrix of known time functions. The formulation above is the same type of the parameter separation that was used in the formulation of the adaptive computed-torque control. Note that $\bar{Y}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \dot{\mathbf{v}})$ is independent of the joint acceleration. Similar to the formulation above, we also have

$$\hat{H}(\mathbf{q})\dot{\mathbf{v}} + \hat{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \hat{\tau}_g(\mathbf{q}) = \bar{Y}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \dot{\mathbf{v}})\hat{\mathbf{a}}. \quad (6.88)$$

Substituting the control input into the equation of motion, it follows that

$$\begin{aligned} & \mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \tau_g(\mathbf{p}) \\ &= \hat{H}(\mathbf{q})\dot{\mathbf{v}} + \hat{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \hat{\tau}_g(\mathbf{q}) + \mathbf{K}_{Ds}. \end{aligned}$$

Since $\ddot{\mathbf{q}} = \dot{\mathbf{v}} - \dot{\mathbf{s}}$, $\dot{\mathbf{q}} = \mathbf{v} - \mathbf{s}$, the previous result can be rewritten as

$$\mathbf{H}(\mathbf{q})\dot{\mathbf{s}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\mathbf{s} + \mathbf{K}_{Ds} = \bar{Y}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \dot{\mathbf{v}})\tilde{\mathbf{a}}, \quad (6.89)$$

where $\tilde{\mathbf{a}} = \hat{\mathbf{a}} - \mathbf{a}$. The adaptive law is considered as

$$\dot{\tilde{\mathbf{a}}} = -\boldsymbol{\Gamma}\bar{Y}^T(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{v}, \dot{\mathbf{v}})\mathbf{s}. \quad (6.90)$$

The convergence of the tracking error to zero with boundedness on all internal signals can be shown through Lyapunov stability theory using the following Lyapunov-like function

$$V = \frac{1}{2}\mathbf{s}^\top \mathbf{H}(\mathbf{q})\mathbf{s} + \frac{1}{2}\tilde{\mathbf{a}}^\top \boldsymbol{\Gamma}^{-1}\tilde{\mathbf{a}}, \quad (6.91)$$

whose time derivative along the trajectories of the closed-loop systems can be found to be

$$\dot{V} = -\mathbf{s}^\top \mathbf{K}_{Ds}. \quad (6.92)$$

The detailed stability analysis is given in [6.32].

Remark.

- The restrictions for adaptive computed-torque control formerly seen have been removed here.
- The term \mathbf{K}_{Ds} introduces a PD-type linear stabilizing control action to the error system model.
- The estimated parameters converge to the true parameters provided the reference trajectory satisfies the condition of persistency of excitation,

$$\begin{aligned} \alpha_1 \mathbf{I}_r &\leq \int_{t_0}^{t_0+t} \mathbf{Y}^\top(\mathbf{q}_d, \dot{\mathbf{q}}_d, \mathbf{v}, \dot{\mathbf{v}}) \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \mathbf{v}, \dot{\mathbf{v}}) dt \\ &\leq \alpha_2 \mathbf{I}_r, \end{aligned}$$

for all t_0 , where α_1 , α_2 , and t are all positive constants.

6.7.3 Adaptive Control Based on Passivity

Taking a physics viewpoint of control, we see that the concept of passivity has become popular for the development of adaptive control schemes. Here, we illustrate how the concept of passivity can be used to design a class of adaptive control laws for robot manipulators. First, we define an auxiliary filtered tracking error signal \mathbf{r} as

$$\mathbf{r} = \mathbf{F}^{-1}(s)\mathbf{e}_q, \quad (6.93)$$

where

$$\mathbf{F}^{-1}(s) = \left[s\mathbf{I}_n + \frac{1}{s}\mathbf{K}(s) \right] \quad (6.94)$$

and s is the Laplace transform variable. The $(n \times n)$ matrix $\mathbf{K}(s)$ is chosen such that $\mathbf{F}(s)$ is a strictly proper, stable transfer function matrix. As in the preceding schemes, the adaptive control strategies has close ties to the ability to separate the known functions from the unknown constant parameters. We use the expression given above to define

$$\begin{aligned} \mathbf{Z}\boldsymbol{\varphi} &= \mathbf{H}(\mathbf{q})[\ddot{\mathbf{q}}_d + \mathbf{K}(s)\mathbf{e}_q] \\ &+ \mathbf{V}(\mathbf{q}, \dot{\mathbf{q}}) \left[\dot{\mathbf{q}}_d + \frac{1}{s}\mathbf{K}(s)\mathbf{e}_q \right] + \tau_g(\mathbf{q}), \end{aligned}$$

where \mathbf{Z} is a known $(n \times r)$ regression matrix and $\boldsymbol{\varphi}$ is a vector of unknown system parameters in the adaptive context. It is important to note that the above can be arranged such that \mathbf{Z} and \mathbf{r} do not depend on the measurement of the joint acceleration $\dot{\mathbf{q}}$. The adaptive control scheme given here is called the passivity approach because the mapping of $-\mathbf{r} \rightarrow \mathbf{Z}\tilde{\boldsymbol{\varphi}}$ is constructed to be

a passive mapping. That is, we develop an adaptive law such that

$$\int_0^t -\mathbf{r}^\top(\sigma) \mathbf{Z}(\sigma) \ddot{\mathbf{q}}(\sigma) d\sigma \geq -\beta \quad (6.95)$$

is satisfied for all time and for some positive scalar constant β . For this class of adaptive controllers, the control input is given by

$$\boldsymbol{\tau} = \mathbf{Z}\dot{\boldsymbol{\phi}} + \mathbf{K}_D \mathbf{r}, \quad (6.96)$$

Detailed analysis of stability is given in [6.44].

Remarks.

- If $\mathbf{K}(s)$ is selected such that $\mathbf{H}(s)$ has a relative degree of one, \mathbf{Z} and \mathbf{r} will not depend on $\ddot{\mathbf{q}}$.
- Many types of control schemes can be generated from the adaptive passive control approach by selected different transfer function matrices $\mathbf{K}(s)$ in the definition of \mathbf{r} .
- Note that, by defining $\mathbf{K}(s) = s\Lambda$ such that $\mathbf{F}(s) = (s\mathbf{I}_n + \Lambda)^{-1}$, we have the control input

$$\boldsymbol{\tau} = \mathbf{Z}\hat{\boldsymbol{\phi}} - \mathbf{K}_D \mathbf{r},$$

with

$$\begin{aligned} \mathbf{Z}\hat{\boldsymbol{\phi}} &= \hat{\mathbf{H}}(\mathbf{q})(\ddot{\mathbf{q}}_d + \Lambda \dot{\mathbf{e}}_q) + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})(\dot{\mathbf{q}}_d + \Lambda \mathbf{e}_q) \\ &\quad + \hat{\boldsymbol{\tau}}_g(\mathbf{q}). \end{aligned}$$

The adaptive law may be chosen as

$$\dot{\boldsymbol{\phi}} = \boldsymbol{\Gamma} \mathbf{Z}^\top (\dot{\mathbf{e}}_q + \Lambda \mathbf{e}_q)$$

to satisfy the condition of passive mapping. This indicates that adaptive inertia-related control can be viewed as a special case of adaptive passive control.

6.7.4 Adaptive Control with Desired Compensation

In order to implement the adaptive control scheme, one needs to calculate the elements of $\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ in real time. However, this procedure may be excessively time consuming since it involves computations with highly nonlinear functions of joint position and velocity. Consequently, the real-time implementation of such a scheme is rather difficult. To overcome this difficulty, the adaptive control with desired compensation was proposed and is discussed here. In other words, the variables \mathbf{q} , $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$ are replaced with the desired ones, namely, \mathbf{q}_d ,

$\dot{\mathbf{q}}_d$, and $\ddot{\mathbf{q}}_d$. Since the desired quantities are known in advance, all their corresponding calculations can be performed offline, which renders real-time implementation more plausible. Let us consider the control input

$$\boldsymbol{\tau} = \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)\hat{\mathbf{a}} + k_a s + k_p \mathbf{e}_q + k_n \|\mathbf{e}_q\|^2 s, \quad (6.97)$$

where the positive constants k_a , k_p , and k_n are sufficiently large, and the auxiliary signal s is defined as $s = \dot{\mathbf{e}}_q + \mathbf{e}_q$. The adaptive law is considered as

$$\dot{\hat{\mathbf{a}}} = -\boldsymbol{\Gamma} \mathbf{Y}^\top(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)s. \quad (6.98)$$

It is worth noting that the desired compensation is adopted in both the control and adaptive laws such that the computational load can be drastically reduced. For the sake of this analysis, we note that

$$\begin{aligned} &\|\mathbf{Y}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})\mathbf{a} - \mathbf{Y}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)\hat{\mathbf{a}}\| \\ &\leq \zeta_1 \|\mathbf{e}_q\| + \zeta_2 \|\mathbf{e}_q\|^2 + \zeta_3 \|s\| + \zeta_4 \|s\| \|\mathbf{e}_q\|, \end{aligned}$$

where ζ_1 , ζ_2 , ζ_3 , and ζ_4 are positive constants. In order to achieve trajectory tracking, it is required that

$$\begin{aligned} k_a &> \zeta_2 + \zeta_4, \\ k_p &> \frac{\zeta_1}{2} + \frac{\zeta_2}{4}, \\ k_n &> \frac{\zeta_1}{2} + \zeta_3 + \frac{\zeta_2}{4}, \end{aligned}$$

(i.e., the gains k_a , k_p , and k_n must be sufficiently large). The convergence of the tracking error to zero with boundedness on all internal signals can be proved through application of Lyapunov stability theory with the following Lyapunov-like function

$$V = \frac{1}{2} s^\top \mathbf{H}(\mathbf{q}) s + \frac{1}{2} k_p \mathbf{e}_q^\top \mathbf{e}_q + \frac{1}{2} \tilde{\mathbf{a}}^\top \boldsymbol{\Gamma}^{-1} \tilde{\mathbf{a}}, \quad (6.99)$$

whose time derivative along the trajectories of the closed-loop system can be derived as

$$\dot{V} \leq -\mathbf{x}^\top \mathbf{Q} \mathbf{x}, \quad (6.100)$$

where

$$\mathbf{x} = \begin{pmatrix} \|\mathbf{e}_q\| \\ \|s\| \end{pmatrix}, \quad \mathbf{Q} = \begin{pmatrix} k_p - \zeta_2/4 & -\zeta_1/2 \\ -\zeta_1/2 & k_n - \zeta_3 - \zeta_4/4 \end{pmatrix}.$$

Detailed stability analysis can be found in [6.45].

6.7.5 Summary

Since the computed-torque control suffers from parametric uncertainty, a variety of adaptive control schemes

have been proposed. Firstly, we have presented an adaptive control scheme based on computed-torque control. Then, in order to overcome the mentioned drawbacks such as the measurability of the joint acceleration and the invertibility of the estimated inertia matrix, we presented an alternative adaptive control scheme that is free of these drawbacks. Recently, to incorporate a physics viewpoint into control, adaptive passivity-based control has become popular, and hence is introduced and discussed here. Finally, to reduce the computational load of the adaptive schemes, we presented an adaptive control with desired compensation.

Further Reading

A computationally very fast scheme dealing with adaptive control of rigid manipulators was presented in [6.46]. The stability analysis was completed by assuming that the joint dynamics are decoupled, i. e., that each joint is considered as an independent second-order linear system. Other pioneering works in the field can be found, for example, in [6.47, 48]; although none of the fundamental dynamic model properties are used, the complete dynamics are taken into account, but the control input is discontinuous and may lead to chattering. Positive definiteness of the inertia matrix is explicitly used in [6.49], although it was assumed that some time-varying quantities remain constant during the adap-

tation. It is interesting to note that all of these schemes were based on the concept of model reference adaptive control (MRAC) developed in [6.50] for linear systems. Therefore, they are conceptually very different from the truly nonlinear schemes presented in this section.

A passive-based modified version of the least-squares estimation scheme has been proposed in [6.51] and [6.52], which guaranteed closed-loop stability of the scheme. Other schemes can be found in [6.53], where no use is made of the skew-symmetry property, and in [6.54], where the recursive Newton–Euler formulations is used instead of the Lagrange formulation to derive the manipulator dynamics, and thus computation is simplified to facilitate practical implementation.

Even though adaptive control provides a solution to the problem of parametric uncertainty, the robustness of adaptive controllers remains a topic of great interest in the field. Indeed, measurement noise or unmodeled dynamics (e.g., flexibility) may result in unbounded closed-loop signals. In particular, the estimated parameters may diverge; this is a well-known phenomenon in adaptive control and is called parameter drift. Solutions inspired from the adaptive control of linear systems have been studied [6.55, 56], where a modified estimation ensures boundedness of the estimates. In [6.57], the controller in [6.32] is modified to enhance robustness.

6.8 Optimal and Robust Control

Given a nonlinear system, such as robotic manipulators, one can develop many stabilizing controls [6.29, 41]. In other words, the stability of the control system cannot determine a unique controller. It is natural that one seeks an optimal controller among the many stable ones. However, the design of an optimal controller is possible provided that a rather exact information on the target system is available, such as an exact system model [6.34, 58]. In the presence of discrepancy between the real system and its mathematical model, a designed optimal controller is no longer optimal, and may even end up being unstable in the actual system. Generally speaking, the optimal control design framework is not the best one to deal with system uncertainty. To handle system uncertainty from the control design stage, a robust control design framework is necessary [6.59]. One of main objectives of robust control is to keep the controlled system stable even in presence of uncertainties in the mathematical model, unmodeled dynamics, and the like.

Let us consider an affine nonlinear system described by nonlinear time-varying differential equation in the state $\mathbf{x} = (x_1, x_2, \dots, x_n)^\top \in R^n$

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}, t) + \mathbf{G}(\mathbf{x}, t)\mathbf{u} + \mathbf{P}(\mathbf{x}, t)\mathbf{w}, \quad (6.101)$$

where $\mathbf{u} \in R^m$ is the control input, and $\mathbf{w} \in R^w$ is the disturbance. Without disturbances or unmodeled dynamics, the system simplifies to

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}, t) + \mathbf{G}(\mathbf{x}, t)\mathbf{u}. \quad (6.102)$$

Actually, there are many kinds of methods describing the nonlinear system according to the objective of control [6.1, 16, 21, 23, 34, 53].

6.8.1 Quadratic Optimal Control

Every optimal controller is based on its own cost function [6.60, 61]. One can define a cost function as [6.62, 63]

$$z = \mathbf{H}(\mathbf{x}, t)\mathbf{x} + \mathbf{K}(\mathbf{x}, t)\mathbf{u}$$

such that $\mathbf{H}^\top(\mathbf{x}, t)\mathbf{K}(\mathbf{x}, t) = \mathbf{0}$, $\mathbf{K}^\top(\mathbf{x}, t)\mathbf{K}(\mathbf{x}, t) = \mathbf{R}(\mathbf{x}, t) > \mathbf{0}$, and $\mathbf{H}^\top(\mathbf{x}, t)\mathbf{H}(\mathbf{x}, t) = \mathbf{Q}(\mathbf{x}, t) > \mathbf{0}$. Then, we have

$$\frac{1}{2}\mathbf{z}^\top\mathbf{z} = \frac{1}{2}\mathbf{x}^\top\mathbf{Q}(\mathbf{x}, t)\mathbf{x} + \frac{1}{2}\mathbf{u}^\top\mathbf{R}(\mathbf{x}, t)\mathbf{u}.$$

The quadratic optimal control for the system (6.102) is found by solving, for a first order differentiable positive-definite function $V(\mathbf{x}, t)$, the Hamilton–Jacobi–Bellman (HJB) equation [6.34, 58]

$$\begin{aligned} 0 &= \text{HJB}(\mathbf{x}, t; V) = V_t(\mathbf{x}, t) + V_x(\mathbf{x}, t)f(\mathbf{x}, t) \\ &\quad - \frac{1}{2}V_x(\mathbf{x}, t)\mathbf{G}(\mathbf{x}, t)\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^\top(\mathbf{x}, t)V_x^\top(\mathbf{x}, t) \\ &\quad + \frac{1}{2}\mathbf{Q}(\mathbf{x}, t), \end{aligned}$$

where $V_t = \frac{\partial V}{\partial t}$ and $V_x = \frac{\partial V}{\partial \mathbf{x}^\top}$. Then the quadratic optimal control is defined by

$$\mathbf{u} = -\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^\top(\mathbf{x}, t)V_x^\top(\mathbf{x}, t). \quad (6.103)$$

Note that the HJB equation is a nonlinear second-order partial differential equation in $V(\mathbf{x}, t)$.

Unlike the aforementioned optimal control problem, the so-called inverse quadratic optimal control problem is to find a set of $\mathbf{Q}(\mathbf{x}, t)$ and $\mathbf{R}(\mathbf{x}, t)$ for which the HJB equation has a solution $V(\mathbf{x}, t)$. Then the inverse quadratic optimal control is defined by (6.103).

6.8.2 Nonlinear \mathcal{H}_∞ Control

When disturbances are not negligible, one can deal with their effect such that

$$\int_0^t \mathbf{z}^\top(\mathbf{x}, \tau)\mathbf{z}(\mathbf{x}, \tau)d\tau \leq \gamma^2 \int_0^t \mathbf{w}^\top \mathbf{w} d\tau, \quad (6.104)$$

where $\gamma > 0$ specifies the L_2 -gain of the closed-loop system from the disturbance input \mathbf{w} to the cost variable \mathbf{z} . This is called the L_2 -gain attenuation requirement [6.62–64]. One systematic way to design an optimal and robust control is given by the nonlinear \mathcal{H}_∞ optimal control. Let $\gamma > 0$ be given, by solving the following equation:

$$\begin{aligned} \text{HJI}_\gamma(\mathbf{x}, t; V) &= V_t(\mathbf{x}, t) + V_x(\mathbf{x}, t)f(\mathbf{x}, t) \\ &\quad - \frac{1}{2}V_x(\mathbf{x}, t)\{\mathbf{G}(\mathbf{x}, t)\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^\top(\mathbf{x}, t) \\ &\quad - \gamma^{-2}\mathbf{P}(\mathbf{x}, t)\mathbf{P}^\top(\mathbf{x}, t)\}V_x^\top(\mathbf{x}, t) \\ &\quad + \frac{1}{2}\mathbf{Q}(\mathbf{x}, t) \leq 0, \end{aligned} \quad (6.105)$$

then the control is defined by

$$\mathbf{u} = -\mathbf{R}^{-1}(\mathbf{x}, t)\mathbf{G}^\top(\mathbf{x}, t)V_x^\top(\mathbf{x}, t). \quad (6.106)$$

The partial differential inequality (6.105) is called the Hamilton–Jacobi–Isaac (HJI) inequality. Then one can define the inverse nonlinear \mathcal{H}_∞ optimal control problem that finds a set of $\mathbf{Q}(\mathbf{x}, t)$ and $\mathbf{R}(\mathbf{x}, t)$ such that the L_2 -gain requirement is achieved for a prescribed L_2 -gain γ [6.65].

Two things deserve further comment. The first is that the L_2 -gain requirement is only valid for disturbance signals \mathbf{w} whose L_2 -norm is bounded. The second is that \mathcal{H}_∞ optimal control is not uniquely defined. Hence, one can choose a quadratic optimal among many \mathcal{H}_∞ optimal controllers. Precisely speaking, the control (6.106) should be called \mathcal{H}_∞ suboptimal control, since the desired L_2 -gain is prescribed a priori. A true \mathcal{H}_∞ optimal control is to find a minimal value of γ , such that the L_2 -gain requirement is achieved.

6.8.3 Passivity-Based Design of Nonlinear \mathcal{H}_∞ Control

There are many methodologies for the design of optimal and/or robust controls. Among these, passivity-based controls can take full advantage of the properties described above [6.31]. They consist of two parts: one coming from the reference motion compensation while preserving the passivity of the system, and the other to achieve stability, robustness, and/or optimality [6.65, 66].

Let us suppose that the dynamic parameters are identified as $\widehat{\mathbf{H}}(\mathbf{q})$, $\widehat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})$, and $\widehat{\boldsymbol{\tau}}_g(\mathbf{q})$, whose counterparts are $\mathbf{H}(\mathbf{q})$, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$, and $\boldsymbol{\tau}_g(\mathbf{q})$, respectively. Then, passivity-based control generates the following tracking control laws

$$\mathbf{r} = \widehat{\mathbf{H}}(\mathbf{q})\ddot{\mathbf{q}}_{\text{ref}} + \widehat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}_{\text{ref}} + \widehat{\boldsymbol{\tau}}_g(\mathbf{q}) - \mathbf{u}, \quad (6.107)$$

where $\ddot{\mathbf{q}}_{\text{ref}}$ is the reference acceleration defined by

$$\ddot{\mathbf{q}}_{\text{ref}} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \quad (6.108)$$

where $\mathbf{K}_V = \text{diag}\{kv_{i,i}\} > 0$ and $\mathbf{K}_P = \text{diag}\{kp_{i,i}\} > 0$. Two parameters are involved in generating the reference acceleration. Sometimes the following alternative method can be adopted

$$\ddot{\mathbf{q}}_{\text{ref}} = \ddot{\mathbf{q}}_d + \mathbf{K}_V \dot{\mathbf{e}}_q^\top.$$

This reduces the order of the closed-loop system because the state $\mathbf{x} = (\mathbf{e}_q^\top, \dot{\mathbf{e}}_q^\top)^\top$ is sufficient for the system

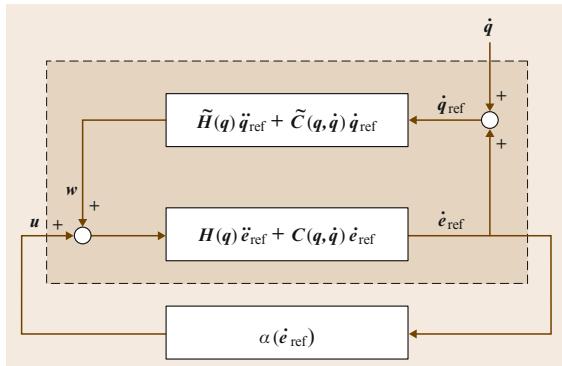

Fig. 6.7 The closed-loop system according to (6.109)

description, while the definition of (6.108) requires the state $\mathbf{x} = (\int \mathbf{e}_q^\top, \mathbf{e}_q^\top, \dot{\mathbf{e}}_q^\top)^\top$.

The closed-loop dynamics under the control is given by

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{e}}_{ref} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{e}}_{ref} = \mathbf{u} + \mathbf{w}, \quad (6.109)$$

where

$$\begin{aligned}\ddot{\mathbf{e}}_{ref} &= \ddot{\mathbf{e}}_q + \mathbf{K}_V \dot{\mathbf{e}}_q + \mathbf{K}_P \mathbf{e}_q, \\ \dot{\mathbf{e}}_{ref} &= \dot{\mathbf{e}}_q + \mathbf{K}_V \mathbf{e}_q + \mathbf{K}_P \int \mathbf{e}_q.\end{aligned}$$

If $\mathbf{d}(t) = 0$ and $\widehat{\mathbf{H}} = \mathbf{H}$, $\widehat{\mathbf{C}} = \mathbf{C}$, $\widehat{\boldsymbol{\tau}}_g = \boldsymbol{\tau}_g$, then $\mathbf{w} = 0$. Otherwise, the disturbance is defined as

$$\mathbf{w} = \widetilde{\mathbf{H}}(\mathbf{q})\ddot{q}_{ref} + \widetilde{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{q}_{ref} + \widetilde{\boldsymbol{\tau}}_g(\mathbf{q}) + \mathbf{d}(t), \quad (6.110)$$

where $\widetilde{\mathbf{H}} = \mathbf{H} - \widehat{\mathbf{H}}$, $\widetilde{\mathbf{C}} = \mathbf{C} - \widehat{\mathbf{C}}$, and $\widetilde{\boldsymbol{\tau}}_g = \widehat{\boldsymbol{\tau}}_g - \boldsymbol{\tau}_g$. It is of particular interest that the system (6.109) defines a passive mapping between $\mathbf{u} + \mathbf{w}$ and $\dot{\mathbf{e}}_{ref}$.

According to the manner in which the auxiliary control input \mathbf{u} is specified, passivity-based control can achieve stability, robustness, and/or optimality.

6.8.4 A Solution to Inverse Nonlinear \mathcal{H}_∞ Control

Let us define the auxiliary control input by the reference-error feedback

$$\mathbf{u} = -\alpha \mathbf{R}^{-1}(\mathbf{x}, t) \dot{\mathbf{e}}_{ref}, \quad (6.111)$$

where $\alpha > 1$ is arbitrary. Then, the control provides the inverse nonlinear \mathcal{H}_∞ optimality.

Theorem 6.1 Inverse Nonlinear \mathcal{H}_∞ Optimality [6.65]

Let the reference acceleration generation gain matrices \mathbf{K}_V and \mathbf{K}_P satisfy

$$\mathbf{K}_V^2 > 2\mathbf{K}_P. \quad (6.112)$$

Then for a given $\gamma > 0$, the reference error feedback

$$\mathbf{u} = -\mathbf{K} \dot{\mathbf{e}}_{ref} = -\mathbf{K} \left(\dot{\mathbf{e}}_q + \mathbf{K}_V \mathbf{e}_q + \mathbf{K}_P \int \mathbf{e}_q \right) \quad (6.113)$$

satisfies the L_2 -gain attenuation requirement for

$$\mathbf{Q} = \begin{pmatrix} \mathbf{K}_P^2 \mathbf{K}_\gamma & 0 & 0 \\ 0 & (\mathbf{K}_V^2 - 2\mathbf{K}_P) \mathbf{K}_\gamma & 0 \\ 0 & 0 & \mathbf{K}_\gamma \end{pmatrix}, \quad (6.114)$$

$$\mathbf{R} = \mathbf{K}^{-1}, \quad (6.115)$$

provided that

$$\mathbf{K}_\gamma = \mathbf{K} - \frac{1}{\gamma^2} \mathbf{I} > 0. \quad (6.116)$$

Given γ , one can set $\mathbf{K} = \alpha \frac{1}{\gamma^2} \mathbf{I}$ for $\alpha > 1$. This yields

$$\mathbf{K}_\gamma = (\alpha - 1) \frac{1}{\gamma^2} \mathbf{I}.$$

When the inertia matrix is identified as a diagonal constant matrix such as $\widehat{\mathbf{H}} = \text{diag}\{\widehat{m}_i\}$, one should set $\widetilde{\mathbf{C}} = \mathbf{0}$. In addition, one can set $\widetilde{\boldsymbol{\tau}}_g = \mathbf{0}$. Then this results in a decoupled PID control of the form

$$\begin{aligned}t_i &= \widehat{m}_i (\ddot{q}_{d,i} + k_{V,i} \dot{e}_{q,i} + k_{P,i} e_{q,i}) \\ &\quad + \alpha \frac{1}{\gamma^2} \left(\dot{e}_{q,i} + k_{V,i} e_{q,i} + k_{P,i} \int e_{q,i} \right)\end{aligned}$$

for $\alpha > 1$, which can be rewritten as

$$\begin{aligned}t_i &= \widehat{m}_i \ddot{q}_{d,i} + \left(\widehat{m}_i k_{V,i} + \alpha \frac{1}{\gamma^2} \right) \dot{e}_{q,i} \\ &\quad + \left(\widehat{m}_i k_{P,i} + \alpha \frac{k_{V,i}}{\gamma^2} \right) e_{q,i} + \alpha \frac{k_{P,i}}{\gamma^2} \int e_{q,i}.\end{aligned} \quad (6.117)$$

This leads to a PID control with the desired acceleration feedforward [6.67] given by

$$t_i = \widehat{m}_i \ddot{q}_{d,i} + k_{V,i}^* \dot{e}_{q,i} + k_{P,i}^* e_{q,i} + k_{I,i}^* \int e_{q,i}, \quad (6.118a)$$

where

$$k_{V,i}^* = \widehat{m}_i k_{V,i} + \alpha \frac{1}{\gamma^2}, \quad (6.118b)$$

$$k_{P,i}^* = \widehat{m}_i k_{P,i} + \alpha \frac{k_{V,i}}{\gamma^2}, \quad (6.118c)$$

$$k_{I,i}^* = \alpha \frac{k_{P,i}}{\gamma^2}. \quad (6.118d)$$

6.9 Digital Implementation

Most controllers introduced in the previous sections are digitally implemented on microprocessors. In this section basic but essential practical issues related to their computer implementation are discussed. When the controller is implemented on a computer control system, the analog inputs are read and the outputs are set with a certain sampling period. This is a drawback compared to analog implementations, since sampling introduces time delays into the control loop. Figure 6.8 shows the overall block diagram of control system with a boxed digital implementation part. When a digital computer is used to implement a control law, it is convenient to divide coding sequence in the interrupt routine into four process routines, as shown in Fig. 6.9. Reading the input signal from sensors and writing the control signal to digital-to-analog (D/A) converters synchronized at the correct frequency is very important. Therefore, these processes are located in the first routine. After saving counter values and extracting D/A values, which are already calculated one step before, the next routine produces reference values. Control routines with filters follow and produce scalar or vector control outputs. Finally, the user interface for checking parameter values is made and will be used for tuning and debugging.

6.9.1 Reference Trajectory Generation

Reference trajectory generation is a starting point and is used as a target value of control. It is a set of

values referred to the set point in every interrupt of the control processor and is therefore called the motion profile. Proper design of this profile is important because tracking and settling errors are very sensitive to it, since the target of the practical servo control is not regulating but tracking. A general trapezoidal shape profile is simple to calculate and constant current is required during acceleration and deceleration periods. However, large jerks occur at both ends of the motion, resulting in vibration. Large jerks (rapid change in acceleration, and therefore rapid changes in force) could cause substantial damage to the dynamic systems and induce unwanted vibrations, therefore a smoother profile is required, although this needs more calculation time. A simple motion profile using a third-order polynomial is as follows.

$$\begin{aligned}y(t) &= a + bt + ct^2 + dt^3, \\ \dot{y}(t) &= b + 2ct + 3dt^2, \\ \ddot{y}(t) &= 2c + 6dt.\end{aligned}$$

In practice, the motion profile equations are normalized and programmed as functions. With the constraints

$$\begin{aligned}y(0) &= 0, & y(1) &= 1, \\ \dot{y}(0) &= 0, & \dot{y}(1) &= 0,\end{aligned}$$

the program code takes the form shown in (6.119) when moving time and distance are normalized.

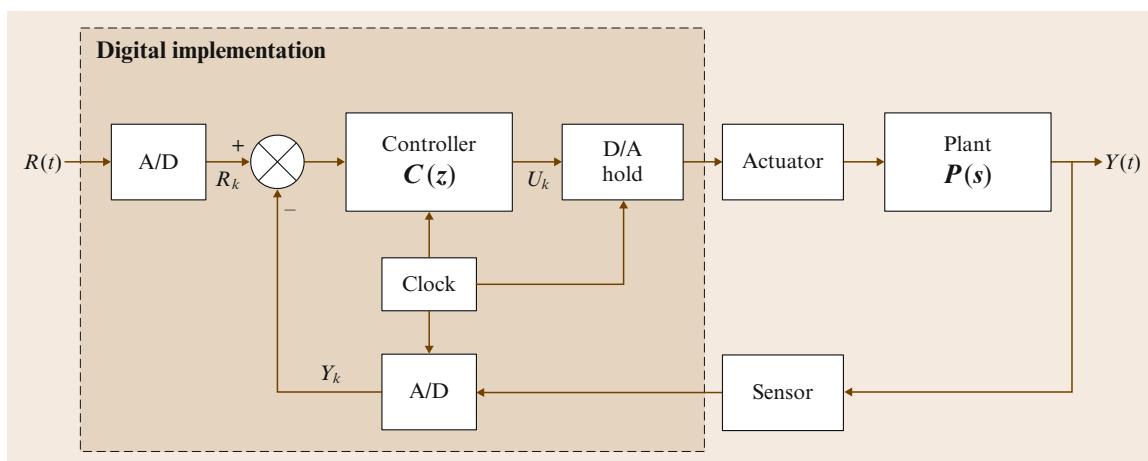

Fig. 6.8 Digital implementation of system control

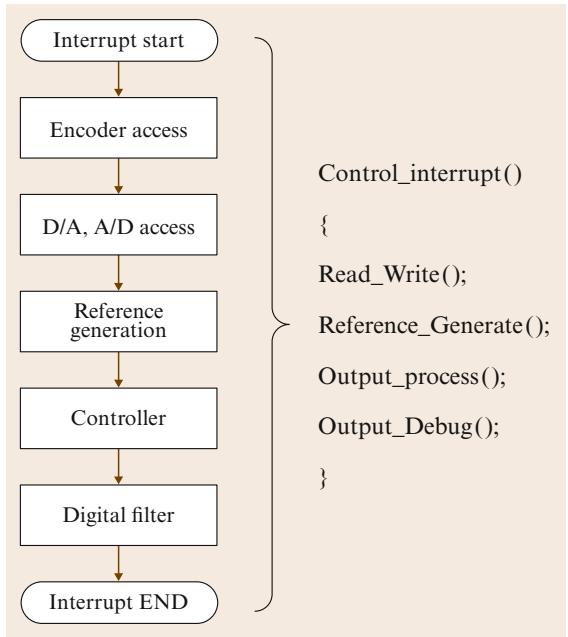

Fig. 6.9 The sequence in the interrupt routine for digital control

$$\begin{aligned}
 y\left(\frac{t}{T}\right) &= \left[3\left(\frac{t}{T}\right)^2 - 2\left(\frac{t}{T}\right)^3 \right] S, \\
 \dot{y}\left(\frac{t}{T}\right) &= \left[\frac{6}{T}\left(\frac{t}{T}\right) - \frac{6}{T}\left(\frac{t}{T}\right)^2 \right] S, \\
 \ddot{y}\left(\frac{t}{T}\right) &= \left[\frac{6}{T^2} - \frac{12}{T^2}\left(\frac{t}{T}\right) \right] S, \\
 \dddot{y}\left(\frac{t}{T}\right) &= -\frac{12}{T^3} S,
 \end{aligned} \tag{6.119}$$

where S is the distance and T is the time for motion.

For high-speed servo systems, the jerk profile is constant during runtime with large changes at start and stop. This means that high mechanical stiffness is required. Even though the calculation load increases, either fifth- or seventh-order polynomial profiles can be designed in order to satisfy acceleration or jerk constraints.

The motion profile is often saved in read-only memory (ROM) in the form of a table or located in the interrupt routine *Reference_Generate()* in the form of a function, as shown in Fig. 6.9. In most tracking servo control problem, a position profile is generated. However, velocity and acceleration are also calculated in the interrupt routine in real time to be used as inputs for the feedforward control. These are able to improve the

tracking performance, and the algorithm is as follows:

$$\begin{aligned}
 Pos_{ref} &= PosTable(pointer) \times Distance; \\
 Vel_{ref} &= Pos_{ref} - Pos_{ref,OLD} \\
 Acc_{ref} &= Vel_{ref} - Vel_{ref,OLD} \\
 &\vdots
 \end{aligned} \tag{6.120}$$

where Vel_{ref} and Acc_{ref} do not mean the real reference velocity and acceleration, but the reference velocity scaled by the interrupt time interval and the acceleration scaled by the square of the interrupt time interval, respectively, for practical use. Also, the limited size of the registers of a digital signal processor (DSP) or processor can cause errors due to the loss of significant digits when the velocity profile is calculated from the position profile using the simple difference formula in (6.120). This means that the velocity profile includes a periodic noise signal. This kind of numerical error creates real noise in the motion and reduces the performance of the control system when profiles of velocity, acceleration, and jerk are used as inputs for the feedforward control system for high-speed tracking.

Instead of the simple difference in (6.120), numerical differential equations can be used. Equation (6.121) shows the first-order backward-difference equations, which are the simplest form,

$$\begin{aligned}
 \dot{y}_k &= \frac{y_k - y_{k-1}}{\Delta t}, \\
 \ddot{y}_k &= \frac{y_k - 2y_{k-1} + y_{k-2}}{\Delta t^2}, \\
 \dddot{y}_k &= \frac{y_k - 3y_{k-1} + 3y_{k-2} - y_{k-3}}{\Delta t^3}.
 \end{aligned} \tag{6.121}$$

Saving each profiles in the form of a table can be another good method if the memory is large enough.

The important thing is that the maximum specification for the movement of controlled system, such as speed or acceleration or even jerk, should be considered in the profile design step. If the profile forces the system to breach the maximum specification, the possibility for the system to be driven recklessly is greatly increased due to missing of encoder pulses.

6.9.2 Z-Transform for Coding

Continuous-time systems are transformed into discrete-time systems by using the Z-transform. A discrete-time system is used to obtain a mathematical model that gives the behavior of a physical process at the sampling points, although the physical process is still a continuous-time

system. A Laplace transform is used for the analysis of control system in the s -domain. In most cases, the design of controllers and filters are done using tools in the s -domain. In order to realize those results in program code, understanding the Z -transform is essential. All controllers and filters designed in the s -domain can be easily translated to a program code through a Z -transform because it has the form of digitized difference sequences.

A coding PID controller is used as an example. In transfer-function form, this controller has the basic structure

$$\frac{Y(s)}{E(s)} = K_P + \frac{K_I}{s} + sK_V . \quad (6.122)$$

There are several methods for transformation from the frequency to the discrete domain. For stability conservation, backward Euler and Tustin algorithms are often used. Though the Tustin algorithm is known as the more exact one, the backward Euler algorithm is utilized in the following procedure.

After substituting the backward Euler equation into (6.122),

$$s \cong \frac{z - 1}{zT}$$

the following discrete form is produced

$$\frac{Y(z)}{E(z)} = \frac{\alpha + \beta z^{-1} + \gamma z^{-2}}{T(1 - z^{-1})} , \quad (6.123)$$

where

$$\begin{aligned} \alpha &= K_I T^2 + K_P T + K_V , \\ \beta &= -K_P T - 2K_V , \\ \gamma &= K_V . \end{aligned}$$

Now, this is rearranged using the difference equation:

$$\begin{aligned} T(y_k - y_{k-1}) &= \alpha e_k + \beta e_{k-1} + \gamma e_{k-2} , \\ y_k &= y_{k-1} + \frac{1}{T}(\alpha e_k + \beta e_{k-1} + \gamma e_{k-2}) , \\ y_k - y_{k-1} &= +\frac{\alpha}{T}e_k + \frac{\beta}{T}e_{k-1} + \frac{\gamma}{T}e_{k-2} . \end{aligned} \quad (6.124)$$

6.10 Learning Control

Since many robotic applications, such as pick-and-place operations, paintings, and circuit-board assembly, involve repetitive motions, it is natural to consider the use

This can be directly coded in the program as follows:

$$\begin{aligned} e_k &= p_{k,\text{ref}} - p_k , \\ e_k^v &= v_{k,\text{ref}} - v_k \\ &= (p_{k,\text{ref}} - p_{k-1,\text{ref}}) - (p_k - p_{k-1}) \\ &= e_k - e_{k-1} , \\ \text{sum}_k &= \text{sum}_{k-1} + e_k = \sum_{j=0}^k e_j , \\ y_k &= K_{P,c}e_k + K_{V,c}(e_k - e_{k-1}) + K_{I,c}\text{sum}_k , \\ y_k - y_{k-1} &= \\ &= (K_{P,c}e_k - K_{P,c}e_{k-1}) \\ &\quad + [K_{V,c}(e_k - e_{k-1})] - [K_{V,c}(e_{k-1} - e_{k-2})] \\ &\quad + (K_{I,c}\text{sum}_k - K_{I,c}\text{sum}_{k-1}) \\ &= (K_{P,c} + K_{V,c} + K_{I,c})e_k \\ &\quad - (K_{P,c} + 2K_{V,c})e_{k-1} + K_{V,c}e_{k-2} , \end{aligned} \quad (6.125)$$

where p_k is the present position, v_k is the present velocity, ref means reference, and c means code.

Comparing the parameters in (6.124) and (6.125), one obtains

$$\begin{aligned} \frac{\alpha}{T} &= K_P + \frac{K_V}{T} + K_I T = (K_{P,c} + K_{V,c} + K_{I,c}) , \\ \frac{\beta}{T} &= -K_P - \frac{2K_V}{T} = -(K_{P,c} + 2K_{V,c}) , \\ \frac{\gamma}{T} &= \frac{K_V}{T} = K_{V,c} , \end{aligned}$$

which shows that there is a relation between the designed and coded forms of the gains:

$$\begin{aligned} K_{P,c} &= K_P , \\ K_{V,c} &= \frac{K_V}{T} , \\ K_{I,c} &= K_I T . \end{aligned} \quad (6.126)$$

As the sampling frequency is increased in the same system, the coded K_V gain should be increased and the coded K_I gain should be decreased. Using this method, the designed controller can be coded in a DSP or microprocessor. However, sufficient analysis and simulation for control algorithms should be performed beforehand to obtain successful control system performance.

of data gathered in previous cycles to try to improve the performance of the manipulator in subsequent cycles. This is the basic idea of repetitive control or learn-

ing control. Consider the robot model given in Sect. 6.1 and suppose that one is given a desired joint trajectory $\mathbf{q}_d(t)$ on a finite time interval $0 \leq t \leq T$. The reference trajectory \mathbf{q}_d is used in repeated trials of the manipulator, assuming either that the trajectory is periodic, $\mathbf{q}_d(T) = \mathbf{q}_d(0)$, (repetitive control) or that the robot is reinitialized to lie on the desired trajectory at the beginning of each trial (learning control). Hereafter, we use the term learning control to mean either repetitive or learning control.

6.10.1 Pure P-type Learning Control

Let $\boldsymbol{\tau}_k$ be the input torque during the k -th cycle, which produces an output $\mathbf{q}_k(t)$, $0 \leq t \leq T_{\text{bnd}}$. Now, let us consider the following set of assumptions:

- Assumption 1: Every trial ends at a fixed time of duration $T_{\text{bnd}} > 0$.
- Assumption 2: Repetition of the initial setting is satisfied.
- Assumption 3: Invariance of the system dynamics is ensured throughout these repeated trials.
- Assumption 4: Every output \mathbf{q}_k can be measured and thus the error signal $\Delta \mathbf{q}_k = \mathbf{q}_k - \mathbf{q}_d$ can be utilized in the construction of the next input $\boldsymbol{\tau}_{k+1}$.
- Assumption 5: The dynamics of the robot manipulators is invertible.

The learning control problem is to determine a recursive learning law \mathbf{L}

$$\boldsymbol{\tau}_{k+1} = \mathbf{L}[\boldsymbol{\tau}_k(t), \Delta \mathbf{q}_k(t)], \quad 0 \leq t \leq T_{\text{bnd}}, \quad (6.127)$$

where $\Delta \mathbf{q}_k(t) = \mathbf{q}_k(t) - \mathbf{q}_d(t)$, such that $\|\Delta \mathbf{q}_k\| \rightarrow 0$ as $k \rightarrow \infty$ in some suitably defined function norm, $\|\cdot\|$. The initial control input can be any control input that produces a stable output, such as PD control. Such learning control schemes are attractive because accurate models of the dynamics need not be known a priori.

Several approaches have been used to generate a suitable learning law \mathbf{L} and to prove convergence of the output error. A pure P-type learning law is one of the form

$$\boldsymbol{\tau}_{k+1}(t) = \boldsymbol{\tau}_k(t) - \boldsymbol{\Phi} \Delta \mathbf{q}_k(t), \quad (6.128)$$

and is given this name because the correction term for the input torque at each iteration is proportional to the error $\Delta \mathbf{q}_k$. Now let $\boldsymbol{\tau}_d$ be defined by the computed-torque control, i.e.,

$$\begin{aligned} \boldsymbol{\tau}_d(t) = & \mathbf{H}[\mathbf{q}_d(t)] \ddot{\mathbf{q}}_d(t) + \mathbf{C}[\mathbf{q}_d(t), \dot{\mathbf{q}}_d(t)] \dot{\mathbf{q}}_d(t) \\ & + \boldsymbol{\tau}_g[\mathbf{q}_d(t)]. \end{aligned} \quad (6.129)$$

One should recall that the function $\boldsymbol{\tau}_k$ actually does not need to be computed; it is sufficient to know that it exists. Considering the P-type learning control law, we have

$$\Delta \boldsymbol{\tau}_{k+1}(t) = \Delta \boldsymbol{\tau}_k(t) - \boldsymbol{\Phi} \Delta \mathbf{q}_k(t), \quad (6.130)$$

where $\Delta \boldsymbol{\tau}_k(t) = \boldsymbol{\tau}_k(t) - \boldsymbol{\tau}_d(t)$, so that

$$\|\Delta \boldsymbol{\tau}_{k+1}(t)\|^2 \leq \|\Delta \boldsymbol{\tau}_k(t)\|^2 - \beta \|\boldsymbol{\Phi} \Delta \mathbf{q}_k(t)\|^2 \quad (6.131)$$

provided there exist positive constant λ and β such that

$$\int_0^{T_{\text{bnd}}} e^{-\lambda t} \Delta \mathbf{q}_k^\top \Delta \boldsymbol{\tau}_k(t) dt \geq \frac{1+\beta}{2} \|\boldsymbol{\Phi} \Delta \mathbf{q}_k(t)\|^2 \quad (6.132)$$

for all k . It then follows from the inequality above that $\Delta \mathbf{q}_k \rightarrow 0$ in the norm sense as $k \rightarrow \infty$. Detailed stability analysis of this control scheme is given in [6.68, 69].

6.10.2 P-Type Learning Control with a Forgetting Factor

Although pure P-type learning control achieves the desired goal, several strict assumptions may be not valid in actual implementations, for example, there may be an initial setting error. Furthermore, there may be small but nonrepeatable fluctuations of dynamics. Finally, there may exit a (bounded) measurement noise $\boldsymbol{\xi}_k$ such that

$$\Delta \mathbf{q}_k(t) + \boldsymbol{\xi}_k(t) = [\mathbf{q}_k(t) + \boldsymbol{\xi}_k(t)] - \mathbf{q}_d(t). \quad (6.133)$$

Thus the learning control scheme may fail. In order to enhance the robustness of P-type learning control, a forgetting factor is introduced in the form

$$\begin{aligned} \boldsymbol{\tau}_{k+1}(t) = & (1-\alpha) \boldsymbol{\tau}_k(t) + \alpha \boldsymbol{\tau}_0(t) \\ & - \boldsymbol{\Phi} [\Delta \mathbf{q}_k(t) + \boldsymbol{\xi}_k(t)]. \end{aligned} \quad (6.134)$$

The original idea of using a forgetting factor in learning control originated with [6.70].

It has been rigorously proven that P-type learning control with a forgetting factor guarantees convergence to a neighborhood of the desired one of size $O(\alpha)$. Moreover, if the content of a long-term memory is refreshed after every k trials, where k is of $O(1/\alpha)$, then the trajectories converge to an ε -neighborhood of the desired control goal. The size of ε is dependent on the magnitude of the initial setting error, the nonrepeatable fluctuations of the dynamics, and the measurement noise. For a detailed stability investigation, please refer to [6.71, 72].

6.10.3 Summary

By applying learning control, the performance of repetitive tasks (such as painting or pick-and-place operation) is improved by utilizing data gathered in the previous cycles. In this section, two learning control schemes were introduced. First, pure P-type learning control and its ro-

bustness problem were described. Then P-type learning control with a forgetting factor was presented, enhancing the robustness of learning control.

Further Reading

Rigorous and refined exploration of learning control is first discussed independently in [6.2, 12].

Force Control

Luigi Villani, Joris De Schutter

A fundamental requirement for the success of a manipulation task is the capability to handle the physical contact between a robot and the environment. Pure motion control turns out to be inadequate because the unavoidable modeling errors and uncertainties may cause a rise of the contact force, ultimately leading to an unstable behavior during the interaction, especially in the presence of rigid environments. Force feedback and force control becomes mandatory to achieve a robust and versatile behavior of a robotic system in poorly structured environments as well as safe and dependable operation in the presence of humans. This chapter starts from the analysis of *indirect force control* strategies, conceived to keep the contact forces limited by ensuring a suitable compliant behavior to the end effector, without requiring an accurate model of the environment. Then the problem of *interaction tasks* modeling is analyzed, considering both the case of a rigid environment and the case of a compliant environment. For the specification of an interaction task, natural constraints set by the task geometry and artificial constraints set by the control strategy are established, with respect to suitable task frames. This formula-

tion is the essential premise to the synthesis of hybrid force/motion control schemes.

7.1 Background

Research on robot force control has flourished in the past three decades. Such a wide interest is motivated by the general desire of providing robotic systems with enhanced sensory capabilities. Robots using force, touch, distance, and visual feedback are expected to autonomously operate in unstructured environments other than the typical industrial shop floor.

Since the early work on telemanipulation, the use of force feedback was conceived to assist the human op-

erator in the remote handling of objects with a slave manipulator. More recently, cooperative robot systems have been developed where two or more manipulators (viz. the fingers of a dexterous robot hand) are to be controlled so as to limit the exchanged forces and avoid squeezing of a commonly held object. Force control plays a fundamental role also in the achievement of robust and versatile behavior of robotic systems in open-ended environments, providing intelligent response in

unforeseen situations and enhancing human–robot interaction.

7.1.1 From Motion Control to Interaction Control

Control of the physical interaction between a robot manipulator and the environment is crucial for the successful execution of a number of practical tasks where the robot end-effector has to manipulate an object or perform some operation on a surface. Typical examples in industrial settings include polishing, deburring, machining or assembly. A complete classification of possible robot tasks, considering also nonindustrial applications, is practically infeasible in view of the large variety of cases that may occur, nor would such a classification be really useful to find a general strategy to control the interaction with the environment.

During contact, the environment may set constraints on the geometric paths that can be followed by the end-effector, denoted as *kinematic constraints*. This situation, corresponding to the contact with a stiff surface, is generally referred to as *constrained motion*. In other cases, the contact task is characterized by a dynamic interaction between the robot and the environment that can be inertial (as in pushing a block), dissipative (as in sliding on a surface with friction) or elastic (as in pushing against an elastically compliant wall). In all these cases, the use of a pure motion control strategy for controlling interaction is prone to failure, as explained below.

Successful execution of an interaction task with the environment by using motion control could be obtained only if the task were accurately planned. This would in turn require an accurate model of both the robot manipulator (kinematics and dynamics) and the environment (geometry and mechanical features). A manipulator model may be known with sufficient precision, but a detailed description of the environment is difficult to obtain.

To understand the importance of task planning accuracy, it is sufficient to observe that in order to perform a mechanical part mating with a positional approach the relative positioning of the parts should be guaranteed with an accuracy of an order of magnitude greater than part mechanical tolerance. Once the absolute position of one part is exactly known, the manipulator should guide the motion of the other with the same accuracy.

In practice, the planning errors may give rise to a contact force and moment, causing a deviation of the end-effector from the desired trajectory. On the other hand, the control system reacts to reduce such devia-

tions. This ultimately leads to a build-up of the contact force until saturation of the joint actuators is reached or breakage of the parts in contact occurs.

The higher the environment stiffness and position control accuracy are, the more easily a situation like the one just described can occur. This drawback can be overcome if a *compliant behavior* is ensured during the interaction. This compliant behavior can be achieved either in a passive or in an active fashion.

Passive Interaction Control

In passive interaction control the trajectory of the robot end-effector is modified by the interaction forces due to the inherent compliance of the robot. The compliance may be due to the structural compliance of the links, joints, and end-effector, or to the compliance of the position servo. Soft robot arms with elastic joints or links are purposely designed for intrinsically safe interaction with humans. In industrial applications, a mechanical device with passive compliance, known as the remote center of compliance (**RCC**) device [7.1], is widely adopted. An **RCC** is a compliant end-effector mounted on a rigid robot, designed and optimized for peg-into-hole assembly operations.

The passive approach to interaction control is very simple and cheap, because it does not require force/torque sensors; also, the preprogrammed trajectory of the end-effector must not be changed at execution time; moreover, the response of a passive compliance mechanism is much faster than active repositioning by a computer control algorithm. However, the use of passive compliance in industrial applications lacks flexibility, since for every robotic task a special-purpose compliant end-effector has to be designed and mounted. Also, it can only deal with small position and orientation deviations of the programmed trajectory. Finally, since no forces are measured, it can not guarantee that high contact forces will never occur.

Active Interaction Control

In active interaction control, the compliance of the robotic system is mainly ensured by a purposely designed control system. This approach usually requires the measurement of the contact force and moment, which are fed back to the controller and used to modify or even generate online the desired trajectory of the robot end-effector.

Active interaction control may overcome the aforementioned disadvantages of passive interaction control, but it is usually slower, more expensive, and more sophisticated. To obtain a reasonable task execution speed

and disturbance rejection capability, active interaction control has to be used in combination with some degree of passive compliance [7.2]: feedback, by definition, always comes after a motion and force error has occurred, hence some passive compliance is needed in order to keep the reaction forces below an acceptable threshold.

Force Measurements

For a general force-controlled task, six force components are required to provide complete contact force information: three translational force components and three torques. Often, a force/torque sensor is mounted at the robot wrist [7.3], but other possibilities exist, for example, force sensors can be placed on the fingertips of robotic hands [7.4]; also, external forces and moments can be estimated via shaft torque measurements of joint torque sensors [7.5, 6]. However, the majority of the applications of force control (including industrial applications) is concerned with wrist force/torque sensors. In this case, the weight and inertia of the tool mounted between the sensor and the environment (i.e., the robot end-effector) is assumed to be negligible or suitably compensated from the force/torque measurements. The force signals may be obtained using strain measurements, which results in a stiff sensor, or deformation measurements (e.g., optically), resulting in a compliant sensor. The latter approach has an advantage if additional passive compliance is desired.

7.1.2 From Indirect Force Control to Hybrid Force/Motion Control

Active interaction control strategies can be grouped into two categories: those performing indirect force control and those performing direct force control. The main difference between the two categories is that the former achieve force control via motion control, without explicit closure of a force feedback loop; the latter instead offer the possibility of controlling the contact force and moment to a desired value, thanks to the closure of a force feedback loop.

To the first category belongs *impedance control* (or *admittance control*) [7.7, 8], where the deviation of the end-effector motion from the desired motion due to the interaction with the environment is related to the contact force through a mechanical impedance/admittance with adjustable parameters. A robot manipulator under impedance (or admittance) control is described by an equivalent mass–spring–damper system with adjustable parameters. This relationship is an impedance if the robot control reacts to the motion deviation by gener-

ating forces, while it corresponds to an admittance if the robot control reacts to interaction forces by imposing a deviation from the desired motion. Special cases of impedance and admittance control are *stiffness control* and *compliance control* [7.9], respectively, where only the static relationship between the end-effector position and orientation deviation from the desired motion and the contact force and moment is considered. Notice that, in the robot control literature, the terms impedance control and admittance control are often used to refer to the same control scheme; the same happens for stiffness and compliance control. Moreover, if only the relationship between the contact force and moment and the end-effector linear and angular velocity is of interest, the corresponding control scheme is referred to as *damping control* [7.10].

Indirect force control schemes do not require, in principle, measurements of contact forces and moments; the resulting impedance or admittance is typically nonlinear and coupled. However, if a force/torque sensor is available, then force measurements can be used in the control scheme to achieve a linear and decoupled behavior.

Differently from indirect force control, direct force control requires an explicit model of the interaction task. In fact, the user has to specify the desired motion and the desired contact force and moment in a consistent way with respect to the constraints imposed by the environment. A widely adopted strategy belonging to this category is *hybrid force/motion control*, which aims at controlling the motion along the unconstrained task directions and force (and moment) along the constrained task directions. The starting point is the observation that, for many robotic tasks, it is possible to introduce an orthogonal reference frame, known as the compliance frame [7.11] (or task frame [7.12]) which allows one to specify the task in terms of natural and artificial constraints acting along and about the three orthogonal axes of this frame. Based on this decomposition, hybrid force/motion control allows simultaneous control of both the contact force and the end-effector motion in two mutually independent subspaces. Simple selection matrices acting on both the desired and feedback quantities serve this purpose for planar contact surfaces [7.13], whereas suitable projection matrices must be used for general contact tasks, which can also be derived from the explicit constraint equations [7.14–16]. Several implementation of hybrid motion control schemes are available, e.g., based on inverse dynamics control in the operational space [7.17], passivity-based control [7.18], or outer force control

loops closed around inner motion loops, typically available in industrial robots [7.2].

If an accurate model of the environment is not available, the force control action and the motion control action can be superimposed, resulting in a *parallel*

force/position control scheme. In this approach, the force controller is designed so as to dominate the motion controller; hence, a position error would be tolerated along the constrained task directions in order to ensure force regulation [7.19].

7.2 Indirect Force Control

To gain insight into the problems arising at the interaction between the end-effector of a robot manipulator and the environment, it is worth analyzing the effects of a motion control strategy in the presence of a contact force and moment. To this aim, assume that a reference frame Σ_e is attached to the end-effector, and let p_e denote the position vector of the origin and R_e the rotation matrix with respect to a fixed base frame. The end-effector velocity is denoted by the 6×1 twist vector $v_e = (\dot{p}_e^\top \omega_e^\top)^\top$ where \dot{p}_e is the translational velocity and ω_e the angular velocity, and can be computed from the $n \times 1$ joint velocity vector \dot{q} using the linear mapping

$$v_e = J(q)\dot{q}. \quad (7.1)$$

The matrix J is the $6 \times n$ end-effector geometric Jacobian. For simplicity, the case of nonredundant nonsingular manipulators is considered; therefore, $n = 6$ and the Jacobian is a square nonsingular matrix. The force f_e and moment m_e applied by the end-effector to the environment are the components of the wrench $h_e = (f_e^\top \ m_e^\top)^\top$.

It is useful to consider the operational space formulation of the dynamic model of a rigid robot manipulator in contact with the environment

$$\Lambda(q)v_e + \Gamma(q, \dot{q})v_e + \eta(q) = h_c - h_e, \quad (7.2)$$

where $\Lambda(q) = (JH(q)^{-1}J^\top)^{-1}$ is the 6×6 operational space inertia matrix, $\Gamma(q, \dot{q}) = J^{-\top}C(q, \dot{q})J^{-1} - \Lambda(q)J^\top J^{-1}$ is the wrench including centrifugal and Coriolis effects, and $\eta(q) = J^{-\top}g(q)$ is the wrench of the gravitational effects; $H(q)$, $C(q, \dot{q})$ and $g(q)$ are the corresponding quantities defined in the joint space. The vector $h_c = J^{-\top}\tau$ is the equivalent end-effector wrench corresponding to the input joint torques τ .

7.2.1 Stiffness Control

In the classical operational space formulation, the end-effector position and orientation is described by a 6×1 vector $x_e = (p_e^\top \ \varphi_e^\top)^\top$, where φ_e is a set of Euler angles

extracted from R_e . Hence, a desired end-effector position and orientation can be assigned in terms of a vector x_d , corresponding to the position of the origin p_d and the rotation matrix R_d of a desired frame Σ_d . The end-effector error can be denoted as $\Delta x_{de} = x_d - x_e$, and the corresponding velocity error, assuming a constant x_d , can be expressed as $\Delta \dot{x}_{de} = -\dot{x}_e = -A^{-1}(\varphi_e)v_e$, with

$$A(\varphi_e) = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & T(\varphi_e) \end{pmatrix},$$

where I is the 3×3 identity matrix, $\mathbf{0}$ is a 3×3 null matrix, and T is the 3×3 matrix of the mapping $\omega_e = T(\varphi_e)\dot{\varphi}_e$, depending on the particular choice of the Euler angles.

Consider the motion control law

$$h_c = A^{-\top}(\varphi_e)K_P\Delta x_{de} - K_D v_e + \eta(q), \quad (7.3)$$

corresponding to a simple PD + gravity compensation control in the operational space, where K_P and K_D are symmetric and positive-definite 6×6 matrices.

In the absence of interaction with the environment (i.e., when $h_e = \mathbf{0}$), the equilibrium $v_e = \mathbf{0}$, $\Delta x_{de} = \mathbf{0}$ for the closed-loop system, corresponding to the desired position and orientation for the end-effector, is asymptotically stable. The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2}v_e^\top \Lambda(q)v_e + \frac{1}{2}\Delta x_{de}^\top K_P \Delta x_{de},$$

whose time derivative along the trajectories of the closed-loop system is the negative semidefinite function

$$\dot{V} = -v_e^\top K_D v_e. \quad (7.4)$$

In the presence of a constant wrench h_e , using a similar Lyapunov argument, a different asymptotically stable equilibrium can be found, with a nonnull Δx_{de} . The new equilibrium is the solution of the equation

$$A^{-\top}(\varphi_e)K_P\Delta x_{de} - h_e = \mathbf{0},$$

which can be written in the form

$$\Delta x_{de} = K_P^{-1}A^\top(\varphi_e)h_e, \quad (7.5)$$

or, equivalently, as

$$\mathbf{h}_e = \mathbf{A}^{-\top}(\boldsymbol{\varphi}_e) \mathbf{K}_P \Delta \mathbf{x}_{de}. \quad (7.6)$$

Equation (7.6) shows that in the steady state the end-effector, under a proportional control action on the position and orientation error, behaves as a six-degree-of-freedom (DOF) spring in respect of the external force and moment \mathbf{h}_e . Thus, the matrix \mathbf{K}_P plays the role of an *active stiffness*, ensuring that it is possible to act on the elements of \mathbf{K}_P so as to ensure a suitable elastic behavior of the end-effector during the interaction. Analogously, (7.5) represents a compliance relationship, where the matrix \mathbf{K}_P^{-1} plays the role of an *active compliance*. This approach, consisting of assigning a desired position and orientation and a suitable static relationship between the deviation of the end-effector position and orientation from the desired motion and the force exerted on the environment, is known as *stiffness control*.

The selection of the stiffness/compliance parameters is not easy, and strongly depends on the task to be executed. A higher value of the active stiffness means a higher accuracy of the position control at the expense of higher interaction forces. Hence, if it is expected to meet some physical constraint in a particular direction, the end-effector stiffness in that direction should be made low to ensure low interaction forces. Conversely, along the directions where physical constraints are not expected, the end-effector stiffness should be made high so as to follow closely the desired position. This allows discrepancies between the desired and achievable positions due to the constraints imposed by the environment to be resolved without excessive contact forces and moments.

It must be pointed out, however, that a selective stiffness behavior along different directions cannot be effectively assigned in practice on the basis of (7.6). This can easily be understood by using the classical definition of a mechanical stiffness for two bodies connected by a 6-DOF spring, in terms of the linear mapping between the infinitesimal twist displacement of the two bodies at an unloaded equilibrium and the elastic wrench.

In the case of the active stiffness, the two bodies are, respectively, the end-effector, with the attached frame Σ_e , and a virtual body, attached to the desired frame Σ_d . Hence, from (7.6), the following mapping can be derived

$$\mathbf{h}_e = \mathbf{A}^{-\top}(\boldsymbol{\varphi}_e) \mathbf{K}_P \mathbf{A}^{-1}(\boldsymbol{\varphi}_e) \Delta \mathbf{x}_{de}, \quad (7.7)$$

in the case of an infinitesimal twist displacement $\Delta \mathbf{x}_{de}$ defined as

$$\Delta \mathbf{x}_{de} = \begin{pmatrix} \Delta \mathbf{p}_{de} \\ \Delta \boldsymbol{\theta}_{de} \end{pmatrix} = \begin{pmatrix} \Delta \dot{\mathbf{p}}_{de} \\ \Delta \boldsymbol{\omega}_{de} \end{pmatrix} dt = - \begin{pmatrix} \dot{\mathbf{p}}_e \\ \boldsymbol{\omega}_e \end{pmatrix} dt,$$

where $\Delta \dot{\mathbf{p}}_{de} = \dot{\mathbf{p}}_d - \dot{\mathbf{p}}_e$ is the time derivative of the position error $\Delta \mathbf{p}_{de} = \mathbf{p}_d - \mathbf{p}_e$ and $\Delta \boldsymbol{\omega}_{de} = \boldsymbol{\omega}_d - \boldsymbol{\omega}_e$ is the angular velocity error. Equation (7.7) shows that the actual stiffness matrix is $\mathbf{A}^{-\top}(\boldsymbol{\varphi}_e) \mathbf{K}_P \mathbf{A}^{-1}(\boldsymbol{\varphi}_e)$, which depends on the end-effector orientation through the vector $\boldsymbol{\varphi}_e$, so that, in practice, the selection of the stiffness parameters is quite difficult.

This problem can be overcome by defining a *geometrically consistent active stiffness*, with the same structure and properties as ideal mechanical springs.

Mechanical Springs

Consider two elastically coupled rigid bodies A and B and two reference frames Σ_a and Σ_b , attached to A and B , respectively. Assuming that at equilibrium frames Σ_a and Σ_b coincide, the compliant behavior near the equilibrium can be described by the linear mapping

$$\mathbf{h}_b^b = \mathbf{K} \Delta \mathbf{x}_{ab}^b = \begin{pmatrix} \mathbf{K}_t & \mathbf{K}_c \\ \mathbf{K}_c^\top & \mathbf{K}_o \end{pmatrix} \Delta \mathbf{x}_{ab}^b, \quad (7.8)$$

where \mathbf{h}_b^b is the elastic wrench applied to body B , expressed in frame B , in the presence of an infinitesimal twist displacement $\Delta \mathbf{x}_{ab}^b$ of frame Σ_a with respect to frame Σ_b , expressed in frame B . The elastic wrench and the infinitesimal twist displacement in (7.8) can also be expressed equivalently in frame Σ_a , since Σ_a and Σ_b coincide at equilibrium. Therefore, $\mathbf{h}_b^b = \mathbf{h}_a^a$ and $\Delta \mathbf{x}_{ab}^b = \Delta \mathbf{x}_{ab}^a$; moreover, for the elastic wrench applied to body A , $\mathbf{h}_a^a = \mathbf{K}_t \Delta \mathbf{x}_{ba}^a = -\mathbf{h}_b^b$ being $\Delta \mathbf{x}_{ba}^a = -\Delta \mathbf{x}_{ab}^b$. This property of the mapping (7.8) is known as *port symmetry*.

In (7.8), \mathbf{K} is the 6×6 symmetric positive-semidefinite stiffness matrix. The 3×3 matrices \mathbf{K}_t and \mathbf{K}_o , called respectively the *translational stiffness* and *rotational stiffness*, are also symmetric. It can be shown that, if the 3×3 matrix \mathbf{K}_c , called the *coupling stiffness* is symmetric, there is maximum decoupling between rotation and translation. In this case, the point corresponding to the coinciding origins of the frames Σ_a and Σ_b is called the *center of stiffness*. Similar definitions and results can be formulated for the case of the compliance matrix $\mathbf{C} = \mathbf{K}^{-1}$. In particular, it is possible to define a *center of compliance* in the case that the off-diagonal blocks of the compliance matrix are symmetric. The center of stiffness and compliance do not necessarily coincide.

There are special cases in which no coupling exists between translation and rotation, i. e., a relative transla-

tion of the bodies results in a wrench corresponding to a pure force along an axis through the center of stiffness; also, a relative rotation of the bodies results in a wrench that is equivalent to a pure torque about an axis through the centers of stiffness. In these cases, the center of stiffness and compliance coincide. Mechanical systems with completely decoupled behavior are, e.g., the remote center of compliance (RCC) devices.

Since \mathbf{K}_t is symmetric, there exists a rotation matrix \mathbf{R}_t with respect to the frame $\Sigma_a = \Sigma_b$ at equilibrium, such that $\mathbf{K}_t = \mathbf{R}_t \boldsymbol{\Gamma}_t \mathbf{R}_t^\top$, and $\boldsymbol{\Gamma}_t$ is a diagonal matrix whose diagonal elements are the *principal translational stiffnesses* in the directions corresponding to the columns of the rotation matrix \mathbf{R}_t , known as the *principal axes of translational stiffness*. Analogously, \mathbf{K}_o can be expressed as $\mathbf{K}_o = \mathbf{R}_o \boldsymbol{\Gamma}_o \mathbf{R}_o^\top$, where the diagonal elements of $\boldsymbol{\Gamma}_o$ are the *principal rotational stiffnesses* about the axes corresponding to the columns of rotation matrix \mathbf{R}_o , known as the *principal axes of rotational stiffness*. Moreover, assuming that the origins of Σ_a and Σ_b at equilibrium coincide with the center of stiffness, the expression $\mathbf{K}_c = \mathbf{R}_c \boldsymbol{\Gamma}_c \mathbf{R}_c^\top$ can be found, where the diagonal elements of $\boldsymbol{\Gamma}_c$ are the *principal coupling stiffnesses* along the directions corresponding to the columns of the rotation matrix \mathbf{R}_c , known as the *principal axes of coupling stiffness*. In sum, a 6×6 stiffness matrix can be specified, with respect to a frame with origin in the center of stiffness, in terms of the principal stiffness parameters and principal axes.

Notice that the mechanical stiffness defined by (7.8) describes the behavior of an ideal 6-DOF spring which stores potential energy. The potential energy function of an ideal stiffness depends only on the relative position and orientation of the two attached bodies and is port symmetric. A physical 6-DOF spring has a predominant behavior similar to the ideal one, but nevertheless it always has parasitic effects causing energy dissipation.

Geometrically Consistent Active Stiffness

To achieve a geometrically consistent 6-DOF active stiffness, a suitable definition of the proportional control action in control law (7.3) is required. This control action can be interpreted as the elastic wrench applied to the end-effector, in the presence of a *finite displacement* of the desired frame Σ_d with respect to the end-effector frame Σ_e . Hence, the properties of the ideal mechanical stiffness for small displacements should be extended to the case of finite displacements. Moreover, to guarantee asymptotic stability in the sense of Lyapunov, a suitable potential elastic energy function must be defined.

For simplicity, it is assumed that the coupling stiffness matrix is zero. Hence, the potential elastic energy can be computed as the sum of a translational potential energy and a rotational potential energy.

The translational potential energy can be defined as

$$V_t = \frac{1}{2} \Delta \mathbf{p}_{de}^\top \mathbf{K}'_{Pt} \Delta \mathbf{p}_{de} \quad (7.9)$$

with

$$\mathbf{K}'_{Pt} = \frac{1}{2} \mathbf{R}_d \mathbf{K}_{Pt} \mathbf{R}_d^\top + \frac{1}{2} \mathbf{R}_e \mathbf{K}_{Pt} \mathbf{R}_e^\top ,$$

where \mathbf{K}_{Pt} is a 3×3 symmetric positive-definite matrix. The use of \mathbf{K}'_{Pt} in lieu of \mathbf{K}_{Pt} in (7.9) guarantees that the potential energy is port symmetric also in the case of finite displacements. Matrices \mathbf{K}'_{Pt} and \mathbf{K}_{Pt} coincide at equilibrium (i.e., when $\mathbf{R}_d = \mathbf{R}_e$) and in the case of isotropic translational stiffness (i.e., when $\mathbf{K}_{Pt} = k_{Pt} \mathbf{I}$).

The computation of the power \dot{V}_t yields

$$\dot{V}_t = \Delta \dot{\mathbf{p}}_{de}^{e\top} \mathbf{f}_{\Delta t}^e + \Delta \omega_{de}^{e\top} \mathbf{m}_{\Delta t}^e ,$$

where $\Delta \dot{\mathbf{p}}_{de}^e$ is the time derivative of the position displacement $\Delta \mathbf{p}_{de}^e = \mathbf{R}_e^\top (\mathbf{p}_d - \mathbf{p}_e)$, while $\Delta \omega_{de}^e = \mathbf{R}_e^\top (\boldsymbol{\omega}_d - \boldsymbol{\omega}_e)$. The vectors $\mathbf{f}_{\Delta t}^e$ and $\mathbf{m}_{\Delta t}^e$ are, respectively, the elastic force and moment applied to the end-effector in the presence of the finite position displacement $\Delta \mathbf{p}_{de}^e$. These vectors have the following expressions when computed in the base frame

$$\mathbf{f}_{\Delta t} = \mathbf{K}'_{Pt} \Delta \mathbf{p}_{de} \quad \mathbf{m}_{\Delta t} = \mathbf{K}''_{Pt} \Delta \mathbf{p}_{de} \quad (7.10)$$

with

$$\mathbf{K}''_{Pt} = \frac{1}{2} \mathbf{S}(\Delta \mathbf{p}_{de}) \mathbf{R}_d \mathbf{K}_{Pt} \mathbf{R}_d^\top ,$$

where $\mathbf{S}(\cdot)$ is the skew-symmetric operator performing the vector product. The vector $\mathbf{h}_{\Delta t} = (\mathbf{f}_{\Delta t}^\top \ \mathbf{m}_{\Delta t}^\top)^\top$ is the elastic wrench applied to the end-effector in the presence of a finite position displacement $\Delta \mathbf{p}_{de}$ and a null orientation displacement. The moment $\mathbf{m}_{\Delta t}$ is null in the case of isotropic translational stiffness.

To define the rotational potential energy, a suitable definition of the orientation displacement between the frames Σ_d and Σ_e has to be adopted. A possible choice is the vector part of the unit quaternion $\{\eta_{de}, \epsilon_{de}^e\}$ that can be extracted from matrix $\mathbf{R}_d^e = \mathbf{R}_e^\top \mathbf{R}_d$. Hence, the orientation potential energy has the form

$$V_o = 2 \epsilon_{de}^{e\top} \mathbf{K}_{Po} \epsilon_{de}^e , \quad (7.11)$$

where \mathbf{K}_{Po} is a 3×3 symmetric positive-definite matrix. The function V_o is port symmetric because $\epsilon_{de}^e = -\epsilon_{ed}^d$.

The computation of the power \dot{V}_o yields

$$\dot{V}_o = \Delta\omega_{de}^{e\top} \mathbf{m}_{\Delta o}^e,$$

where

$$\mathbf{m}_{\Delta o} = \mathbf{K}'_{Po} \epsilon_{de}, \quad (7.12)$$

with

$$\mathbf{K}'_{Po} = 2\mathbf{E}^\top(\eta_{de}, \epsilon_{de}) \mathbf{R}_e \mathbf{K}_{Po} \mathbf{R}_e^\top$$

and $\mathbf{E}(\eta_{de}, \epsilon_{de}) = \eta_{de}\mathbf{I} - \mathbf{S}(\epsilon_{de})$. The above equations show that a finite orientation displacement $\epsilon_{de} = \mathbf{R}_e^\top \epsilon_{de}^e$ produces an elastic wrench $\mathbf{h}_{\Delta o} = (\mathbf{0}^\top \mathbf{m}_{\Delta o}^e)^\top$ which is equivalent to a pure moment.

Hence, the total elastic wrench in the presence of a finite position and orientation displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e can be defined in the base frame as

$$\mathbf{h}_\Delta = \mathbf{h}_{\Delta t} + \mathbf{h}_{\Delta o}. \quad (7.13)$$

where $\mathbf{h}_{\Delta t}$ and $\mathbf{h}_{\Delta o}$ are computed according to (7.10) and (7.12), respectively.

Using (7.13) for the computation of the elastic wrench in the case of an infinitesimal twist displacement $\delta\mathbf{x}_{de}^e$ near the equilibrium, and discarding the high-order infinitesimal terms, yields the linear mapping

$$\mathbf{h}_e^e = \mathbf{K}_P \delta\mathbf{x}_{de}^e = \begin{pmatrix} \mathbf{K}_{Pt} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{Po} \end{pmatrix} \delta\mathbf{x}_{de}^e. \quad (7.14)$$

Therefore, \mathbf{K}_P represents the stiffness matrix of an ideal spring with respect to a frame Σ_e (coinciding with Σ_d at equilibrium) with the origin at the center of stiffness. Moreover, it can be shown, using definition (7.13), that the physical/geometrical meaning of the principal stiffnesses and of the principal axes for the matrices \mathbf{K}_{Pt} and \mathbf{K}_{Po} are preserved also in the case of large displacements.

The above results imply that the active stiffness matrix \mathbf{K}_P can be set in a geometrically consistent way with respect to the task at hand.

Notice that geometrical consistency can also be ensured with different definitions of the orientation error in the potential orientation energy (7.11), for example, any error based on the angle/axis representation of \mathbf{R}_e^d can be adopted (the unit quaternion belongs to this category), or, more generally, homogeneous matrices or exponential coordinates (for the case of both position and orientation errors). Also, the XYZ Euler angles extracted from the matrix \mathbf{R}_e^d could be used; however, in this case, it can be shown that the principal axes of rotational stiffness cannot be set arbitrarily but must coincide with those of the end-effector frame.

Compliance control with a geometrically consistent active stiffness can be defined using the control law

$$\mathbf{h}_c = \mathbf{h}_\Delta - \mathbf{K}_D \mathbf{v}_e + \boldsymbol{\eta}(\mathbf{q}),$$

with \mathbf{h}_Δ in (7.13). The asymptotic stability about the equilibrium in the case $\mathbf{h}_e = \mathbf{0}$ can be proven using the Lyapunov function

$$V = \frac{1}{2} \mathbf{v}_e^\top \boldsymbol{\Lambda}(\mathbf{q}) \mathbf{v}_e + V_t + V_o,$$

with V_t and V_o given in (7.9) and (7.11), respectively, whose time derivative along the trajectories of the closed-loop system, in case the frame Σ_d is motionless, has the same expression as in (7.4). When $\mathbf{h}_e \neq \mathbf{0}$, a different asymptotically stable equilibrium can be found, corresponding to a nonnull displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e . The new equilibrium is the solution of the equation $\mathbf{h}_\Delta = \mathbf{h}_e$.

Stiffness control allows to keep the interaction force and moment limited at the expense of the end-effector position and orientation error, with a proper choice of the stiffness matrix, without the need of a force/torque sensor. However, in the presence of disturbances (e.g., joint friction) which can be modeled as an equivalent end-effector wrench, the adoption of low values for the active stiffness may produce large deviations with respect to the desired end-effector position and orientation, also in the absence of interaction with the environment.

7.2.2 Impedance Control

Stiffness control is designed to achieve a desired *static* behavior of the interaction. In fact, the dynamics of the controlled system depends on that of the robot manipulator, which is nonlinear and coupled. A more demanding objective may be that of achieving a desired *dynamic* behavior for the end-effector, e.g., that of a second-order mechanical system with six degrees of freedom, characterized by a given mass, damping, and stiffness, known as mechanical *impedance*.

The starting point to pursue this goal may be the acceleration-resolved approach used for motion control, which is aimed at decoupling and linearizing the nonlinear robot dynamics at the acceleration level via an inverse dynamics control law. In the presence of interaction with the environment, the control law

$$\mathbf{h}_c = \boldsymbol{\Lambda}(\mathbf{q}) \boldsymbol{\alpha} + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} + \mathbf{h}_e \quad (7.15)$$

cast into the dynamic model (7.2) results in

$$\dot{\mathbf{v}}_e = \boldsymbol{\alpha}, \quad (7.16)$$

where α is a properly designed control input with the meaning of an acceleration referred to the base frame. Considering the identity $\dot{\mathbf{v}}_e = \bar{\mathbf{R}}_e^\top \dot{\mathbf{v}}_e^e + \dot{\bar{\mathbf{R}}}_e^\top \mathbf{v}_e^e$, with

$$\bar{\mathbf{R}}_e = \begin{pmatrix} \mathbf{R}_e & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_e \end{pmatrix},$$

the choice

$$\alpha = \bar{\mathbf{R}}_e^\top \alpha^e + \dot{\bar{\mathbf{R}}}_e^\top \mathbf{v}_e^e \quad (7.17)$$

gives

$$\dot{\mathbf{v}}_e^e = \alpha^e, \quad (7.18)$$

where the control input α^e has the meaning of an acceleration referred to the end-effector frame Σ_e . Hence, setting

$$\alpha^e = \mathbf{K}_M^{-1} (\dot{\mathbf{v}}_d^e + \mathbf{K}_D \Delta \mathbf{v}_{de}^e + \mathbf{h}_\Delta^e - \mathbf{h}_e^e), \quad (7.19)$$

the following expression can be found for the closed-loop system

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{de}^e + \mathbf{K}_D \Delta \mathbf{v}_{de}^e + \mathbf{h}_\Delta^e = \mathbf{h}_e^e, \quad (7.20)$$

where \mathbf{K}_M and \mathbf{K}_D are 6×6 symmetric and positive-definite matrices, $\Delta \dot{\mathbf{v}}_{de}^e = \dot{\mathbf{v}}_d^e - \dot{\mathbf{v}}_e^e$, $\Delta \mathbf{v}_{de}^e = \mathbf{v}_d^e - \mathbf{v}_e^e$, $\dot{\mathbf{v}}_d^e$ and \mathbf{v}_d^e are, respectively, the acceleration and the velocity of a desired frame Σ_d and \mathbf{h}_e^e is the elastic wrench (7.13); all the quantities are referred to the end-effector frame Σ_e .

The above equation describing the dynamic behavior of the controlled end-effector can be interpreted as a generalized mechanical impedance. The asymptotic stability of the equilibrium in the case $\mathbf{h}_e = \mathbf{0}$ can be proven by considering the Lyapunov function

$$V = \frac{1}{2} \Delta \mathbf{v}_{de}^e \top \mathbf{K}_M \Delta \mathbf{v}_{de}^e + V_t + V_o, \quad (7.21)$$

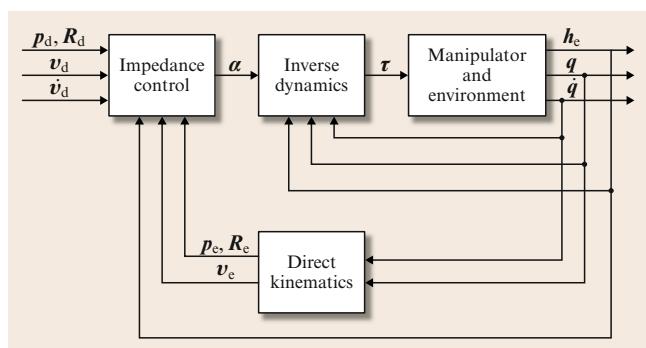

Fig. 7.1 Impedance control

where V_t and V_o are defined in (7.9) and (7.11), respectively, and whose time derivative along the trajectories of system (7.20) is the negative semidefinite function

$$\dot{V} = -\Delta \mathbf{v}_{de}^e \top \mathbf{K}_D \Delta \mathbf{v}_{de}^e.$$

When $\mathbf{h}_e \neq \mathbf{0}$, a different asymptotically stable equilibrium can be found, corresponding to a nonnull displacement of the desired frame Σ_d with respect to the end-effector frame Σ_e . The new equilibrium is the solution of the equation $\mathbf{h}_\Delta^e = \mathbf{h}_e^e$.

In case Σ_d is constant, (7.20) has the meaning of a true 6-DOF mechanical impedance if \mathbf{K}_M is chosen as

$$\mathbf{K}_M = \begin{pmatrix} mI & \mathbf{0} \\ \mathbf{0} & \mathbf{M} \end{pmatrix},$$

where m is a mass and \mathbf{M} is a 3×3 inertia tensor, and \mathbf{K}_D is chosen as a block-diagonal matrix with 3×3 blocks. The physically equivalent system is a body of mass m with inertia tensor \mathbf{M} with respect to a frame Σ_e attached to the body, subject to an external wrench \mathbf{h}^e . This body is connected to a virtual body attached to frame Σ_d through a 6-DOF ideal spring with stiffness matrix \mathbf{K}_P and is subject to viscous forces and moments with damping \mathbf{K}_D . The function V in (7.21) represents the total energy of the body: the sum of the kinetic and potential elastic energy.

A block diagram of the resulting impedance control is sketched in Fig. 7.1. The impedance control computes the acceleration input as in (7.17) and (7.19) on the basis of the position and orientation feedback as well as the force and moment measurements. Then, the inverse dynamics control law computes the torques for the joint actuators $\tau = \mathbf{J}^\top \mathbf{h}_c$ with \mathbf{h}_c in (7.15). This control scheme, in the absence of interaction, guarantees that the end-effector frame Σ_e asymptotically follows the desired frame Σ_d . In the presence of contact with the environment, a compliant dynamic behavior is imposed on the end-effector, according to the impedance (7.20), and the contact wrench is bounded at the expense of a finite position and orientation displacement between Σ_d and Σ_e . Differently from stiffness control, a force/torque sensor is required for the measurement of the contact force and moment.

Implementation Issues

The selection of good impedance parameters ensuring a satisfactory behavior is not an easy task. In fact, the dynamics of the closed-loop system is different in free space and during interaction. The control objectives are different as well, since motion tracking and disturbance

rejection must be ensured in free space, while, during the interaction, the main goal is achieving a suitable compliant dynamic behavior for the end-effector. Notice also that the dynamics of the controlled system during the interaction depends on the dynamics of the environment.

To gain insight into these problems, assume that the interaction of the end-effector with the environment can be approximated by that derived from an ideal 6-DOF spring connecting end-effector frame Σ_e to the environment frame Σ_o . Therefore, according to (7.8), the elastic wrench exerted by the end-effector on the environment, in the presence of an infinitesimal twist displacement of Σ_e with respect to Σ_o , can be computed as

$$\mathbf{h}_e^e = \mathbf{K} \delta \mathbf{x}_{eo}^e, \quad (7.22)$$

where Σ_e and Σ_o coincide at equilibrium and \mathbf{K} is a stiffness matrix. The above model holds only in the presence of interaction, while the contact wrench is null when the end-effector moves in free space.

The disturbances acting on the robot manipulator and the unmodeled dynamics (joint friction, modeling errors, etc.) may be taken into account by introducing an additive term on the right-hand side of the dynamic model of the robot manipulator (7.2), corresponding to an equivalent disturbance wrench acting on the end-effector. This term produces an additive acceleration disturbance γ^e on the right-hand side of (7.18). Therefore, using the control law (7.19), the following closed-loop impedance equation can be found

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{de}^e + \mathbf{K}_D \Delta \mathbf{x}_{de}^e + \mathbf{h}_\Delta^e = \mathbf{h}_e^e + \mathbf{K}_M \gamma^e. \quad (7.23)$$

The tuning procedure for the impedance parameters can be set up starting from the linearized model that can be computed from (7.23) in the case of infinitesimal displacements, i. e.:

$$\begin{aligned} \mathbf{K}_M \Delta \dot{\mathbf{x}}_{de}^e + \mathbf{K}_D \Delta \mathbf{x}_{de}^e + (\mathbf{K}_P + \mathbf{K}) \delta \mathbf{x}_{de}^e \\ = \mathbf{K} \delta \mathbf{x}_{do}^e + \mathbf{K}_M \gamma^e, \end{aligned} \quad (7.24)$$

where (7.22) and the equality $\delta \mathbf{x}_{eo}^e = -\delta \mathbf{x}_{de}^e + \delta \mathbf{x}_{do}^e$ have been used. The above equation is valid both for constrained ($\mathbf{K} \neq \mathbf{0}$) and for free motion ($\mathbf{K} = \mathbf{0}$).

It is evident that suitable dynamics of the position and orientation errors can be set by suitably choosing the matrix gains \mathbf{K}_M , \mathbf{K}_D , and \mathbf{K}_P . This task is easier under the hypothesis that all the matrices are diagonal, resulting in a decoupled behavior for the six components of the infinitesimal twist displacement. In this case, the transient behavior of each component can be set, e.g., by assigning the natural frequency and damping ratio with

the relations

$$\omega_n = \sqrt{\frac{k_p + k}{k_M}}, \quad \zeta = \frac{1}{2} \frac{k_D}{\sqrt{k_M(k_p + k)}}.$$

Hence, if the gains are chosen so that a given natural frequency and damping ratio are ensured during the interaction (i. e., for $k \neq 0$), a smaller natural frequency with a higher damping ratio will be obtained when the end-effector moves in free space (i. e., for $k = 0$). As for the steady-state performance, the end-effector error for the generic component is

$$\delta x_{de} = \frac{k}{(k_p + k)} \delta x_{do} + \frac{k_M}{k_p + k} \gamma$$

and the corresponding interaction force is

$$h = \frac{k_p k}{k_p + k} \delta x_{do} - \frac{k_M k}{k_p + k} \gamma.$$

The above relations show that, during interaction, the contact force can be made small at the expense of a large position error in steady state, as long as the active stiffness k_p is set low with respect to the stiffness of the environment k , and vice versa. However, both the contact force and the position error also depend on the external disturbance γ ; in particular, the lower k_p , the higher the influence of γ on both δx_{de} and h . Moreover, a low active stiffness k_p may result in a large position error also in the absence of interaction (i. e., when $k = 0$).

Admittance Control

A solution to this drawback can be devised by separating motion control from impedance control as follows. The motion control action is purposefully made stiff so as to enhance disturbance rejection but, rather than ensuring tracking of the desired end-effector position and orientation, it ensures tracking of a reference position and orientation resulting from the impedance control action. In other words, the desired position and orientation, together with the measured contact wrench, are input to the impedance equation which, via a suitable integration, generates the position and orientation to be used as a reference for the motion control.

To implement this solution, it is worth introducing a reference frame other than the desired frame Σ_d . This frame is referred to as the *compliant frame* Σ_c , and is specified by the quantities \mathbf{p}_c , \mathbf{R}_c , \mathbf{v}_c , and $\dot{\mathbf{v}}_c$ that are computed from \mathbf{p}_d , \mathbf{R}_d , \mathbf{v}_d , and $\dot{\mathbf{v}}_d$ and the measured wrench \mathbf{h}_c , by integrating the equation

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{dc}^c + \mathbf{K}_D \Delta \mathbf{x}_{dc}^c + \mathbf{h}_\Delta^c = \mathbf{h}_c^c, \quad (7.25)$$

where \mathbf{h}_Δ^c is the elastic wrench in the presence of a finite displacement between the desired frame Σ_d and the

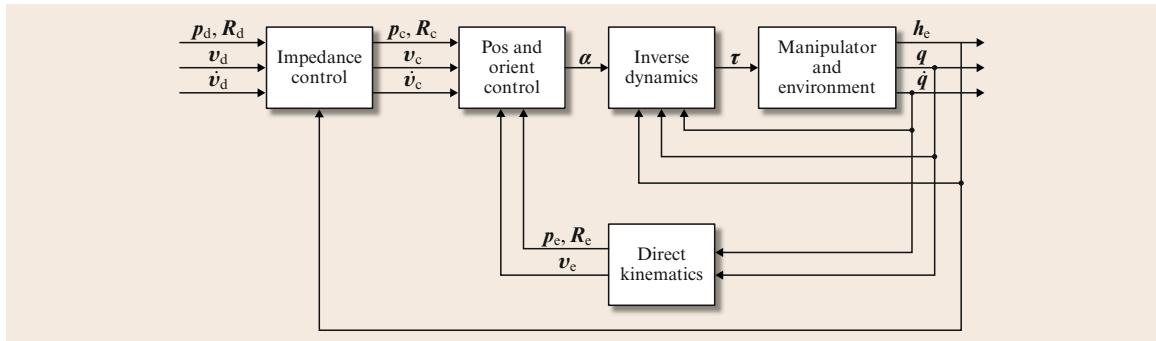

Fig. 7.2 Impedance control with inner motion control loop (admittance control)

compliant frame Σ_c . Then, a motion control strategy, based on inverse dynamics, is designed so that the end-effector frame Σ_e is taken to coincide with the compliant frame Σ_c . To guarantee the stability of the overall system, the bandwidth of the motion controller should be higher than the bandwidth of the impedance controller.

A block diagram of the resulting scheme is sketched in Fig. 7.2. It is evident that, in the absence of interaction, the compliant frame Σ_c coincides with the desired frame Σ_d and the dynamics of the position and orientation error, as well as the disturbance rejection capabilities, depend only on the gains of the inner motion control loop. On the other hand, the dynamic behavior in the presence of interaction is imposed by the impedance gains (7.25).

The control scheme of Fig. 7.2 is also known as *admittance control* because, in (7.25), the measured force (the input) is used to compute the motion of the compliant frame (the output), given the motion of the desired frame; a mapping with a force as input and a position or velocity as output corresponds to a mechanical *admittance*. Vice versa, (7.20), mapping the end-effector displacement (the input) from the desired motion trajectory into the contact wrench (the output), has the meaning of a mechanical *impedance*.

Simplified Schemes

The inverse dynamics control is model based and requires modification of current industrial robot controllers, which are usually equipped with independent PI joint velocity controllers with very high bandwidth. These controllers are able to decouple the robot dynamics to a large extent, especially in the case of slow motion, and to mitigate the effects of external forces on the manipulator motion if the environment is sufficiently compliant. Hence, the closed-loop dynamics of the controlled robot can be approximated by

$$\dot{\mathbf{q}} = \dot{\mathbf{q}}_r$$

in joint space, or equivalently

$$\dot{\mathbf{v}}_e = \dot{\mathbf{v}}_r$$

in the operational space, where $\dot{\mathbf{q}}_r$ and $\dot{\mathbf{v}}_r$ are the control signals for the inner velocity motion loop generated by a suitably designed outer control loop. These control signals are related by

$$\dot{\mathbf{q}}_r = \mathbf{J}^{-1}(\mathbf{q})\dot{\mathbf{v}}_r .$$

The velocity $\dot{\mathbf{v}}_r$, corresponding to a *velocity-resolved control*, can be computed as

$$\dot{\mathbf{v}}_r^e = \dot{\mathbf{v}}_d^e + \mathbf{K}_D^{-1}(\mathbf{h}_\Delta^e - \mathbf{h}_e^e) ,$$

where the control input has been referred to the end-effector frame, \mathbf{K}_D is a 6×6 positive-definite matrix and \mathbf{h}_Δ is the elastic wrench (7.13) with stiffness matrix \mathbf{K}_P . The resulting closed-loop equation is

$$\mathbf{K}_D \Delta \mathbf{v}_{de}^e + \mathbf{h}_\Delta^e = \mathbf{h}_e^e$$

corresponding to a compliant behavior of the end-effector characterized by a damping \mathbf{K}_D and a stiffness \mathbf{K}_P . In the case $\mathbf{K}_P = \mathbf{0}$, the resulting scheme is known as *damping control*.

Alternatively, an admittance-type control scheme can be adopted, where the motion of a compliant frame Σ_c can be computed as the solution of the differential equation

$$\mathbf{K}_D \Delta \mathbf{v}_{dc}^e + \mathbf{h}_\Delta^c = \mathbf{h}_e^c$$

in terms of the position \mathbf{p}_c , orientation \mathbf{R}_c , and velocity \mathbf{v}_c , where the inputs are the motion variables of the desired frame Σ_d and the contact wrench \mathbf{h}_e^c . The motion variables of Σ_c are then input to an inner position and velocity controller. In the case $\mathbf{K}_D = \mathbf{0}$, the resulting scheme is known as *compliance control*.

7.3 Interaction Tasks

Indirect force control does not require explicit knowledge of the environment, although to achieve a satisfactory dynamic behavior the control parameters have to be tuned for a particular task. On the other hand, a model of the interaction task is required for the synthesis of direct force control algorithms.

An interaction task is characterized by complex contact situations between the manipulator and the environment. To guarantee proper task execution, it is necessary to have an analytical description of the interaction force and moment, which is very demanding from a modeling viewpoint.

A real contact situation is a naturally distributed phenomenon in which the local characteristics of the contact surfaces as well as the global dynamics of the manipulator and environment are involved. In detail:

- the environment imposes kinematic constraints on the end-effector motion, due to one or more contacts of different type, and a reaction wrench arises when the end-effector tends to violate the constraints (e.g., the case of a robot sliding a rigid tool on a frictionless rigid surface);
- the end-effector, while being subject to kinematic constraints, may also exert a dynamic wrench on the environment, in the presence of environment dynamics (e.g., the case of a robot turning a crank, when the crank dynamics is relevant, or a robot pushing against a compliant surface);
- the contact wrench may depend on the structural compliance of the robot, due to the finite stiffness of the joints and links of the manipulator, as well as of the wrist force/torque sensor or of the tool (e.g., an end-effector mounted on an RCC device);
- local deformation of the contact surfaces may occur during the interaction, producing distributed contact areas (e.g., the case of a soft contact surface of the tool or of the environment);
- static and dynamic friction may occur in the case of non ideally smooth contact surfaces.

The design of the interaction control and the performance analysis are usually carried out under simplifying assumptions. The following two cases are considered:

1. the robot and the environment are perfectly rigid and purely kinematics constraints are imposed by the environment,
2. the robot is perfectly rigid, all the compliance in the system is localized in the environment, and the

contact wrench is approximated by a linear elastic model.

In both cases, frictionless contact is assumed. It is obvious that these situations are only ideal. However, the robustness of the control should be able to cope with situations where some of the ideal assumptions are relaxed. In that case the control laws may be adapted to deal with nonideal characteristics.

7.3.1 Rigid Environment

The kinematic constraints imposed by the environment can be represented by a set of equations that the variables describing the end-effector position and orientation must satisfy; since these variables depend on the joint variables through the direct kinematic equations, the constraint equations can also be expressed in the joint space as

$$\phi(q) = \mathbf{0}. \quad (7.27)$$

The vector ϕ is an $m \times 1$ function, with $m < n$, where n is the number of joints of the manipulator, assumed to be nonredundant; without loss of generality, the case $n = 6$ is considered. Constraints of the form (7.27), involving only the generalized coordinates of the system, are known as holonomic constraints. The case of time-varying constraints of the form $\phi(q, t) = \mathbf{0}$ is not considered here but can be analyzed in a similar way. Moreover, only bilateral constraints expressed by equalities of the form (7.27) are of concern; this means that the end-effector always keeps contact with the environment. The analysis presented here is known as *kinetostatic analysis*.

It is assumed that the vector (7.27) is twice differentiable and that its m components are linearly independent at least locally in a neighborhood of the operating point. Hence, differentiation of (7.27) yields

$$J_\phi(q)\dot{q} = \mathbf{0}, \quad (7.28)$$

where $J_\phi(q) = \partial\phi/\partial q$ is the $m \times 6$ Jacobian of $\phi(q)$, known as the *constraint Jacobian*. By virtue of the above assumption, $J_\phi(q)$ is of rank m at least locally in a neighborhood of the operating point.

In the absence of friction, the generalized interaction forces are represented by a reaction wrench that tends to violate the constraints. This end-effector wrench produces reaction torques at the joints that can be computed

using the principle of virtual work as

$$\tau_e = J_\phi^\top(\mathbf{q})\lambda,$$

where λ is an $m \times 1$ vector of Lagrange multipliers. The end-effector wrench corresponding to τ_e can be computed as

$$\mathbf{h}_e = J^{-\top}(\mathbf{q})\tau_e = S_f(\mathbf{q})\lambda, \quad (7.29)$$

where

$$S_f = J^{-\top}(\mathbf{q})J_\phi^\top(\mathbf{q}). \quad (7.30)$$

From (7.29) it follows that \mathbf{h}_e belongs to the m -dimensional vector space spanned by the columns of the $6 \times m$ matrix S_f . The inverse of the linear transformation (7.29) is computed as

$$\lambda = S_f^\dagger(\mathbf{q})\mathbf{h}_e, \quad (7.31)$$

where S_f^\dagger denotes a weighted pseudoinverse of the matrix S_f , i.e.,

$$S_f^\dagger = (S_f^\top W S_f)^{-1} S_f^\top W \quad (7.32)$$

where W is a suitable weighting matrix.

Notice that, while the range space of the matrix S_f in (7.30) is uniquely defined by the geometry of the contact, the matrix S_f itself is not unique; also, the constraint equations (7.27), the corresponding Jacobian J_ϕ as well as the pseudoinverse S_f^\dagger and the vector λ are not uniquely defined.

In general, the physical units of measure of the elements of λ are not homogeneous and the columns of the matrix S_f , as well as of the matrix S_f^\dagger , do not necessarily represent homogeneous entities. This may produce invariance problems in the transformation (7.31) if \mathbf{h}_e represents a measured wrench that is subject to disturbances and, as a result, may have components outside the range space of S_f . If a physical unit or a reference frame is changed, the matrix S_f undergoes a transformation; however, the result of (7.31) with the transformed pseudoinverse in general depends on the adopted physical units or on the reference frame. The reason is that the pseudoinverse is the weighted least-squares solution of a minimization problem based on the norm of the vector $\mathbf{h}_e - S_f(\mathbf{q})\lambda$, and the invariance can be guaranteed only if a physically consistent norm of this vector is used. In the ideal case that \mathbf{h}_e is in the range space of S_f , there is a unique solution for λ in (7.31), regardless of the weighting matrix, and hence the invariance problem does not appear.

A possible solution consists of choosing S_f so that its columns represent linearly independent wrenches. This

implies that (7.29) gives \mathbf{h}_e as a linear combination of wrenches and λ is a dimensionless vector. A physically consistent norm on the wrench space can be defined based on the quadratic form $\mathbf{h}_e^\top K^{-1}\mathbf{h}_e$, which has the meaning of an elastic energy if K is a positive-definite matrix corresponding to a stiffness. Hence, the choice $W = K^{-1}$ can be made for the weighting matrix of the pseudoinverse.

Notice that, for a given S_f , the constraint Jacobian can be computed from (7.30) as $J_\phi(\mathbf{q}) = S_f^\top J(\mathbf{q})$; moreover, the constraint equations can be derived by integrating (7.28).

Using (7.1) and (7.30), the equality (7.28) can be rewritten in the form

$$J_\phi(\mathbf{q})J^{-1}(\mathbf{q})J(\mathbf{q})\dot{\mathbf{q}} = S_f^\top \mathbf{v}_e = \mathbf{0}, \quad (7.33)$$

which, by virtue of (7.29), is equivalent to

$$\mathbf{h}_e^\top \mathbf{v}_e = 0. \quad (7.34)$$

Equation (7.34) represents the kinetostatic relationship, known as *reciprocity*, between the ideal reaction wrench \mathbf{h}_e (belonging to the so-called *force-controlled* subspace) and the end-effector twist that obeys the constraints (belonging to the so-called *velocity-controlled* subspace). The concept of reciprocity, expressing the physical fact that, in the hypothesis of rigid and frictionless contact, the wrench does not cause any work against the twist, is often confused with the concept of *orthogonality*, which makes no sense in this case because twists and wrenches belong to different spaces.

Equations (7.33) and (7.34) imply that the velocity-controlled subspace is the reciprocal complement of the m -dimensional force-controlled subspace, identified by the range of matrix S_f . Hence, the dimension of the velocity-controlled subspace is $6 - m$ and a $6 \times (6 - m)$ matrix S_v can be defined, whose columns span the velocity-controlled subspace, i.e.,

$$\mathbf{v}_e = S_v(\mathbf{q})\mathbf{v}, \quad (7.35)$$

where \mathbf{v} is a suitable $(6 - m) \times 1$ vector. From (7.33) and (7.35) the following equality holds

$$S_f^\top(\mathbf{q})S_v(\mathbf{q}) = \mathbf{0}; \quad (7.36)$$

moreover, the inverse of the linear transformation (7.35) can be computed as

$$\mathbf{v} = S_v^\dagger(\mathbf{q})\mathbf{v}_e, \quad (7.37)$$

where S_v^\dagger denotes a suitable weighted pseudoinverse of the matrix S_v , computed as in (7.32).

Notice that, as for the case of S_f , although the range space of the matrix S_v is uniquely defined, the choice of the matrix S_v itself is not unique. Moreover, the columns of S_v are not necessarily twists and the scalar v may have nonhomogeneous physical dimensions. However, in order to avoid invariance problems analogous to that considered for the case of S_f , it is convenient to select the columns of S_v as twists so that the vector v is dimensionless; moreover, the weighting matrix used to compute the pseudoinverse in (7.37) can be set as $W = M$, being M a 6×6 inertia matrix; this corresponds to defining a norm in the space of twists based on the kinetic energy. It is worth observing that the transformation matrices of twists and wrenches, corresponding to a change of reference frame, are different; however, if twists are defined with angular velocity on top and translational velocity on bottom, then their transformation matrix is the same as for wrenches.

The matrix S_v may also have an interpretation in terms of Jacobians, as for S_f in (7.30). Due to the presence of m independent holonomic constraints (7.27), the configuration of the robot in contact with the environment can be described in terms of a $(6-m) \times 1$ vector r of independent variables. From the implicit function theorem, this vector can be defined as

$$r = \psi(q), \quad (7.38)$$

where $\psi(q)$ is any $(6-m) \times 1$ twice-differentiable vector function such that the m components of $\phi(q)$ and the $n-m$ components of $\psi(q)$ are linearly independent at least locally in a neighborhood of the operating point. This means that the mapping (7.38), together with the constraint (7.27), is locally invertible, with inverse defined as

$$q = \rho(r), \quad (7.39)$$

where $\rho(r)$ is a 6×1 twice-differentiable vector function. Equation (7.39) explicitly provides all the joint vectors which satisfy the constraint (7.27). Moreover, the joint velocity vectors that satisfy (7.28) can be computed as

$$\dot{q} = J_\phi(q)\dot{r},$$

where $J_\phi(r) = \partial \rho / \partial r$ is a $6 \times (6-m)$ full-rank Jacobian matrix. Therefore, the following equality holds

$$J_\phi(q)J_\rho(r) = \mathbf{0},$$

which can be interpreted as a reciprocity condition between the subspace of the reaction torques spanned by the columns of the matrix J_ϕ^\top and the subspace of the

constrained joint velocities spanned by the columns of the matrix J_ρ .

Rewriting the above equation as

$$J_\phi(q)J(q)^{-1}J(q)J_\rho(r) = \mathbf{0},$$

and taking into account (7.30) and (7.36), the matrix S_v can be expressed as

$$S_v = J(q)J_\rho(r), \quad (7.40)$$

which, by virtue of (7.38) and (7.39), it can be equivalently expressed as a function of either q or r .

The matrices S_f and S_v , and their pseudoinverse S_f^\dagger and S_v^\dagger are known as selection matrices. They play a fundamental role for the task specification, i.e., the specification of the desired end-effector motion and interaction forces and moments, as well as for the control synthesis.

7.3.2 Compliant Environment

In many applications, the interaction wrench between the end-effector and a compliant environment can be approximated by an ideal elastic model of the form (7.22). However, since the stiffness matrix K is positive definite, this model describes a fully constrained case, when the environment deformation coincides with the infinitesimal twist displacement of the end-effector. In general, however, the end-effector motion is only partially constrained by the environment and this situation can be modeled by introducing a suitable positive-semidefinite stiffness matrix.

The stiffness matrix describing the partially constrained interaction between the end-effector and the environment can be computed by modeling the environment as a couple of rigid bodies, S and O, connected through an ideal 6-DOF spring of compliance $C = K^{-1}$. Body S is attached to a frame Σ_s and is in contact with the end-effector; body O is attached to a frame Σ_o which, at equilibrium, coincides with frame Σ_s . The environment deformation about the equilibrium, in the presence of a wrench h_s , is represented by the infinitesimal twist displacement δx_{so} between frames Σ_s and Σ_o , which can be computed as

$$\delta x_{so} = C h_s. \quad (7.41)$$

All the quantities hereafter are referred to frame Σ_s but the superscript s is omitted for brevity.

For the considered contact situation, the end-effector twist does not completely belong to the ideal velocity subspace, corresponding to a rigid environment, because

the environment can deform. Therefore, the infinitesimal twist displacement of the end-effector frame Σ_e with respect to Σ_o can be decomposed as

$$\delta\mathbf{x}_{eo} = \delta\mathbf{x}_v + \delta\mathbf{x}_f, \quad (7.42)$$

where $\delta\mathbf{x}_v$ is the end-effector infinitesimal twist displacement in the velocity-controlled subspace, defined as the $6-m$ reciprocal complement of the force-controlled subspace, while $\delta\mathbf{x}_f$ is the end-effector infinitesimal twist displacement corresponding to the environment deformation. Hence:

$$\delta\mathbf{x}_v = \mathbf{P}_v \delta\mathbf{x}_{eo} \quad (7.43)$$

$$\delta\mathbf{x}_f = (\mathbf{I} - \mathbf{P}_v) \delta\mathbf{x}_{eo} = (\mathbf{I} - \mathbf{P}_v) \delta\mathbf{x}_{so}, \quad (7.44)$$

where $\mathbf{P}_v = \mathbf{S}_v \mathbf{S}_v^\dagger$ and \mathbf{S}_v and \mathbf{S}_v^\dagger are defined as in the rigid environment case. The matrix \mathbf{P}_v is a projection matrix that filters out all the end-effector twists (and infinitesimal twist displacements) that are not in the range space of \mathbf{S}_v , while $\mathbf{I} - \mathbf{P}_v$ is a projection matrix that filters out all the end-effector twists (and infinitesimal twist displacements) that are in the range space of \mathbf{S}_v . The twists $\mathbf{P}_v \mathbf{v}$ are denoted as *twists of freedom* while the twists $(\mathbf{I} - \mathbf{P}_v) \mathbf{v}$ are denoted as *twists of constraint*.

In the hypothesis of frictionless contact, the interaction wrench between the end-effector and the environment is restricted to a force-controlled subspace defined by the m -dimensional range space of a matrix \mathbf{S}_f , as for the rigid environment case, i.e.,

$$\mathbf{h}_e = \mathbf{S}_f \boldsymbol{\lambda} = \mathbf{h}_s, \quad (7.45)$$

where $\boldsymbol{\lambda}$ is an $m \times 1$ dimensionless vector. Premultiplying both sides of (7.42) by \mathbf{S}_f^\top and using (7.41), (7.43), (7.44), and (7.45) yields

$$\mathbf{S}_f^\top \delta\mathbf{x}_{eo} = \mathbf{S}_f^\top \mathbf{C} \mathbf{S}_f \boldsymbol{\lambda},$$

where the identity $\mathbf{S}_f^\top \mathbf{P}_v = \mathbf{0}$ has been exploited. Therefore, the following elastic model can be found:

$$\mathbf{h}_e = \mathbf{S}_f \boldsymbol{\lambda} = \mathbf{K}' \delta\mathbf{x}_{eo}, \quad (7.46)$$

where $\mathbf{K}' = \mathbf{S}_f (\mathbf{S}_f^\top \mathbf{C} \mathbf{S}_f)^{-1} \mathbf{S}_f^\top$ is the positive-semidefinite stiffness matrix corresponding to the partially constrained interaction.

If the compliance matrix \mathbf{C} is adopted as a weighting matrix for the computation of \mathbf{S}_f^\dagger , then \mathbf{K}' can be expressed as

$$\mathbf{K}' = \mathbf{P}_f \mathbf{K}, \quad (7.47)$$

where $\mathbf{P}_f = \mathbf{S}_f \mathbf{S}_f^\dagger$ is a projection matrix that filters out all the end-effector wrenches that are not in the range space of \mathbf{S}_f .

The compliance matrix for the partially constrained interaction cannot be computed as the inverse of \mathbf{K}' , since this matrix is of rank $m < 6$. However, using (7.44), (7.41), and (7.45), the following equality can be found

$$\delta\mathbf{x}_f = \mathbf{C}' \mathbf{h}_e,$$

where the matrix

$$\mathbf{C}' = (\mathbf{I} - \mathbf{P}_v) \mathbf{C}, \quad (7.48)$$

of rank $6-m$, is positive semidefinite. If the stiffness matrix \mathbf{K} is adopted as a weighting matrix for the computation of \mathbf{S}_v^\dagger , then the matrix \mathbf{C}' has the noticeable expression $\mathbf{C}' = \mathbf{C} - \mathbf{S}_v (\mathbf{S}_v^\top \mathbf{K} \mathbf{S}_v)^{-1} \mathbf{S}_v^\top$, showing that \mathbf{C}' is symmetric.

7.3.3 Task Specification

An interaction task can be assigned in terms of a desired end-effector wrench \mathbf{h}_d and twist \mathbf{v}_d . In order to be consistent with the constraints, these vectors must lie in the force- and velocity-controlled subspaces, respectively. This can be guaranteed by specifying vectors $\boldsymbol{\lambda}_d$ and \mathbf{v}_d and computing \mathbf{h}_d and \mathbf{v}_d as

$$\mathbf{h}_d = \mathbf{S}_f \boldsymbol{\lambda}_d, \quad \mathbf{v}_d = \mathbf{S}_v \mathbf{v}_d,$$

where \mathbf{S}_f and \mathbf{S}_v have to be suitably defined on the basis of the geometry of the task, and so that invariance with respect to the choice of the reference frame and change of physical units is guaranteed.

Many robotic tasks have a set of orthogonal reference frames in which the task specification is very easy and intuitive. Such frames are called *task frames* or *compliance frames*. An interaction task can be specified by assigning a desired force/torque or a desired linear/angular velocity along/about each of the frame axes. The desired quantities are known as *artificial constraints* because they are imposed by the controller; these constraints, in the case of rigid contact, are complementary to those imposed by the environment, known as *natural constraints*.

Some examples of task frame definition and task specification are given below.

Peg-in-Hole

The goal of this task is to push the peg into the hole while avoiding wedging and jamming. The peg has two degrees of motion freedom, hence the dimension of the velocity-controlled subspace is $6-m=2$, while the dimension of the force-controlled subspace is $m=4$. The task frame can be chosen as shown in Fig. 7.3 and the

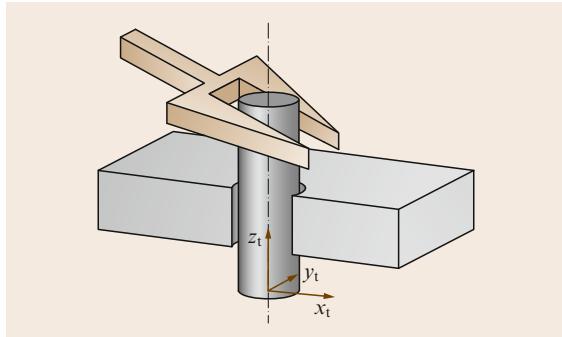

Fig. 7.3 Insertion of a cylindrical peg into a hole

task can be achieved by assigning the following desired forces and torques:

- zero forces along the x_t and y_t axes
- zero torques about the x_t and y_t axes

and the desired velocities

- a nonzero linear velocity along the z_t -axis
- an arbitrary angular velocity about the z_t -axis

The task continues until a *large* reaction force in the z_t direction is measured, indicating that the peg has hit the bottom of the hole, not represented in the figure. Hence, the matrices S_f and S_v can be chosen as

$$S_f = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad S_v = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix},$$

where the columns of S_f have the dimensions of wrenches and those of S_v have the dimensions of twists, defined in the task frame, and they transform accordingly when changing the reference frame. The task frame can be chosen either attached to the end-effector or to the environment.

Turning a Crank

The goal of this task is turning a crank with an idle handle. The handle has two degrees of motion freedom, corresponding to the rotation about the z_t -axis and to the rotation about the rotation axis of the crank. Hence the dimension of the velocity-controlled subspace is $6 - m = 2$, while the dimension of the force-controlled subspace is $m = 4$. The task frame can be assumed as in the Fig. 7.4, attached to the crank. The task can be

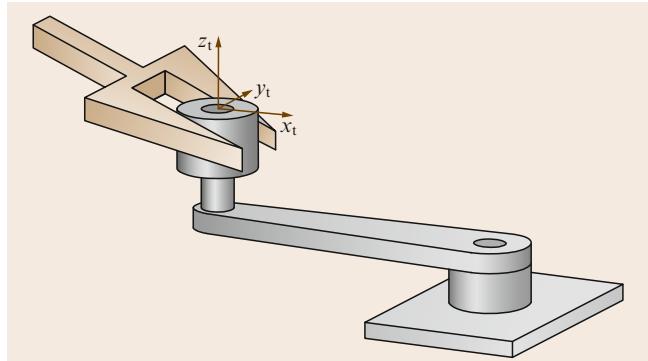

Fig. 7.4 Turning a crank with an idle handle

achieved by assigning the following desired forces and torques:

- zero forces along the x_t and z_t axes
- zero torques about the x_t and y_t axes

and the following desired velocities

- a nonzero linear velocity along the y_t -axis
- an arbitrary angular velocity about the z_t -axis

Hence, the matrices S_f and S_v can be chosen as

$$S_f = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad S_v = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix},$$

referred to the task frame. In this case, the task frame is fixed with respect to the crank, but in motion with respect both the end-effector frame (fixed to the handle) and to the base frame of the robot. Hence, the matrices S_f and S_v are time variant when referred either to the end-effector frame or to the base frame.

Sliding a Block on a Planar Elastic Surface

The goal of this task is to slide a prismatic block over a planar surface along the x_t -axis, while pushing with a given force against the elastic planar surface. The object has three degrees of motion freedom, hence the dimension of the velocity-controlled subspace is $6 - m = 3$ while the dimension of the force-controlled subspace is $m = 3$. The task frame can be chosen attached to the environment, as shown in Fig. 7.5, and the task can be achieved by assigning the desired velocities:

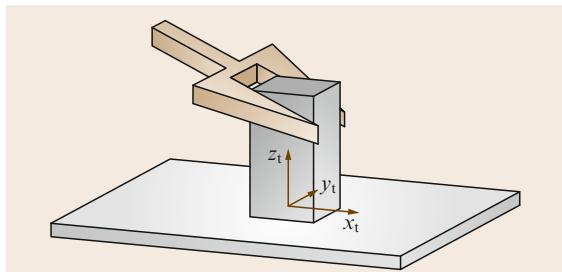

Fig. 7.5 Sliding of a prismatic object on a planar elastic surface

- a nonzero velocity along the x_t -axis
- a zero velocity along the y_t -axis
- a zero angular velocity about the z_t -axis

and the desired forces and torques

- a nonzero force along the z_t -axis
- zero torques about the x_t and y_t axes

Hence, the matrices S_f and S_v can be chosen as

$$S_f = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \quad S_v = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The elements of the 6×6 stiffness matrix K' , corresponding to the partially constrained interaction of the end-effector with the environment, are all zero except those of the 3×3 principal minor K'_m formed by rows 3, 4, 5 and columns 3, 4, 5 of K' , which can be computed as

$$K'_m = \begin{pmatrix} c_{3,3} & c_{3,4} & c_{3,5} \\ c_{4,3} & c_{4,4} & c_{4,5} \\ c_{5,3} & c_{5,4} & c_{5,5} \end{pmatrix}^{-1},$$

where $c_{i,j} = c_{j,i}$ are the elements of the compliance matrix C .

General Contact Model

The task frame concept has proven to be very useful for the specification of a variety of practical robotic tasks. However, it only applies to task geometries with limited complexity, for which separate control modes can be assigned independently to three pure translational and three pure rotational directions along the axes of a single frame. For more complex situations, as in

the case of multiple-point contact, a task frame may not exist and more complex contact models have to be adopted. A possible solution is represented by the *virtual contact manipulator* model, where each individual contact is modeled by a virtual kinematic chain between the manipulated object and the environment, giving the manipulated object (instantaneously) the same motion freedom as the contact. The velocities and force kinematics of the parallel manipulator, formed by the virtual manipulators of all individual contacts, can be derived using the standard kinematics procedures of real manipulators and allow the construction of bases for the twist and wrench spaces of the total motion constraint.

A more general approach, known as *constraint-based task specification* opens up new applications involving complex geometries and/or the use of multiple sensors (force/torque, distance, visual sensors) for controlling different directions in space simultaneously. The concept of task frame is extended to that of multiple *feature frames*. Each of the feature frames makes it possible to model part of the task geometry using translational and rotational directions along the axes of a frame; also, part of the constraints is specified in each of the feature frames. The total model and the total set of constraints are achieved by collecting the partial task and constraints descriptions, each expressed in the individual feature frames.

7.3.4 Sensor-Based Contact Model Estimation

The task specification relies on the definition of the velocity-controlled subspace and of the force-controlled subspace assuming that an accurate model of the contact is available all the time. On the other hand, in most practical implementations, the selection matrices S_f and S_v are not exactly known, however many interaction control strategies turn out to be rather robust against modeling errors. In fact, to cope reliably with these situations is exactly why force control is used. The robustness of the force controller increases if the matrices S_f and S_v can be continuously updated, using motion and/or force measurements, during task execution.

In detail, a nominal model is assumed to be available; when the contact situation evolves differently from what the model predicts, the measured and predicted motion and force will begin to deviate. These small incompatibilities can be measured and can then be used to adapt the model online, using algorithms derived from classical state-space *prediction–correction* estimators such as the Kalman filter.

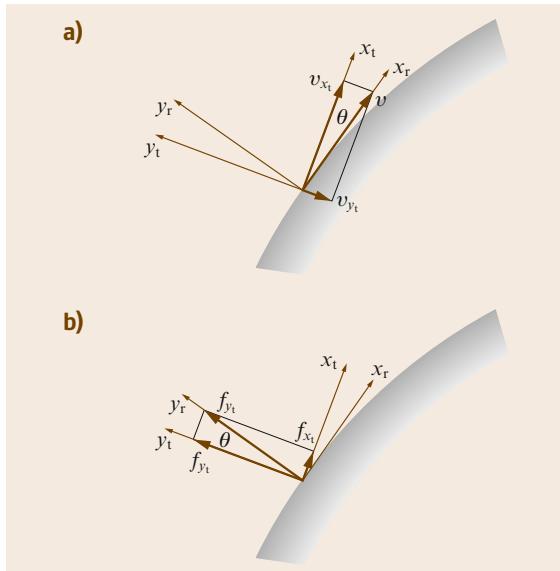

Fig. 7.6a,b Estimation of orientation error: **(a)** velocity-based approach, **(b)** force-based approach

Figure 7.6 reports an example of error between nominal and measured motion and force variables, typical of

a two-dimensional contour-following task. The orientation of the contact normal changes if the environment is not planar. Hence an angular error θ appears between the nominal contact normal, aligned to the y_t -axis of the task frame (the frame with axes x_t and y_t), and the real contact normal, aligned to the y_r -axis of the real task frame (the frame with axes x_r and y_r). This angle can be estimated with either velocity or force measurements only.

- *Velocity-based approach:* the executed linear velocity v , which is tangent to the real contour (aligned to the x_r -axis), does not completely lie along the x_t -axis, but has a small component v_{y_t} along the y_t -axis. The orientation error θ can then be approximated by $\theta = \tan^{-1}(v_{y_t}/v_{x_t})$.
- *Force-based approach:* the measured (ideal) contact force f does not completely lie along the nominal normal direction, aligned to the y_t -axis, but has a small component f_{x_t} along the x_t -axis. The orientation error θ can then be approximated by $\theta = \tan^{-1}(f_{x_t}/f_{y_t})$.

The velocity-based approach is disturbed by mechanical compliance in the system; the force-based approach is disturbed by contact friction.

7.4 Hybrid Force/Motion Control

The aim of hybrid force/motion control is to split up simultaneous control of both end-effector motion and contact forces into two separate decoupled subproblems. In the following, the main control approaches in the hybrid framework are presented for the cases of both rigid and compliant environments.

7.4.1 Acceleration-Resolved Approach

As for the case of motion control, the acceleration-resolved approach is aimed at decoupling and linearizing the nonlinear robot dynamics at the acceleration level, via an inverse dynamics control law. In the presence of interaction with the environment, a complete decoupling between the force- and velocity-controlled subspaces is sought. The basic idea is that of designing a model-based *inner control loop* to compensate for the nonlinear dynamics of the robot manipulator and decouple the force and velocity subspaces; hence an *outer control loop* is designed to ensure disturbance rejection and tracking of the desired end-effector force and motion.

Rigid Environment

In the case of a rigid environment, the external wrench can be written in the form $\mathbf{h}_e = S_f \lambda$. The force multiplier λ can be eliminated from (7.2) by solving (7.2) for $\dot{\mathbf{v}}_e$ and substituting it into the time derivative of the last equality (7.33). This yields:

$$\lambda = \Lambda_f(\mathbf{q}) \left\{ S_f^\top \Lambda^{-1}(\mathbf{q}) [\mathbf{h}_c - \mu(\mathbf{q}, \dot{\mathbf{q}})] + \dot{S}_f^\top \mathbf{v}_e \right\}, \quad (7.49)$$

where $\Lambda_f(\mathbf{q}) = (S_f^\top \Lambda^{-1} S_f)^{-1}$ and $\mu(\mathbf{q}, \dot{\mathbf{q}}) = \Gamma \dot{\mathbf{q}} + \eta$. Therefore the constraint dynamics can be rewritten in the form

$$\Lambda(\mathbf{q}) \ddot{\mathbf{v}}_e + S_f \Lambda_f(\mathbf{q}) \dot{S}_f^\top \mathbf{v}_e = P(\mathbf{q}) [\mathbf{h}_c - \mu(\mathbf{q}, \dot{\mathbf{q}})], \quad (7.50)$$

where $P = I - S_f \Lambda_f S_f^\top \Lambda^{-1}$. Notice that $P S_f = \mathbf{0}$, hence the 6×6 matrix P is a projection matrix that filters out all the end-effector wrenches lying in the range of S_f . These correspond to wrenches that tend to violate the constraints.

Equation (7.49) reveals that the force multiplier vector λ instantaneously depends also on the applied input wrench \mathbf{h}_c . Hence, by suitably choosing \mathbf{h}_c , it is possible to directly control the m independent components of the end-effector wrench that tend to violate the constraints; these components can be computed from the m force multipliers through (7.29). On the other hand, (7.50) represents a set of six second-order differential equations whose solution, if initialized on the constraints, automatically satisfy (7.27) at all times.

The reduced-order dynamics of the constrained system is described by $6 - m$ second-order equations that are obtained by premultiplying both sides of (7.50) by the matrix S_v^\top and substituting the acceleration $\dot{\mathbf{v}}_e$ with

$$\ddot{\mathbf{v}}_e = S_v \dot{\mathbf{v}} + \dot{S}_v \mathbf{v}.$$

The resulting equations are

$$\Lambda_v(\mathbf{q})\ddot{\mathbf{v}} = S_v^\top [\mathbf{h}_c - \mu(\mathbf{q}, \dot{\mathbf{q}}) - \Lambda(\mathbf{q})\dot{S}_v \mathbf{v}], \quad (7.51)$$

where $\Lambda_v = S_v^\top \Lambda S_v$ and the identities (7.36) and $S_v^\top P = S_v$ have been used. Moreover, expression (7.49) can be rewritten as

$$\lambda = \Lambda_f(\mathbf{q})S_f^\top \Lambda^{-1}(\mathbf{q})[\mathbf{h}_c - \mu(\mathbf{q}, \dot{\mathbf{q}}) - \Lambda(\mathbf{q})\dot{S}_v \mathbf{v}],$$

where the identity $\dot{S}_f^\top S_v = -S_f^\top \dot{S}_v$ has been exploited.

An inverse-dynamics *inner control loop* can be designed by choosing the control wrench \mathbf{h}_c as

$$\mathbf{h}_c = \Lambda(\mathbf{q})S_v \alpha_v + S_f f_\lambda + \mu(\mathbf{q}, \dot{\mathbf{q}}) + \Lambda(\mathbf{q})\dot{S}_v \mathbf{v}, \quad (7.52)$$

where α_v and f_λ are properly designed control inputs.

Substituting (7.52) into (7.51) and (7.49) yields

$$\dot{\mathbf{v}} = \alpha_v$$

$$\lambda = f_\lambda,$$

showing that control law (7.52) allows complete decoupling between the force- and velocity-controlled subspaces.

It is worth noticing that, for the implementation of the control law (7.52), the constraint (7.27) as well as (7.38) defining the vector of the configuration variables for the constrained system are not required, provided that the matrices S_f and S_v are known or estimated online. In these cases, the task can easily be assigned by specifying a desired force, in terms of the vector $\lambda_d(t)$, and a desired velocity, in terms of the vector $\mathbf{v}_d(t)$; moreover, a force/velocity control is implemented.

The desired force $\lambda_d(t)$ can be achieved by setting

$$f_\lambda = \lambda_d(t), \quad (7.53)$$

but this choice is very sensitive to disturbance forces, since it contains no force feedback. Alternative choices are

$$f_\lambda = \lambda_d(t) + K_{P\lambda} [\lambda_d(t) - \lambda(t)], \quad (7.54)$$

or

$$f_\lambda = \lambda_d(t) + K_{I\lambda} \int_0^t [\lambda_d(\tau) - \lambda(\tau)] d\tau, \quad (7.55)$$

where $K_{P\lambda}$ and $K_{I\lambda}$ are suitable positive-definite matrix gains. The proportional feedback is able to reduce the force error due to disturbance forces, while the integral action is able to compensate for constant bias disturbances.

The implementation of force feedback requires the computation of the force multiplier λ from the measurement of the end-effector wrench \mathbf{h}_e , which can be achieved by using (7.31).

Velocity control is achieved by setting

$$\begin{aligned} \alpha_v &= \dot{\mathbf{v}}_d(t) + K_{Pv} [\mathbf{v}_d(t) - \mathbf{v}(t)] \\ &\quad + K_{Iv} \int_0^t [\mathbf{v}_d(\tau) - \mathbf{v}(\tau)] d\tau, \end{aligned} \quad (7.56)$$

where K_{Pv} and K_{Iv} are suitable matrix gains. It is straightforward to show that asymptotic tracking of $\mathbf{v}_d(t)$ and $\dot{\mathbf{v}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices K_{Pv} and K_{Iv} .

The computation of the vector \mathbf{v} from the available measurements can be achieved using (7.37), where the end-effector twist is computed from joint position and velocity measurements through (7.1).

Equations (7.54) or (7.55) and (7.56) represent the *outer control loop* ensuring force/velocity control and disturbance rejection.

When equations (7.27) and (7.38) are known, the matrices S_f and S_v can be computed according to (7.30) and (7.40) and a *force/position* control can be designed by specifying a desired force $\lambda_d(t)$ and a desired position $\mathbf{r}_d(t)$.

Force control can be designed as above, while position control can be achieved by setting

$$\alpha_v = \ddot{\mathbf{r}}_d(t) + K_{Dr} [\dot{\mathbf{r}}_d(t) - \mathbf{v}(t)] + K_{Pr} [\mathbf{r}_d(t) - \mathbf{r}(t)].$$

Asymptotic tracking of $\mathbf{r}_d(t)$, $\dot{\mathbf{r}}_d(t)$ and $\ddot{\mathbf{r}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices K_{Dr} and K_{Pr} . The vector \mathbf{r} required for position feedback can be computed from joint position measurements via (7.38).

Compliant Environment

In the case of a compliant environment, according to the decomposition (7.42) of the end-effector displacement, the end-effector twist can be decomposed as

$$\boldsymbol{v}_e = \boldsymbol{S}_v \boldsymbol{v} + \boldsymbol{C}' \boldsymbol{S}_f \dot{\lambda}, \quad (7.57)$$

where the first term is a twist of freedom, the second term is a twist of constraint, the vector \boldsymbol{v} is defined as in (7.40), and \boldsymbol{C}' is defined in (7.48). Assuming a constant contact geometry and compliance, i.e., $\dot{\boldsymbol{S}}_v = \mathbf{0}$, $\dot{\boldsymbol{C}}' = \mathbf{0}$, and $\dot{\boldsymbol{S}}_f = \mathbf{0}$, a similar decomposition holds in terms of acceleration

$$\dot{\boldsymbol{v}}_e = \boldsymbol{S}_v \dot{\boldsymbol{v}} + \boldsymbol{C}' \boldsymbol{S}_f \ddot{\lambda}. \quad (7.58)$$

An inverse-dynamics control law (7.15) can be adopted, resulting in the closed loop (7.16), where $\boldsymbol{\alpha}$ is a properly designed control input.

In view of the acceleration decomposition (7.58), the choice

$$\boldsymbol{\alpha} = \boldsymbol{S}_v \boldsymbol{\alpha}_v + \boldsymbol{C}' \boldsymbol{S}_f f_\lambda \quad (7.59)$$

allows decoupling of the force control from velocity control. In fact, substituting (7.58) and (7.59) into (7.16) and premultiplying both sides of the resulting equation once by \boldsymbol{S}_v^\top and once by \boldsymbol{S}_f^\top , the following decoupled equations can be derived

$$\dot{\boldsymbol{v}} = \boldsymbol{\alpha}_v \quad (7.60)$$

$$\ddot{\lambda} = f_\lambda. \quad (7.61)$$

Hence, by choosing $\boldsymbol{\alpha}_v$ according to (7.56) as for the rigid environment case, asymptotic tracking of a desired velocity $\boldsymbol{v}_d(t)$ and acceleration $\dot{\boldsymbol{v}}_d(t)$ is ensured, with exponential convergence. The control input f_λ can be chosen as

$$\begin{aligned} f_\lambda &= \ddot{\lambda}_d(t) + \boldsymbol{K}_{D\lambda} [\dot{\lambda}_d(t) - \dot{\lambda}(t)] \\ &\quad + \boldsymbol{K}_{P\lambda} [\lambda_d(t) - \lambda(t)], \end{aligned} \quad (7.62)$$

ensuring asymptotic tracking of a desired force trajectory $(\lambda_d(t), \dot{\lambda}_d(t), \ddot{\lambda}_d(t))$ with exponential convergence for any choice of positive-definite matrices $\boldsymbol{K}_{D\lambda}$ and $\boldsymbol{K}_{P\lambda}$.

Differently from the rigid environment case, feedback of $\dot{\lambda}$ is required for the implementation of the force control law (7.62). This quantity could be computed from end-effector wrench measurements \boldsymbol{h}_e as

$$\dot{\lambda} = \boldsymbol{S}_f^\dagger \boldsymbol{h}_e.$$

However, since the wrench measurement signal is often noisy, the feedback of $\dot{\lambda}$ is often replaced by

$$\dot{\lambda} = \boldsymbol{S}_f^\dagger \boldsymbol{K}' \boldsymbol{J}(\boldsymbol{q}) \dot{\boldsymbol{q}}, \quad (7.63)$$

where joint velocities are measured using tachometers or computed from joint positions via numerical differentiation and \boldsymbol{K}' is the positive-semidefinite stiffness matrix (7.47) describing the partially constrained interaction. For the computation of (7.63), only knowledge (or an estimate) of \boldsymbol{K}' is required, and not that of the full stiffness matrix \boldsymbol{K} . Also, the implementation of the control law (7.59) requires knowledge (or an estimate) of the compliance matrix \boldsymbol{C}' of the partially constrained interaction and not that of the full compliance matrix \boldsymbol{C} .

If the contact geometry is known, but only an estimate of the stiffness/compliance of the environment is available, the control law (7.59), with (7.62), may still guarantee the convergence of the force error, if a constant desired force λ_d is assigned. In this case, the control law (7.59) has the form

$$\boldsymbol{\alpha} = \boldsymbol{S}_v \boldsymbol{\alpha}_v + \widehat{\boldsymbol{C}}' \boldsymbol{S}_f f_\lambda,$$

where $\widehat{\boldsymbol{C}}' = (\mathbf{I} - \boldsymbol{P}_v) \widehat{\boldsymbol{C}}$ and $\widehat{\boldsymbol{C}}$ is an estimate of the compliance matrix. Hence, (7.60) still holds, while, in lieu of (7.61), the following equality can be found

$$\ddot{\lambda} = \boldsymbol{L}_f f_\lambda$$

where $\boldsymbol{L}_f = (\boldsymbol{S}_f^\top \boldsymbol{C} \boldsymbol{S}_f)^{-1} \boldsymbol{S}_f^\top \widehat{\boldsymbol{C}} \boldsymbol{S}_f$ is a nonsingular matrix. Thus, the force- and velocity-controlled subspaces remain decoupled and the velocity control law (7.56) does not need to be modified. On the other hand, if the feedback of the time derivative of λ is computed using (7.63), only an estimate $\dot{\lambda}$ can be obtained. Using (7.63), (7.57) and (7.46), the following equality can be found

$$\dot{\lambda} = \boldsymbol{L}_f^{-1} \dot{\lambda}.$$

Therefore, computing the force control law f_λ as in (7.62) with a constant λ_d , $\dot{\lambda}$ in lieu of $\dot{\lambda}$ and $\boldsymbol{K}_{D\lambda} = \boldsymbol{K}_{D\lambda} \mathbf{I}$, the dynamics of the closed-loop system is

$$\ddot{\lambda} + \boldsymbol{K}_{D\lambda} \dot{\lambda} + \boldsymbol{L}_f \boldsymbol{K}_{P\lambda} \lambda = \boldsymbol{L}_f \boldsymbol{K}_{P\lambda} \lambda_d,$$

showing that exponential asymptotic stability of the equilibrium $\lambda = \lambda_d$ can be ensured, also in the presence of the uncertain matrix \boldsymbol{L}_f , with a suitable choice of the gains $\boldsymbol{K}_{D\lambda}$ and $\boldsymbol{K}_{P\lambda}$.

7.4.2 Passivity-Based Approach

The passivity-based approach exploits the passivity properties of the dynamic model of the manipulator, which hold also for the constrained dynamic model (7.2). It can be easily shown that the choice of the matrix

$C(\mathbf{q}, \dot{\mathbf{q}})$ that guarantees the skew symmetry of the matrix $\dot{H}(\mathbf{q}) - 2C(\mathbf{q}, \dot{\mathbf{q}})$ in the joint space, also makes the matrix $\Lambda(\mathbf{q}) - 2\Gamma(\mathbf{q}, \dot{\mathbf{q}})$ skew symmetric. This fundamental property of Lagrangian systems is at the base of passivity-based control algorithms.

Rigid Environment

The control wrench \mathbf{h}_c can be chosen as

$$\begin{aligned}\mathbf{h}_c = & \Lambda(\mathbf{q})S_v\dot{\mathbf{v}}_r + \Gamma'(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v}_r + (S_v^\dagger)^\top \mathbf{K}_v(\mathbf{v}_r - \mathbf{v}) \\ & + \eta(\mathbf{q}) + S_f f_\lambda,\end{aligned}\quad (7.64)$$

where $\Gamma'(\mathbf{q}, \dot{\mathbf{q}}) = \Gamma S_v + \Lambda \dot{S}_v$, \mathbf{K}_v is a suitable symmetric and positive-definite matrix, and \mathbf{v}_r and f_λ are properly designed control inputs.

Substituting (7.64) into (7.2) yields

$$\begin{aligned}\Lambda(\mathbf{q})S_v\dot{s}_v + \Gamma'(\mathbf{q}, \dot{\mathbf{q}})s_v + (S_v^\dagger)^\top \mathbf{K}_v s_v \\ + S_f(f_\lambda - \lambda) = \mathbf{0}\end{aligned}\quad (7.65)$$

with $\dot{s}_v = \dot{\mathbf{v}}_r - \dot{\mathbf{v}}$ and $s_v = \mathbf{v}_r - \mathbf{v}$, showing that the closed-loop system remains nonlinear and coupled.

Premultiplying both sides of (7.65) by the matrix S_v , the following expression for the reduced-order dynamics is achieved

$$\Lambda_v(\mathbf{q})\dot{s}_v + \Gamma_v(\mathbf{q}, \dot{\mathbf{q}})s_v + \mathbf{K}_v s_v = \mathbf{0}, \quad (7.66)$$

with $\Gamma_v = S_v^\top \Gamma(\mathbf{q}, \dot{\mathbf{q}})S_v + S_v^\top \Lambda(\mathbf{q})\dot{S}_v$; it can easily be shown that the skew symmetry of the matrix $\dot{\Lambda}(\mathbf{q}) - 2\Gamma(\mathbf{q}, \dot{\mathbf{q}})$ implies that the matrix $\dot{\Lambda}_v(\mathbf{q}) - 2\Gamma_v(\mathbf{q}, \dot{\mathbf{q}})$ is skew symmetric as well.

On the other hand, premultiplying both sides of (7.65) by the matrix $S_f^\top \Lambda^{-1}(\mathbf{q})$, the following expression for the force dynamics can be found

$$\begin{aligned}f_\lambda - \lambda = & -\Lambda_f(\mathbf{q})S_f^\top \\ & \cdot \Lambda^{-1}(\mathbf{q})[\Gamma'(\mathbf{q}, \dot{\mathbf{q}}) - (S_v^\dagger)^\top \mathbf{K}_v]s_v,\end{aligned}\quad (7.67)$$

showing that the force multiplier λ instantaneously depends on the control input f_λ but also on the error s_v in the velocity-controlled subspace.

The asymptotic stability of the reduced-order system (7.66) can be ensured with the choices

$$\dot{\mathbf{v}}_r = \dot{\mathbf{v}}_d + \alpha \Delta \mathbf{v}, \quad (7.68)$$

$$\mathbf{v}_r = \mathbf{v}_d + \alpha \Delta \mathbf{x}_v, \quad (7.69)$$

where α is a positive gain, $\dot{\mathbf{v}}_d$ and \mathbf{v}_d are the desired acceleration and velocity, respectively, $\Delta \mathbf{v} = \mathbf{v}_d - \mathbf{v}$, and

$$\Delta \mathbf{x}_v = \int_0^t \Delta \mathbf{v}(\tau) d\tau.$$

The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2} s_v^\top \Lambda_v(\mathbf{q}) s_v + \alpha \Delta \mathbf{x}_v^\top \mathbf{K}_v \Delta \mathbf{x}_v,$$

whose time derivative along the trajectories of (7.66),

$$\dot{V} = -\Delta \mathbf{v}^\top \mathbf{K}_v \Delta \mathbf{v} - \alpha^2 \Delta \mathbf{x}_v^\top \mathbf{K}_v \Delta \mathbf{x}_v,$$

is a definite semi-negative function. Hence, $\Delta \mathbf{v} = \mathbf{0}$, $\Delta \mathbf{x}_v = \mathbf{0}$, and $s_v = \mathbf{0}$ asymptotically. Therefore, tracking of the desired velocity $\mathbf{v}_d(t)$ is ensured. Moreover, the right-hand side of (7.67) remains bounded and vanishes asymptotically. Hence, tracking of the desired force $\lambda_d(t)$ can be ensured by setting f_λ as for the acceleration-resolved approach, according to the choices (7.53), (7.54), or (7.55).

Notice that position control can be achieved if a desired position $\mathbf{r}_d(t)$ is assigned for the vector \mathbf{r} in (7.38), provided that the matrices S_f and S_v are computed according to (7.30) and (7.40), and the vectors $\dot{\mathbf{v}}_d = \ddot{\mathbf{r}}_d$, $\mathbf{v}_d = \dot{\mathbf{r}}_d$, and $\Delta \mathbf{x}_v = \mathbf{r}_d - \mathbf{r}$ are used in (7.68) and (7.69).

Compliant Environment

The control wrench \mathbf{h}_c can be chosen as

$$\mathbf{h}_c = \Lambda(\mathbf{q})\dot{\mathbf{v}}_r + \Gamma(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v}_r + \mathbf{K}_s(\mathbf{v}_r - \mathbf{v}_e) + \mathbf{h}_e + \eta(\mathbf{q}), \quad (7.70)$$

where \mathbf{K}_s is a suitable symmetric positive-definite matrix while \mathbf{v}_r and its time derivative $\dot{\mathbf{v}}_r$ are chosen as

$$\mathbf{v}_r = \mathbf{v}_d + \alpha \Delta \mathbf{x},$$

$$\dot{\mathbf{v}}_r = \dot{\mathbf{v}}_d + \alpha \Delta \mathbf{v},$$

where α is the positive gain, \mathbf{v}_d and its time derivative $\dot{\mathbf{v}}_d$ are properly designed control inputs, $\Delta \mathbf{v} = \mathbf{v}_d - \mathbf{v}_e$, and

$$\Delta \mathbf{x} = \int_0^t \Delta \mathbf{v} d\tau.$$

Substituting (7.70) into (7.2) yields

$$\Lambda(\mathbf{q})\dot{s} + \Gamma(\mathbf{q}, \dot{\mathbf{q}})s + \mathbf{K}_s s = \mathbf{0} \quad (7.71)$$

with $\dot{s} = \dot{\mathbf{v}}_r - \dot{\mathbf{v}}_e$ and $s = \mathbf{v}_r - \mathbf{v}_e$.

The asymptotic stability of system (7.71) can be ensured by setting:

$$\mathbf{v}_d = S_v \mathbf{v}_d + \mathbf{C}' S_f \dot{\lambda}_d,$$

where $\mathbf{v}_d(t)$ is a desired velocity trajectory and $\lambda_d(t)$ is the desired force trajectory. The stability proof is based on the positive-definite Lyapunov function

$$V = \frac{1}{2} s^\top \Lambda(\mathbf{q}) s + \alpha \Delta \mathbf{x}^\top \mathbf{K}_s \Delta \mathbf{x},$$

whose time derivative along the trajectories of (7.71),

$$\dot{V} = -\Delta \mathbf{v}^\top \mathbf{K}_s \Delta \mathbf{v} - \alpha^2 \Delta \mathbf{x}^\top \mathbf{K}_s \Delta \mathbf{x},$$

is a negative-definite function. Hence, $\Delta \mathbf{v} = \mathbf{0}$ and $\Delta \mathbf{x} = \mathbf{0}$, asymptotically. In the case of constant contact geometry and stiffness, the following equalities hold

$$\Delta \mathbf{v} = \mathbf{S}_v(\mathbf{v}_d - \mathbf{v}) + \mathbf{C}' \mathbf{S}_f(\dot{\lambda}_d - \dot{\lambda}),$$

$$\Delta \mathbf{x} = \mathbf{S}_v \int_0^t (\mathbf{v}_d - \mathbf{v}) d\tau + \mathbf{C}' \mathbf{S}_f(\lambda_d - \lambda),$$

showing that both the velocity and force tracking errors, belonging to reciprocal subspaces, converge asymptotically to zero.

7.4.3 Velocity-Resolved Approach

The acceleration-resolved approach, as well as the passivity-based approach, require modification of the current industrial robot controllers. As for the case of impedance control, if the contact is sufficiently compliant, the closed-loop dynamics of a motion-controlled robot can be approximated by (7.26), corresponding to a velocity-resolved control.

To achieve force and velocity control, according to the end-effector twist decomposition (7.57), the control input \mathbf{v}_r can be chosen as

$$\mathbf{v}_r = \mathbf{S}_v \mathbf{v}_v + \mathbf{C}' \mathbf{S}_f f_\lambda, \quad (7.72)$$

with

$$\mathbf{v}_v = \mathbf{v}_d(t) + \mathbf{K}_{Iv} \int_0^t [\mathbf{v}_d(\tau) - \mathbf{v}(\tau)] d\tau, \quad (7.73)$$

and

$$f_\lambda = \dot{\lambda}_d(t) + \mathbf{K}_{P\lambda}[\lambda_d(t) - \lambda(t)], \quad (7.74)$$

where \mathbf{K}_{Iv} and $\mathbf{K}_{P\lambda}$ are suitable symmetric and positive-definite matrix gains. Decoupling between velocity- and force-controlled subspaces and exponential asymptotic stability of the closed-loop system can be proven as for the acceleration-resolved approach. Also, since the force error has second-order dynamics, an integral action can be added to (7.74) to improve the disturbance rejection capabilities, i. e.:

$$\begin{aligned} f_\lambda &= \dot{\lambda}_d(t) + \mathbf{K}_{P\lambda}[\lambda_d(t) - \lambda(t)] \\ &\quad + \mathbf{K}_{I\lambda} \int_0^t [\lambda_d(\tau) - \lambda(\tau)] d\tau, \end{aligned} \quad (7.75)$$

and the exponential asymptotic stability is guaranteed if the matrices $\mathbf{K}_{P\lambda}$ and $\mathbf{K}_{I\lambda}$ are symmetric and positive definite.

If an estimate $\hat{\mathbf{C}}$ of the stiffness matrix of the environment is used in (7.72), as for the acceleration-resolved approach, the exponential convergence of λ to a constant λ_d can still be ensured for both (7.74) and (7.75).

In some applications, besides the stiffness matrix, also the geometry of the environment is uncertain. In these cases, a force/motion control law similar to (7.72) can be implemented, without using the selection matrices \mathbf{S}_v and \mathbf{S}_f to separate the force-controlled subspace from the velocity-controlled subspace. The motion control law can be set as in (7.73), but using full velocity feedback. Also, the force control law can be set as in (7.75), but using full force and moment feedback. That is, both motion control and force control are applied in all directions of the six-dimensional (6-D) space. The resulting control, known as *force control with feedforward motion or parallel force/position control* guarantees force regulation at the expense of position errors along the constrained task directions, thanks to the dominance of the force controller over the position controller ensured by the presence of the integral action on the force error.

7.5 Conclusions and Further Reading

This chapter has summarized the main approaches to force control in a unifying perspective. However, there are many aspects that have not been considered and that must be carefully taken into account when dealing with interaction robotic tasks. The two major paradigms of force control (impedance and hybrid force/motion control) are based on several simplifying assumptions that are only partially satisfied in practical implemen-

tations. In fact, the performance of a force-controlled robotic system depends on the interaction with a changing environment which is very difficult to model and identify correctly. A general contact situation is far from being completely predictable, not only quantitatively, but also qualitatively: the contact configuration can change abruptly, or be of a different type than expected. Hence, the standard performance indices used

to evaluate a control system, i.e., stability, bandwidth, accuracy, and robustness, cannot be defined by considering the robotic system alone, as for the case of robot motion control, but must be always referred to the particular contact situation at hand. Also, a classification of all these different situations is not easy, especially in the case of dynamics environments and when the task involves multiple contacts acting in parallel.

Due to the inherent complexity of the force control problem, a large number of research papers on this topic have been published in the past three decades. A description of the state of the art of the first decade is provided in [7.20], whereas the progress of the second decade is surveyed in [7.21] and [7.22]. More recently, two monographs on force control [7.23, 24] have appeared. In the following, a list of references is provided, where more details on the arguments presented in the chapter, as well as topics not covered here, can be found.

7.5.1 Indirect Force Control

The concept of generalized spring and damping for force control in joint coordinates was originally proposed in [7.3] and the implementation discussed in [7.10]. Stiffness control in Cartesian coordinates was proposed in [7.9]. Devices based on the remote center of compliance were discussed in [7.25] for successful mating of rigid parts. The original idea of a mechanical impedance model used for controlling the interaction between the manipulator and the environment is presented in [7.7], and a similar formulation is given in [7.8]. Stability of impedance control was analyzed in [7.26] and the problems of interaction with a stiff environment were considered in [7.27].

Adaptive impedance control algorithms [7.28, 29] have been proposed to overcome uncertainties in the dynamic parameters of the robot manipulator, while robust control schemes can be found in [7.30]. Impedance control has also been used in the hybrid force/motion control framework [7.31].

A reference work on modeling 6-DOF (spatial) stiffness is [7.32], while the properties of spatial compliance have been analyzed in detail in [7.33–35]; a 6-DOF variable compliant wrist was proposed in [7.36], while several studies concerning the construction of programmed compliances, optimized for specific tasks, have been proposed [7.37, 38]. The energy-based approach to derive a spatial impedance was introduced in [7.39], using rotation matrices; various 6-DOF impedance control schemes based on different representations of end-effector orientation, including the unit

quaternion, can be found in [7.40]. The quaternion-based formulation is extended to the case of non-block-diagonal stiffness matrix in [7.41]. A rigorous treatment of spatial impedance control in a passivity framework can be found in [7.42].

7.5.2 Task Specification

The concepts of natural and artificial constraints and of compliance frame were introduced in [7.11]. These ideas have been systematically developed in [7.12, 43] within the *task frame formalism*. Theoretical issues on the reciprocity of generalized force and velocity directions are discussed in [7.44, 45], while invariance in computing the generalized inverse in robotics is addressed in [7.46]. The issue of partially constrained tasks is considered in [7.47], where the models of positive-semidefinite stiffness and compliance matrices are developed. The problem of estimating geometric uncertainties is considered in [7.48, 49], as well as the issue of linking constraint-based task specification with real-time task execution control. This approach is generalized in [7.50], where a systematic constraint-based methodology to specify complex tasks is presented.

7.5.3 Hybrid Force/Motion Control

Early works on force control can be found in [7.10]. The original hybrid force/position control concept was introduced in [7.13], based on the natural and artificial constraint task formulation [7.11]. The explicit inclusion of the manipulator dynamic model was presented in [7.17], and a systematic approach to modeling the interaction with a dynamic environment was developed in [7.51]. The constrained formulation with inverse dynamic controllers is treated in [7.14, 52] in the Cartesian space as well as in [7.15] joint space. The constrained approach was also used in [7.16] with a controller based on linearized equations. The invariance problems pointed out in [7.45] were correctly addressed, among other papers, in [7.44, 53]. Transposition of model-based schemes from unconstrained motion control to constrained cases was accomplished for adaptive control in [7.18, 54, 55] and for robust control in [7.56].

Approaches designed to cope with uncertainties in the environment geometry are the force control with feedforward motion scheme proposed in [7.2] and the parallel force/position control [7.19], based on the concept of dominance of force control on motion control, thanks to the use of an integral action on the force error. A parallel force/position regulator was de-

veloped in [7.57]. The integral action for removing steady-state force errors has traditionally been used; its stability was proven in [7.58], while robustness with respect to force measurement delays was investigated in [7.59, 60].

It has generally been recognized that force control may cause unstable behavior during contact with environment. Dynamic models for explaining this phenomenon were introduced in [7.61] and experimental

investigations can be found in [7.62] and [7.63]. Moreover, control schemes are usually derived on the assumption that the manipulator end-effector is in contact with the environment and that this contact is not lost. Impact phenomena may occur and deserve careful consideration, and there is a need for global analysis of control schemes including the transition from noncontact to contact situations and vice versa, see e.g., [7.64–66].

8. Robotic Systems Architectures and Programming

Robotic Systems

David Kortenkamp, Reid Simmons

Robot software systems tend to be complex. This complexity is due, in large part, to the need to control diverse sensors and actuators in real time, in the face of significant uncertainty and noise. Robot systems must work to achieve tasks while monitoring for, and reacting to, unexpected situations. Doing all this concurrently and asynchronously adds immensely to system complexity.

The use of a well-conceived architecture, together with programming tools that support the architecture, can often help to manage that complexity. Currently, there is no single architecture that is best for all applications – different architectures have different advantages and disadvantages. It is important to understand those strengths and weaknesses when choosing an architectural approach for a given application.

This chapter presents various approaches to architecting robotic systems. It starts by defining terms and setting the context, including a recounting of the historical developments in the area of robot architectures. The chapter then discusses in more depth the major types of architectural components in use today – behavioral control (Chap. 38), executives, and task planners (Chap. 9) – along with commonly used techniques for inter-

connecting those components. Throughout, emphasis will be placed on programming tools and environments that support these architectures. A case study is then presented, followed by a brief discussion of further reading.

8.1 Overview

The term *robot architecture* is often used to refer to two related, but distinct, concepts. Architectural *structure* refers to how a system is divided into subsystems and how those subsystems interact. The structure of a robot system is often represented informally using traditional *boxes and arrows* diagrams or more formally using techniques such as unified modeling language (**UML**) [8.1]. In contrast, architectural *style* refers to the computational concepts that underlie a given system. For instance, one

robot system might use a publish–subscribe message passing style of communication, while another may use a more synchronous client–server approach.

All robotic systems use some architectural structure and style. However, in many existing robot systems it is difficult to pin down precisely the architecture being used. In fact, a single robot system will often use several styles together. In part, this is because the system implementation may not have clean subsystem bound-

aries, blurring the architectural structure. Similarly, the architecture and the domain-specific implementation are often intimately tied together, blurring the architectural style(s).

This is unfortunate, as a well-conceived, clean architecture can have significant advantages in the specification, execution, and validation of robot systems. In general, robot architectures facilitate development by providing beneficial constraints on the design and implementation of robotic systems, without being overly restrictive. For instance, separating behaviors into modular units helps to increase understandability and reusability, and can facilitate unit testing and validation.

8.1.1 Special Needs of Robot Architectures

In some sense, one may consider robot architectures as software engineering. However, robot architectures are distinguished from other software architectures because of the special needs of robot systems. The most important of these, from the architectural perspective, are that robot systems need to interact asynchronously, in real time, with an uncertain, often dynamic, environment. In addition, many robot systems need to respond at varying temporal scopes – from millisecond feedback control to minutes, or hours, for complex tasks.

To handle these requirements, many robot architectures include capabilities for acting in real time, controlling actuators and sensors, supporting concurrency, detecting and reacting to exceptional situations, dealing with uncertainty, and integrating high-level (symbolic) planning with low-level (numerical) control.

While the same capability can often be implemented using different architectural styles, there may be advantages of using one particular style over another. As an example, consider how a robot system's style of communications can impact on its reliability. Many robot systems are designed as asynchronous processes that communicate using message passing. One popular communication style is *client-server*, in which a message request from the client is paired with a response from the server. An alternate communication paradigm is *publish-subscribe*, in which messages are broadcast asynchronously and all modules that have previously indicated an interest in such messages receive a copy. With client-server-style message passing, modules typically send a request and then block, waiting for the response. If the response never comes (e.g., the server module crashes) then deadlock can occur. Even if the module does not block, the control flow still typically expects a response, which may lead to unexpected re-

sults if the response never arrives or if a response to some other request happens to arrive first. In contrast, systems that use publish–subscribe tend to be more reliable: because messages are assumed to arrive asynchronously, the control flow typically does not assume any particular order in which messages are processed, and so missing or out-of-order messages tend to have less impact.

8.1.2 Modularity and Hierarchy

One common feature of robot architectures is modular decomposition of systems into simpler, largely independent pieces. As mentioned above, robot systems are often designed as communicating processes, where the communications interface is typically small and relatively low bandwidth. This design enables the processes/modules to handle interactions with the environment asynchronously, while minimizing interactions with one another. Typically, this decreases overall system complexity and increases overall reliability.

Often, system decomposition is hierarchical – modular components are themselves built on top of other modular components. Architectures that explicitly support this type of layered decomposition reduce system complexity through abstraction. However, while hierarchical decomposition of robotic systems is generally regarded as a *desirable quality*, debate continues over the dimensions along which to decompose. Some architectures [8.2] decompose along a temporal dimension – each layer in the hierarchy operates at a characteristic frequency an order of magnitude slower than the layer below. In other architectures [8.3–6], the hierarchy is based on task abstraction – tasks at one layer are achieved by invoking a set of tasks at lower levels. In some situations, decomposition based on spatial abstraction may be more useful, such as when dealing with both local and global navigation [8.7]. The main point is that different applications need to decompose problems in different ways, and architectural styles can often be found to accommodate those different needs.

8.1.3 Software Development Tools

While significant benefit accrues from *designing* systems using well-defined architectural styles, many architectural styles also have associated software tools that facilitate adhering to that style during *implementation*. These tools can take the form of libraries of functions calls, specialized programming languages, or graphical editors. The tools make the constraints of the

architectural style explicit, while hiding the complexity of the underlying concepts.

For instance, inter-process communication libraries, such as common object request broker architecture ([CORBA](#)) [8.8] and inter-process communication ([IPC](#)) package [8.9], make it easy to implement message passing styles, such as client–server and publish–subscribe, respectively. Languages, such as Subsumption [8.10] and Skills [8.11] facilitate the development of data-driven, real-time behaviors, while languages such as the execution support language ([ESL](#)) [8.12] and the plan execution interchange language ([PLEXIL](#)) [8.13] provide support for reliably achieving higher-level tasks. Graphical editors, such as found in Control-Shell [8.14], Labview [8.15] and open robot controller

computer aided design ([ORCCAD](#)) [8.6], provide constrained ways to assemble systems, and then automatically generate code that adheres to the architectural style.

In each case, the tools facilitate the development of software in the given style and, more importantly, make it impossible (or, at least, very difficult) to violate the constraints of that architectural style. The result is that systems implemented using such tools are typically easier to implement, understand, debug, verify, and maintain. They also tend to be more reliable, since the tools provide well-engineered capabilities for commonly needed control constructs, such as message passing, interfacing with actuators and sensors, and handling concurrent tasks.

8.2 History

Robot architectures and programming began in the late 1960s with the Shakey robot at Stanford University [8.16] (Fig. 8.1). Shakey had a camera, a range finder, and bump sensors, and was connected to DEC PDP-10 and PDP-15 computers via radio and video links. Shakey's architecture was decomposed into three

Fig. 8.1 Shakey (courtesy sri.com)

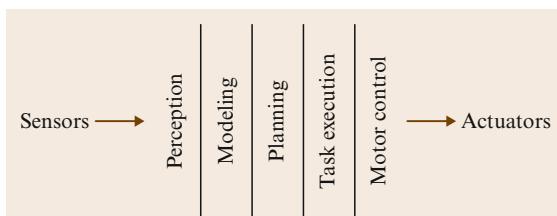

Fig. 8.2 The sense–plan–act ([SPA](#)) paradigm (after [8.3], with permission)

functional elements: sensing, planning, and executing [8.17]. The sensing system translated the camera image into an internal world model. The planner took the internal world model and a goal and generated a plan (i.e., a series of actions) that would achieve the goal. The executor took the plan and sent the actions to the robot. This approach has been called the *sense–plan–act* ([SPA](#)) paradigm (Fig. 8.2). Its main architectural features are that sensing flowed into a world model, which was then used by the planner, and that plan was executed without directly using the sensors that created the model. For many years, robotic control architectures and programming focused almost exclusively on the [SPA](#) paradigm.

8.2.1 Subsumption

In the early 1980s, it became apparent that the [SPA](#) paradigm had problems. First, planning in any real-world domain took a long time, and the robot would be blocked, waiting for planning to complete. Second, and more importantly, execution of a plan without involving sensing was dangerous in a dynamic world. Several new robot control architecture paradigms began to emerge, including reactive planning, in which plans were generated quickly and relied more directly on sensed information instead of internal models [8.4, 18]. The most influential work, however, was the subsumption architecture of [Brooks](#) [8.3]. A subsumption architecture is built from layers of interacting finite-state machines – each connecting sensors to actuators directly (Fig. 8.3). These finite-state machines were called

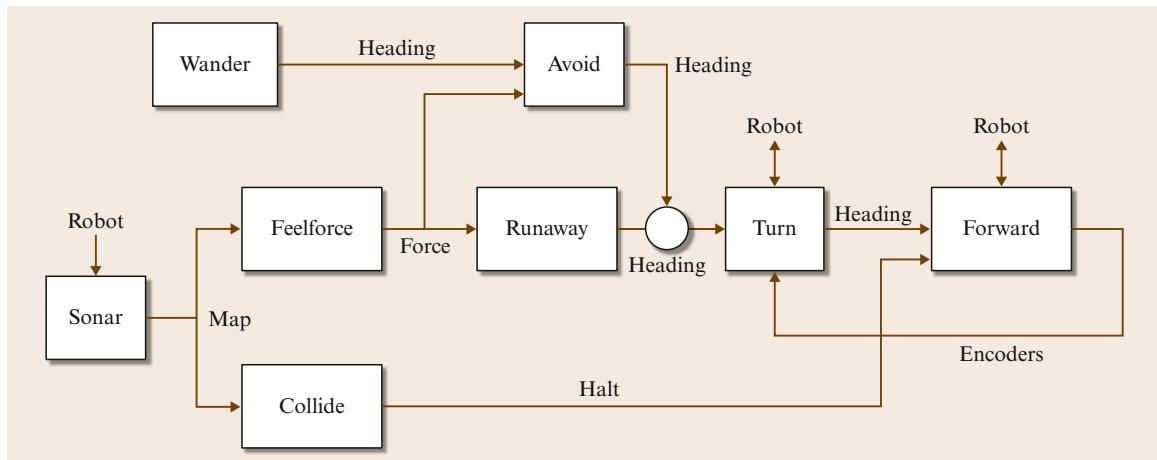

Fig. 8.3 Example of the Subsumption architecture (after [8.3], with permission)

behaviors (leading some to call Subsumption *behavior-based* or *behavioral* robotics [8.19]; see also Ch. 38). Since multiple behaviors could be active at any one time, Subsumption had an *arbitration* mechanism that enabled higher-level behaviors to override signals from lower-level behaviors. For example, the robot might have a behavior that simply drives the robot in random directions. This behavior is always active and the robot is always driving somewhere. A second, higher-level behavior could take sensor input, detect obstacles, and steer the robot away from them. It is also always active. In an environment with no obstacles, the higher-level behavior never generates a signal. However, if it detects an obstacle it overrides the lower-level behavior and steers the robot away. As soon as the obstacle is gone (and the higher-level behavior stops sending signals), the lower-level behavior gets control again. Multiple, interacting layers of behaviors could be built to produce more and more complex robots.

Many robots were built using the subsumption approach – most at MIT [8.20–22]. They were quite successful. Whereas SPA robots were slow and ponderous, Subsumption robots were fast and reactive. A dynamic world did not bother them because they constantly sensed the world and reacted to it. These robots scampered around like insects or small rodents. Several behavioral architectures arose in addition to Subsumption, often with different arbitration schemes for combining the outputs of behaviors [8.23, 24].

A popular example of behavior-based architectures is Arkin's motor-control schemas [8.25]. In this biologically inspired approach, motor and perceptual schemas [8.26] are dynamically connected to one an-

other. The motor schemas generate response vectors based on the outputs of the perceptual schemas, which are then combined in a manner similar to potential fields [8.27]. To achieve more complex tasks, the autonomous robot architecture (AuRA) architecture [8.28, 29] added a navigation planner and a plan sequencer, based on finite-state acceptors (FSAs), to the reactive schemas.

However, behavior-based robots soon reached limits in their capabilities. It proved very difficult to compose behaviors to achieve long-range goals and it proved almost impossible to optimize robot behavior. For example, a behavior-based robot that delivered mail in an office building could easily be built by simply wandering around the office building and having behaviors looking for rooms and then overriding the wandering and entering the office. It was much more difficult to use the behavioral style of architecture to design a system that reasoned about the day's mail to visit the offices in an optimal order to minimize delivery time. In essence, robots needed the planning capabilities of the early architectures wedged to the reactivity of the behavior-based architectures. This realization led to the development of layered, or tiered, robot control architectures.

8.2.2 Layered Robot Control Architectures

One of the first steps towards the integration of reactivity and deliberation was the reactive action packages (RAPs) system created by Firby. In his thesis [8.30], we see the first outline of an integrated, three-layer architecture. The middle layer of that architecture, and the subject of the thesis, was the RAPs system. Firby also

speculated on the form and function of the other two tiers, specifically with the idea of integrating classic deliberative methods with the ideas of the emerging situated reasoning community, but those layers were never implemented. Later, *Firby* would integrate RAPs with a continuous low-level control layer [8.31].

Independently and concurrently, *Bonasso* at MITRE [8.32] devised an architecture that began at the bottom layer with robot behaviors programmed in the Rex language as synchronous circuits [8.33]. These Rex machines guaranteed consistent semantics between the agent's internal states and those of the world. The middle layer was a conditional sequencer implemented in the Gapps language [8.34], which would continuously activate and deactivate the Rex skills until the robot's task was complete. This sequencer based on Gapps was appealing because it could be synthesized through more traditional planning techniques [8.35]. This work culminated in the 3T architecture (named after its three tiers of interacting control processes – planning, sequencing, and real-time control), which has been used on many generations of robots [8.36].

Architectures similar to 3T (Fig. 8.4) have been developed subsequently. One example is ATLANTIS [8.37], which leaves much more control at the sequencing tier. In ATLANTIS, the deliberative tier must be specifically called by the sequencing tier. A third example is *Saridis'* intelligent control architecture [8.38]. The architecture begins with the servo systems available on a given robot and augments them to integrate the execution algorithms of the next level, using VxWorks and the VME bus. The next level consists of a set of coordinating routines for each lower subsystem, e.g., vision, arm motion, and navigation. These are implemented in Petri net transducers (PNTs), a type of scheduling mechanism, and activated by a dispatcher connected to the organizational level. The organizational level is a planner implemented as a Boltzmann neural network. Essentially the neural network finds a sequence of actions that will match the required command received as text input, and then the dispatcher executes each of these steps via the network of PNT coordinators.

The LAAS architecture for autonomous systems (LAAS) is a three-layered architecture that includes software tools to support development/programming at each layer [8.39]. The lowest layer (functional) consists of a network of *modules*, which are dynamically parameterized control and perceptual algorithms. Modules are written in the generator of modules (GenoM) language, which produces standardized templates that facilitate the integration of modules with one another.

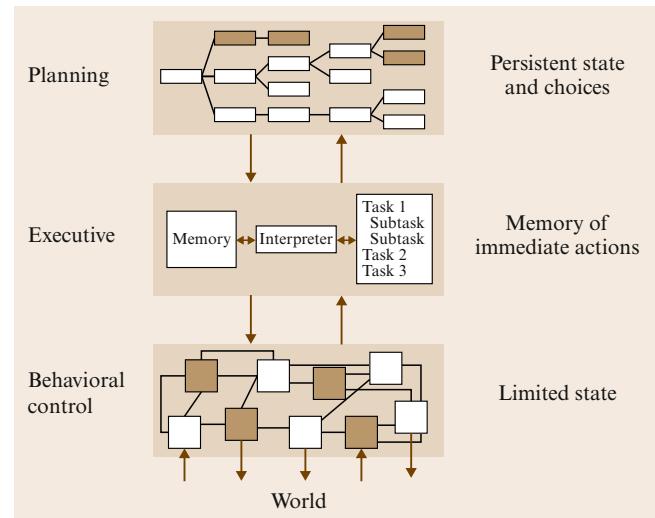

Fig. 8.4 Prototype three-tiered architecture

Unlike most other three-layered architectures, the executive layer is fairly simple – it is purely reactive and does no task decomposition. It serves mainly as a bridge – receiving task sequences from the highest layer and selecting and parameterizing tasks to send to the functional layer. The executive is written in the Kheops language, which automatically generates decision networks that can be formally verified. At the top, the decision layer consists of a planner, implemented using the indexed time table (IxTeT) temporal planner [8.40, 41], and a supervisor, implemented using procedural reasoning system (PRS) [8.42, 43]. The supervisor is similar to the executive layer of other three-layered architectures – it decomposes tasks, chooses alternative methods for achieving tasks, and monitors execution. By combining the planner and supervisor in one layer, LAAS achieves a tighter connection between the two, enabling more flexibility in when, and how, replanning occurs. The LAAS architecture actually allows for multiple decisional layers at increasingly higher levels of abstraction, such as a high-level *mission* layer and a lower-level *task* layer.

Remote agent is an architecture for the autonomous control of spacecraft [8.44]. It actually consists of four layers – a control (behavioral) layer, an executive, a planner/scheduler, and mode identification and recovery (MIR) that combines fault detection and recovery. The control layer is the traditional spacecraft real-time control system. The executive is the core of the architecture – it decomposes, selects, and monitors task execution, performs fault recovery, and does resource management,

turning devices on and off at appropriate times to conserve limited spacecraft power. The planner/scheduler is a batch process that takes goals, an initial (projected) state, and currently scheduled activities, and produces plans that include flexible ranges on start and end times

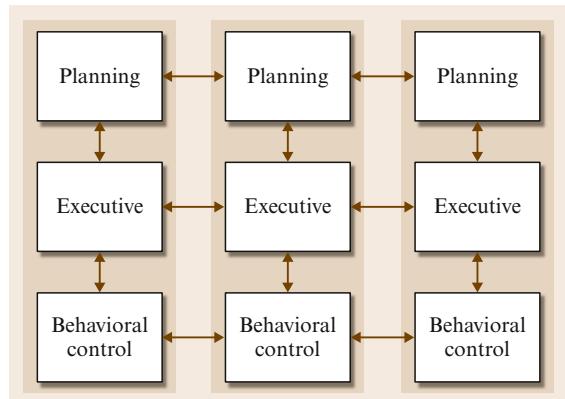

Fig. 8.5 The Syndicate multirobot architecture

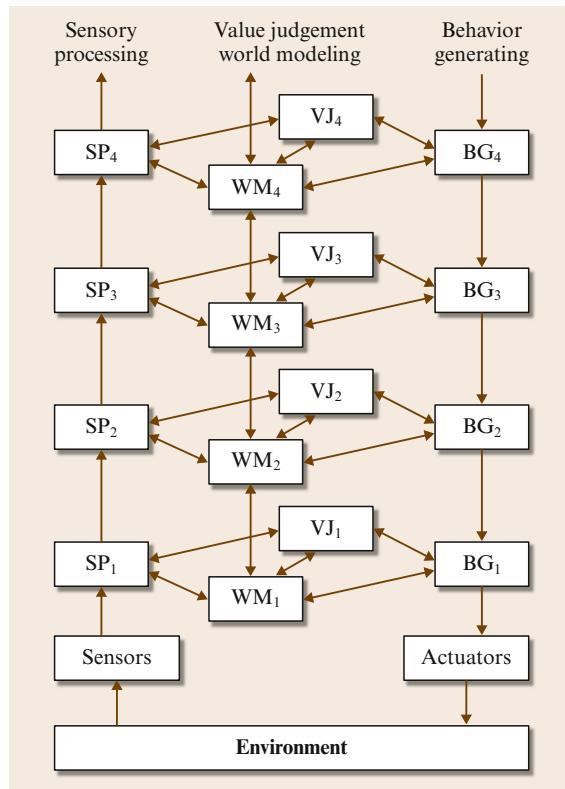

Fig. 8.6 The real-time control system (RCS) reference architecture (after [8.46], with permission)

of tasks. The plan also includes a task to reinvoke the planner to produce the next plan segment. An important part of the remote agent is configuration management – configuring hardware to support tasks and monitoring that the hardware remains in known, stable states. The role of configuration management is split between the executive, which uses reactive procedures, and MIR, which uses declarative models of the spacecraft and deliberative algorithms to determine how to reconfigure the hardware in response to detected faults [8.45].

The Syndicate architecture [8.47] extends the 3T model to multirobot coordination (Chap. 40). In this architecture, each layer interfaces not only with the layers above and below, as usual, but also with the layers of the other robots at the same level (Fig. 8.5). In this way, distributed control loops can be designed at multiple levels of abstraction. The version of Syndicate in [8.48] used a distributed market-based approach for task allocation at the planning layer.

Other noteworthy multilayered architectures have appeared in the literature. The National Bureau of Standards (NBS) developed for the Aeronautics and Space Agency (NASA) the NASA/NBS standard reference model (NASREM) [8.2, 49], later named real-time control system (RCS), was an early reference model for telerobotic control (Fig. 8.6). It is a many-tiered model in which each layer has the same general structure, but operates at increasingly lower frequency as it moves from the servo level to the reasoning levels. With the exception of maintaining a global world model, NASREM, in its original inception, provided for all the data and control paths that are present in architectures such as 3T, but NASREM was a reference model, not an implementation. The subsequent implementations of NASREM followed primarily the traditional sense–plan–act approach and were mainly applied to telerobotic applications, as opposed to autonomous robots. A notable exception was the early work of Blidberg [8.50].

While three-layered robot architectures are very popular, various two-layered architectures have been investigated by researchers. The coupled layered architecture for robot autonomy (CLARAty) was designed to provide reusable software for NASA's space robots, especially planetary rovers [8.51, 52]. CLARAty consists of a functional and a decision layer. The functional layer is a hierarchy of object-oriented algorithms that provide more and more abstract interfaces to the robot, such as motor control, vehicle control, sensor-based navigation, and mobile manipulation. Each object provides a generic interface that is hardware independent, so that

the same algorithms can run on different hardware. The decision layer combines planning and executive capabilities. Similar to the **LAAS** architecture, this is done to provide for tighter coordination between planning and execution, enabling continual replanning in response to dynamic contingencies.

Closed-loop execution and recovery (**CLEaR**) [8.53] is one instantiation of the **CLARAty** decision layer. **CLEaR** combines the continuous activity scheduling, planning, execution and replanning (**CASPER**) repair-based planner [8.54] and the task description language (**TDL**) executive language [8.55]. **CLEaR** provides a tightly coupled approach to goal- and event-driven behavior. At its heart is the capability to do fast, continuous replanning, based on frequent state and resource updates from execution monitoring. This enables the planner to react to many exceptional situations, which can be important in cases where there are many tasks, few resources, and significant uncertainty. In **CLEaR**, both the planning and executive components are able to handle resource conflicts and exceptional situations – heuristics are used to decide which component should be involved in a given situation. The onboard autonomous science investigation system (**OASIS**) system [8.56] extends **CLEaR** to include science data analysis so that the architecture can be driven by opportunistic science-related goals (such as finding unusual rocks or formations). **OASIS** is planner-centric, releasing tasks to the executive component just a few seconds before their scheduled start times.

The cooperative intelligent real-time control architecture (**CIRCA**) is a two-layered architecture concerned with guaranteeing reliable behavior [8.57, 58]. It embodies the notion of *bounded reactivity* – an acknowl-

edgement that the resources of the robot are not always sufficient to guarantee that all tasks can be achieved. **CIRCA** consists of a real-time system (**RTS**) and an artificial intelligence (**AIS**) system (**AIS**) that are largely independent. The **RTS** executes a cyclic schedule of test action pairs (**TAPs**) that have guaranteed worst-case behavior in terms of sensing the environment and conditionally acting in response. It is the responsibility of the **AIS** to create a schedule that is guaranteed to prevent catastrophic failures from occurring, while running in hard real time. The **AIS** does this by planning over a state-transition graph that includes transitions for actions, exogenous events, and the passage of time (e.g., if the robot waits too long, bad things can happen). The **AIS** tests each plan (set of **TAPs**) to see if it can actually be scheduled. If not, it alters the planning model, either by eliminating tasks (based on goal prioritization) or by changing parameters of behaviors (e.g., reducing the robot's velocity). The **AIS** continues this until it finds a plan that can be successfully scheduled, in which case it downloads the new plan to the **RTS** in an atomic operation.

Like **CIRCA**, **ORCCAD** is a two-layered architecture that is concerned with guaranteed reliability [8.6, 59]. In the case of **ORCCAD**, this guarantee is achieved through formal verification techniques. Robot tasks (lower-level behaviors) and robot procedures (higher-level actions) are defined in higher-level languages that are then translated into the Esterel programming language [8.60], for logical verification, or the Timed-Arcus language [8.61], for temporal verification. The verification is geared toward liveness and safety properties, as well as verifying lack of contention for resources.

8.3 Architectural Components

We will take the three-tiered architecture as the prototype for the components discussed in this chapter. Figure 8.4 shows a typical three-tiered architecture. The lowest tier (or layer) is behavioral control and is the layer tied most closely to sensors and actuators. The second tier is the executive layer and is responsible for choosing the current behaviors of the robot to achieve a task. The highest tier is the task-planning layer and it is responsible for achieving long-term goals of the robot within resource constraints. Using the example of an office delivery robot, the behavioral layer is responsible for moving the robot around rooms and hallways,

for avoiding obstacles, for opening doors, etc. The executive layer coordinates the behavioral layer to achieve tasks such as leaving a room, going to an office, etc. The task-planning layer is responsible for deciding the order of deliveries to minimize time, taking into account delivery priorities, scheduling, recharging, etc. The task-planning layer sends tasks (e.g., exit the room, go to office 110) to the executive. All these tiers need to work together and exchange information. The next section deals with the problem of connecting components to each other. We then discuss each component of the three-tiered prototype architecture in detail.

8.3.1 Connecting Components

All of the architecture components that have been discussed in this chapter need to communicate with each other. They need to both exchange data and send commands. The choice of how components communicate (often called the *middleware*) is one of the most important and most constraining of the many decisions a robot architecture designer will make. From previous experience, a great deal of the problems and a majority of the debugging time in developing robot architectures have to do with communication between components. In addition, once a communication mechanism is chosen it becomes extremely difficult to change, so early decisions persist for many years. Many developers *roll their own* communication protocols, usually built on top of Unix sockets. While this allows for customization of messages, it fails to take advantage of the reliability, efficiency, and ease of use that externally available communication packages provide. There are two basic approaches to communication: client–server and publish–subscribe.

Client–Server

In a client–server (also called a point-to-point) communication protocol, components talk directly with other components. A good example of this is remote procedure call ([RPC](#)) protocols in which one component (the client) can call functions and procedures of another component (the server). A modern, and popular, variation on this is the common object request broker architecture ([CORBA](#)). [CORBA](#) allows for one component to call object methods that are implemented by another component. All method calls are defined in an interface definition language ([IDL](#)) file that is language independent. Every component uses the same [IDL](#) to generate code that compiles with component to handle communication. The advantage of this is that, when an [IDL](#) file is changed, all components that use that [IDL](#) can be recompiled automatically (by using *make* or similar code configuration tools). [CORBA](#) object request brokers ([ORBs](#)) are available for most major object-oriented languages. Although free [ORBs](#) are available, many commercial [ORBs](#) offer additional features and support. One disadvantage of [CORBA](#) is that it introduces quite a bit of additional code into applications. Some competitors have tried to address this issue, such as the internet communications engine ([ICE](#)), which has its own version of an [IDL](#) file called the specification language for [ICE](#) ([SLICE](#)). The biggest advantage of a client–server protocol is that the interfaces are very clearly

defined in advance and everyone knows when the interface has changed. Another advantage is that it allows for a distributed approach to communication with no central module that must distribute data. A disadvantage of client–server protocols is that they introduce significant overhead, especially if many components need the same information. It should be noted that [CORBA](#) and [ICE](#) also have a broadcast mechanism (called an event channel, or the notification service, in [CORBA](#)).

Publish–Subscribe

In a publish–subscribe (also called a broadcast) protocol, a component publishes data and any other component can subscribe to that data. Typically, a centralized process routes data between publishers and subscribers. In a typical architecture, most components both publish information and subscribe to information published by other components. There are several existing publish–subscribe middleware solutions. A popular one for robotics is the real-time innovations' ([RTI](#)) data distribution service (DDS), formerly the network data distribution service ([NDDS](#)) [8.62]. Another popular publish–subscribe paradigm is [IPC](#) developed at Carnegie Mellon University [8.9]. Many publish–subscribe protocols are converging on using extensible markup language ([XML](#)) descriptions to define the data being published, with the added convenience of transmitting [XML](#) over HTTP, which allows for significant interoperability with Web-based applications. Publish–subscribe protocols have a large advantage in being simple to use and having low overhead. They are especially useful when it is unknown how many different components might need a piece of data (e.g., multiple user interfaces). Also, components do not get bogged down with repeated requests for information from many different sources. Publish–subscribe protocols are often more difficult to debug because the syntax of the message is often hidden in a simple string type. Thus problems are not revealed until runtime when a component tries, and fails, to parse an incoming message. Publish–subscribe protocols are also not as readable when it comes to sending commands from one module to another. Instead of calling an explicit method or function with parameters, a command is issued by publishing a message with the command and parameters in it and then having that message be parsed by a subscriber. Finally, publish–subscribe protocols often use a single central server to dispatch messages to all subscribers, providing a single point of failure and potential bottleneck.

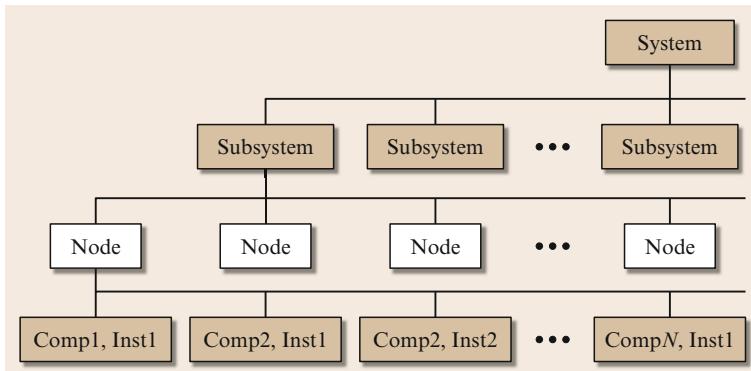

Fig. 8.7 The JAUS reference architecture topology (after JAUS Reference Architecture document [8.63])

JAUS

Recently, a standard has emerged in the defense robotics community not only for a communication protocol but also for definitions of messages that are sent via that communication protocol. The joint architecture for unmanned systems (JAUS) defines a set of reusable messages and interfaces that can be used to command autonomous systems [8.63–65]. These reusable components reduce the cost of integrating new hardware components into autonomous systems. Reuse also allows for components developed for one autonomous system to be used by another autonomous system. JAUS has two components: a *domain model* and a *reference architecture*. The domain model is a representation of the unmanned systems' functions and information. It contains a description of the system's functional and informational capabilities. The former includes models of the system's maneuvering, navigational, sensing, payload, and manipulation capabilities. The latter includes models of the system's internal data, such as maps and system status. The reference architecture provides a well-defined set of messages. Messages cause actions to commence, information to be exchanged, and events to occur. Everything that occurs in a JAUS system is precipitated by messages. This strategy makes JAUS a component-based, message-passing architecture.

The JAUS reference architecture defines a system hierarchy, as shown in Fig. 8.7. The topology defines the *system* as the collection of vehicles, operator control units (**OCU**), and infrastructure necessary to provide the full robotic capability. Subsystems are individual units (e.g., vehicles or **OCUs**) in the system. Nodes define a distinct processing capability within the architecture and route JAUS messages to components. Components provide the different execution capabilities and respond directly to command messages. Components might be

sensors (e.g., a SICK laser or a vision sensor), actuators (a manipulator or a mobile base) or payloads (weapons or task sensors). The topology (the layout of particular system, subsystems, nodes, and components) is defined by the system implementers based on task requirements.

At the core of JAUS is a set of well-defined messages. JAUS supports the following message types.

| | |
|----------------------------|----------------------------------------------|
| <i>Command:</i> | Initiate mode changes or actions |
| <i>Query:</i> | Used to solicit information from a component |
| <i>Inform:</i> | Response to a query |
| <i>Event set up:</i> | Passes parameters to set up an event |
| <i>Event notification:</i> | Sent when the event happens |

JAUS has about 30 predefined messages that can be used to control robots. There are messages for control of a robotic vehicle. For example, the *global vector driver* message performs closed-loop control of the desired global heading, altitude, and speed of a mobile vehicle. There are also sensor messages such as *global pose sensor*, which distributes the global position and orientation of the vehicle. There are also manipulation messages in JAUS. For example, the *set joint positions* message sets the desired joint position values. The *set tool point* message specifies the coordinates of the end-effector tool point in terms of the coordinate system attached to the end-effector.

JAUS also has user-definable messages. Messages have headers that follow a specific format and include message type, destination address (e.g., system, subsystem, node, and component), priority, etc. While JAUS is primarily point to point, JAUS messages can also be marked as *broadcast* and distributed to all components. JAUS also defines coordinate systems for navigation and manipulation to ensure all components understand any coordinates sent to them.

8.3.2 Behavioral Control

Behavioral control represents the lowest level of control in a robot architecture. It directly connects sensors and actuators. While these are typically hand-crafted functions written in C or C++, there have been specialized languages developed for behavioral control, including ALFA [8.66], Behavioral Language [8.67], and Rex [8.68]. It is at this level that traditional control theory (e.g., PID functions, Kalman filters, etc.) resides. In architectures such as 3T, the behavioral layer functions as a *Brooksian machine* – that is, the layer is composed of a small number of behaviors (also called skills) that perceive the environment and carry out the actions of the robot.

Example

Consider an office delivery robot that operates in a typical office building. The behavioral control layer contains the control functions necessary to move around in the building and carry out delivery tasks. Assuming the robot has an a priori map of the building, some possible behaviors for this robot include

1. move to location while avoiding obstacles
2. move down hallway while avoiding obstacles
3. find a door
4. find a door knob
5. grasp a door knob
6. turn a door knob
7. go through door
8. determine location
9. find office number
10. announce delivery

Each of these behaviors ties sensors (vision, range sensing, etc.) to actuators (wheel motors, manipulator motors, etc.) in a tight loop. In architectures such as Subsumption, all behaviors are running concurrently with a hierarchical control scheme inhibiting the outputs of certain behaviors. In AuRA [8.29], behaviors are combined using potential functions. Other architectures [8.24, 68] use explicit arbitration mechanisms to choose amongst potentially conflicting behaviors.

In architectures such as 3T [8.36], not all of the behaviors are active at the same time. Typically, only a few behaviors that do not conflict would be active at a time (e.g., behaviors 2 and 9 in the example above). The executive layer (see Sect. 8.3.3) is responsible for activating and deactivating behaviors to achieve higher-level tasks and to avoid conflicts between two behaviors competing for the same resource (e.g., an actuator).

Situated Behaviors

An important aspect of these behaviors is that they be *situated*. This means that the behavior works only in very specific situations. For example, behavior 2 above moves down a hallway, but this is appropriate only when the robot is situated in a hallway. Similarly, behavior 5, which grasps a door knob, is appropriate only when the robot is within grasping distance of a door knob. The behavior is not responsible for putting the robot in the particular situation. However, it should recognize that the situation is not appropriate and signal as such.

Cognizant Failure

A key requirement for behaviors is that they know when they are not working. This is called *cognizant failure* [8.69]. For example, behavior 5 in our example (grasping the door knob) should not continually grasp at air if it is failing. More succinctly, the behavior should not continue to *bang its head against the wall*. A common problem with early Subsumption robots is that the behaviors did not know they were failing and continued to take actions that were not resulting in progress. It is not the job of the behavioral control layer to decide what to do in a failure situation; it is only necessary to announce that the behavior has failed and halt activity.

Implementation Constraints

The behavioral control layer is designed to bring the speed and reactivity of Subsumption to robot control. For this reason, the behaviors in the behavioral control layer need to follow the philosophies of Subsumption. In particular, the algorithms used for behaviors should be constant in state and time complexity. There should be little or no search at the behavioral control level, and little iteration. Behaviors should simply be transfer functions that take in signals (from sensors or other behaviors) and send out signals (to actuators or other behaviors), and repeat these several times a second. This will allow for reactivity to changing environments. More controversial is how much state should be allowed at the behavioral level. Brooks famously said several years ago to “use the world as its own best model” [8.67] – that is, instead of maintaining internal models of the world and querying those models, the robot should instead directly sense the world to get its data. State such as maps, models, etc. belong at the higher levels of the three-tiered prototype architecture, not at the behavioral control layer. Certain exceptions, such as maintaining state for data filtering calculations, could be made on a case-by-case basis. Gat [8.70] argues that any state kept at the behavioral layer should be ephemeral and limited.

8.3.3 Executive

The executive layer is the interface between the numerical behavioral control and the symbolic planning layers. The executive is responsible for translating high-level plans into low-level behaviors, invoking behaviors at the appropriate times, monitoring execution, and handling exceptions. Some executives also allocate and monitor resource usage, although that functionality is more commonly performed by the planning layer.

Example

Continuing the example of an office delivery robot, the main high-level task would be to deliver mail to a given office. The executive would decompose this task into a set of subtasks. It may use a geometric path planner to determine the sequence of corridors to move down and intersections at which to turn. If there are doorways along the route, a task would be inserted to open and pass through the door. At the last corridor, the executive would add a concurrent task that looks for the office number. The final subtasks would be to announce that the person has mail and to concurrently monitor whether the mail has been picked up. If it is not picked up after some period of time, an exception would be triggered that invokes some recovery action (perhaps announcing again, perhaps checking to make sure the robot is at the correct office, perhaps notifying the planning layer to reschedule the delivery for a later time).

Capabilities

The example above illustrates many of the capabilities of the executive layer. First, the executive decomposes high-level tasks (goals) into low-level tasks (behaviors). This is typically done in a *procedural* fashion: the knowledge encoded in the executive describes *how* to achieve tasks, rather than describing *what* needs to be done and having the executive figure out the *how* by itself. Sometimes, though, the executive may also use specialized planning techniques, such as the route planner used in the example above. The decomposition is typically a hierarchical *task tree* (Fig. 8.8), with the leaves of the task tree being invocations and parameterizations of behaviors.

Besides decomposing tasks into subtasks, executives add and maintain temporal constraints between tasks (usually between sibling tasks only, but some executive languages permit temporal constraints between any pair of tasks). The most common constraints are *serial* and *concurrent*, but most executives support more expressive constraint languages, such as having one task begin 10 s

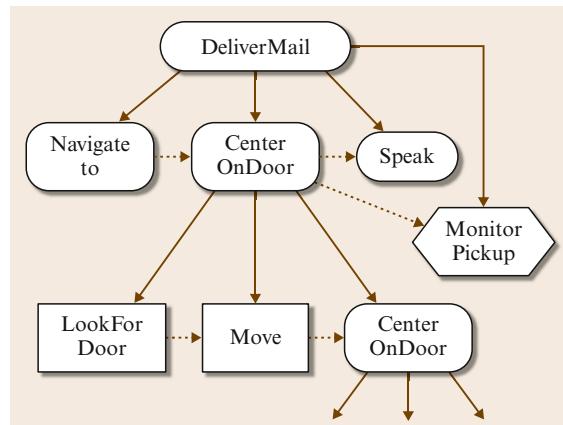

Fig. 8.8 Hierarchical task tree for mail-delivery task (*lozenge nodes* are interior; *rectangular nodes* are leaves; *hexagonal node* is an execution monitor; *solid arrows* are parent-child relationships; *dashed arrows* are sequential constraints)

after another one starts or having one task end when another ends.

The executive is responsible for dispatching tasks when their temporal constraints are satisfied. In some executives, tasks may also specify resources (e.g., the robot's motors or camera) that must be available before the task can be dispatched. As with behaviors, arbitrating between conflicting tasks can be a problem. In the case of executives, however, this arbitration is typically either programmed in explicitly (e.g., a rule that says what to do in cases where the robot's attempt to avoid obstacles takes it off the preferred route) or handled using priorities (e.g., recharging is more important than mail delivery).

The final two important executive capabilities are execution monitoring and error recovery. One may wonder why these capabilities are needed if the underlying behaviors are reliable. There are two reasons. First, as described in Sect. 8.3.2, the behaviors are situated, and the situation may change unexpectedly. For instance, a behavior may be implemented assuming that a person is available to pick up the mail, but that may not always be the case. Second, in trying to achieve some goal, the behavior may move the robot into a state that is unexpected by the executive. For instance, people may take advantage of the robot's obstacle avoidance behavior to *herd* it into a closet. While the behavior layer may, in fact, keep the robot safe in such situations, the executive needs to detect the situation in order to get the robot back on track.

Typically, execution monitoring is implemented as a concurrent task that either analyzes sensor data directly or activates a behavior that sends a signal to the executive when the monitored situation arises. These correspond to *polling* and *interrupt-driven* monitors, respectively.

Executives support various responses to monitors being triggered. A monitor may spawn subtasks that handle the situation, it may terminate already spawned subtasks, it may cause the parent task to fail, or it may raise an exception. The latter two responses involve the *error recovery* (also called *exception handling*) capability. Many executives have tasks return status values (success or failure) and allow parent tasks to execute conditionally based on the return values. Other executives use a hierarchical exception mechanism that throws named exceptions to ancestor nodes in the task tree. The closest task that has registered a handler for that exception tries to handle it; if it cannot, it rethrows the exception up the tree. This mechanism, which is inspired by the exception handling mechanisms of C++, Java, and Lisp, is strictly more expressive than the return-value mechanism, but it is also much more difficult to design systems using that approach, due to the nonlocal nature of the control flow.

Implementation Constraints

The underlying formalism for most executives is a hierarchical finite-state controller. Petri nets [8.71] are a popular choice for representing executive functions. In addition, various languages have been developed specifically to assist programmers in implementing executive-level capabilities. We briefly discuss aspects of several of these languages: reactive action packages (**RAPs**) [8.4, 30], the procedural reasoning system (**PRS**) [8.42, 43], the execution support language (**ESL**) [8.12], the task description language (**TDL**) [8.55], and the plan execution interchange language (**PLEXIL**) [8.13].

These languages all share features and exhibit differences. One distinction is whether the language is stand-alone (**RAPs**, **PRS**, **PLEXIL**) or an extension of an existing language (**ESL** is an extension of Common Lisp; **TDL** is an extension of C++). Stand-alone languages are typically easier to analyze and verify, but extensions are more flexible, especially with respect to integration with legacy software. While stand-alone executive languages all support interfaces to user-defined functions. These interfaces are usually limited in capability (such as what types of data structures can be passed around).

All of these executive languages provide support for hierarchical decomposition of tasks into subtasks. All

except **PLEXIL** allow for recursive invocation of tasks. **RAPs**, **TDL**, and **PLEXIL** have syntax that distinguishes leaf nodes of the task tree/graph from interior nodes.

All these languages provide capabilities for expressing conditionals and iteration, although with **RAPs** and **PLEXIL** these are not core-language constructs, but must be expressed as combinations of other constructs. Except for **TDL**, the languages all provide explicit support for encoding pre- and post-conditions of the tasks and for specifying success criteria. With **TDL**, these concepts must be programmed in, using more primitive constructs. The stand-alone languages all enable local variables to be defined within a task description, but provide for only limited computation with those variables. Obviously, with extension languages the full capability of the base language is available for defining tasks.

All the languages support the simple serial (sequential) and concurrent (parallel) temporal constraints between tasks, as well as timeouts that can be specified to trigger after waiting a specified amount of time. In addition, **TDL** directly supports a wide range of temporal constraints – one can specify constraints between the start and end times of tasks (e.g., *task B starts after task A starts* or *task C ends after task D starts*) as well as metric constraints (e.g., *task B starts 10 seconds after task A ends* or *task C starts at 1pm*). **ESL** and **PLEXIL** support the signaling of events (e.g., when tasks transition to new states) that can be used to implement similarly expressive types of constraints. In addition, **ESL** and **TDL** support task termination based on the occurrence of events (e.g., *task B terminates when task A starts*).

The languages presented differ considerably in how they deal with execution monitoring and exception handling. **ESL** and **TDL** both provide explicit execution monitoring constructs and support exceptions that are *thrown* and then *caught* by registered handlers in a hierarchical fashion. This type of exception handling is similar to that used in C++, Java, and Lisp. **ESL** and **TDL** also support *clean-up* procedures that can be invoked when tasks are terminated. **RAPs** and **PLEXIL** use return values to signal failure, and do not have hierarchical exception handling. **PLEXIL**, though, does support clean up procedures that are run when tasks fail. **PRS** has support for execution monitoring, but not exception handling. **ESL** and **PRS** support the notion of *resources* that can be shared. Both provide support for automatically preventing contention amongst tasks for the resources. In the other executive languages, this must be implemented separately (although there are plans to extend **PLEXIL** in this area).

Finally, **RAPs**, **PRS** and **ESL** all include a symbolic database (*world model*) that connects either directly to sensors or to the behavior layer to maintain synchrony with the real world. Queries to the database are used to determine the truth of preconditions, to determine which methods are applicable, etc. PLEXIL has the concept of a *lookup* that performs a similar function, although it is transparent to the task how this is implemented (e.g., by a database lookup or by invoking a behavior-level function). **TDL** leaves it up to the programmer to specify how the tasks connect to the world.

8.3.4 Planning

The planning component of our prototype layered architecture is responsible for determining the long-range activities of the robot based on high-level goals. Where the behavioral control component is concerned with the here-and-now and the executive is concerned with what has just happened and what should happen next, the planning component looks towards the future. In our running example of an office delivery robot, the planning component would look at the day's deliveries, the resources of the robot, and a map, and determine the optimal delivery routes and schedule, including when the robot should recharge. The planning component is also responsible for replanning when the situation changes. For example, if an office is locked, the planning component would determine a new delivery schedule that puts that office's delivery later in the day.

Types of Planning

Chapter 9 describes approaches to robot planning in detail. Here, we summarize issues with respect to different types of planners as they relate to layered architectures.

The two most common approaches used are hierarchical task net (**HTN**) planners and planner/schedulers. **HTN** planners [8.72, 73] decompose tasks into subtasks, in a manner similar to what many executives do. The main differences are that **HTN** planners typically operate at higher levels of abstraction, take resource utilization into account, and have methods for dealing with conflicts between tasks (e.g., tasks needing the same resources, or one task negating a precondition needed by another task). The knowledge needed by **HTN** planners is typically fairly easy to specify, since one indicates directly *how* tasks are to be achieved.

Planner/schedulers [8.74, 75] are useful in domains where time and resources are limited. They create high-level plans that schedule when tasks should occur, but typically leave it to the executive to determine exactly

how to achieve the tasks. Planner/schedulers typically work by laying out tasks on time lines, with separate time lines for the various resources that are available on the robot (motors, power, communication, etc.). The knowledge needed by planner/schedulers includes the goals that tasks achieve, the resources they need, their duration, and any constraints between tasks.

Many architectures provide for specialized planning *experts* that are capable of solving particular problems efficiently. In particular, these include motion planners, such as path planners and trajectory planners. Sometimes, the planning layer of the architecture invokes these specialized planners directly; in other architectural styles, the motion planners are part of the lower levels of the architecture (the executive, or even the behavioral layer). Where to put these specialized planners is often a question of style and performance (see Sect. 8.5).

Additionally, some architectures provide for multiple planning layers [8.39, 44, 76]. Often, there is a *mission* planning layer at the very top that plans at a very abstract level, over relatively long periods of time. This layer is responsible mainly for selecting which high-level goals are to be achieved over the next period of time (and, in some cases, determining in which order to achieve them) in order to maximize some objective function (e.g., net reward). The lower *task* planning layer is then responsible for determining exactly how and when to achieve each goal. This breakdown is usually done for efficiency reasons, since it is difficult to plan simultaneously at both a detailed level and over a long time horizon.

Integrating Planning and Execution

There are two main approaches to the integration of the planning and execution components in robotic architectures. The first approach is that the planning component is invoked as needed by the executive and returns a plan. The planning component is then dormant until called again. Architectures such as ATLANTIS [8.70] and Remote Agent [8.44] use this approach, which requires that the executive either leave enough time for planning to complete or that it *safes* the system until planning is complete. In the Remote Agent, for instance, a special *planning* task is explicitly scheduled.

The second approach is that the planning component sends high-level tasks down to the executive as required and monitors the progress of those tasks. If tasks fail, replanning is done immediately. In this approach, the planning component is always running and always planning and replanning. Signals must pass in real time between the planner and the executive to keep

them synchronized. Architectures such as 3T [8.36] use this second approach. The first approach is useful when the system is relatively static, so that planning can occur infrequently, at relatively predictable times. The second approach is more suited to dynamic environments, where replanning is more frequent and less predictable.

Other decisions that need to be made when integrating planning and execution are when to stop task decomposition, where to monitor plan execution, and how to handle exceptions. By planning all the way down to primitive actions/behaviors, the planner has a very good notion of what will happen during execution, but at a price of much more computation. Also, some task decompositions are easier to describe procedurally (using an executive language) rather than declaratively (using a planning language). Similarly, monitoring at the execu-

tive level tends to be more efficient, since the monitoring happens closer to the robot sensors, but the planner may be able to use its more global knowledge to detect exceptions earlier and/or more accurately. With respect to handling exceptions, executives can handle many on their own, at the price of breaking the expectations used by the planner in scheduling tasks. On the other hand, having exceptions handled by the planner typically involves replanning, which can be computationally expensive.

For all these integration issues, however, a middle ground usually exists. For instance, one can choose to decompose some tasks more deeply than others, or handle certain exceptions in the executive and others in the planner. In general, the *right* approach usually involves a compromise and is determined by analyzing the domain in detail (see Sect. 8.5).

8.4 Case Study – GRACE

In this section, we present the architecture of a fairly complex autonomous mobile robot. Graduate robot attending conference (**GRACE**) resulted from the efforts of five research institutions (Carnegie Mellon, Naval Research Laboratory, Northwestern University, Metrika, and Swarthmore College) to tackle the American Association for Artificial Intelligence (**AAAI**) Robot Challenge. The Challenge was for a robot to attend the **AAAI** National Conference on Artificial Intelligence as a participant – the robot must find the registration desk (without knowing the layout of the convention center beforehand), register for the conference, and then, after being provided with a map, find its way to a given location in time to give a technical talk about itself.

The architectural design of the robot was particularly important given the complexity of the task and the need to integrate techniques that had been previously developed by the five institutions. These techniques included localization in a dynamic environment, safe navigation in the presence of moving people, path planning, dynamic replanning, visual tracking of people, signs and landmarks, gesture and face recognition, speech recognition and natural language understanding, speech generation, knowledge representation, and social interaction with people.

GRACE is built on top of an real world interface (**RWI**) B21 base and has an expressive computer-animated face projected on a flat-panel liquid-crystal display (LCD) screen (Fig. 8.9). Sensors that come with the B21 include touch, infrared, and sonar sen-

sors. Near the base is a SICK scanning laser range finder that provides a 180° field of view. In addition, **GRACE** has several cameras, including a stereo camera head on a pan–tilt unit (**PTU**) built by Metrica TRACLabs and a single-color camera with pan–tilt–zoom capability, built by Canon. **GRACE** can speak using a high-quality speech-generation software (Festival), and receive speech responses using a wireless microphone headset (a Shure **TC** computer wireless transmitter/receiver pair).

The behavioral layer of the architecture consisted of individual processes that controlled particular pieces of hardware. These programs provided abstract interfaces to either control the hardware or return information from

Fig. 8.9 The robot **GRACE**

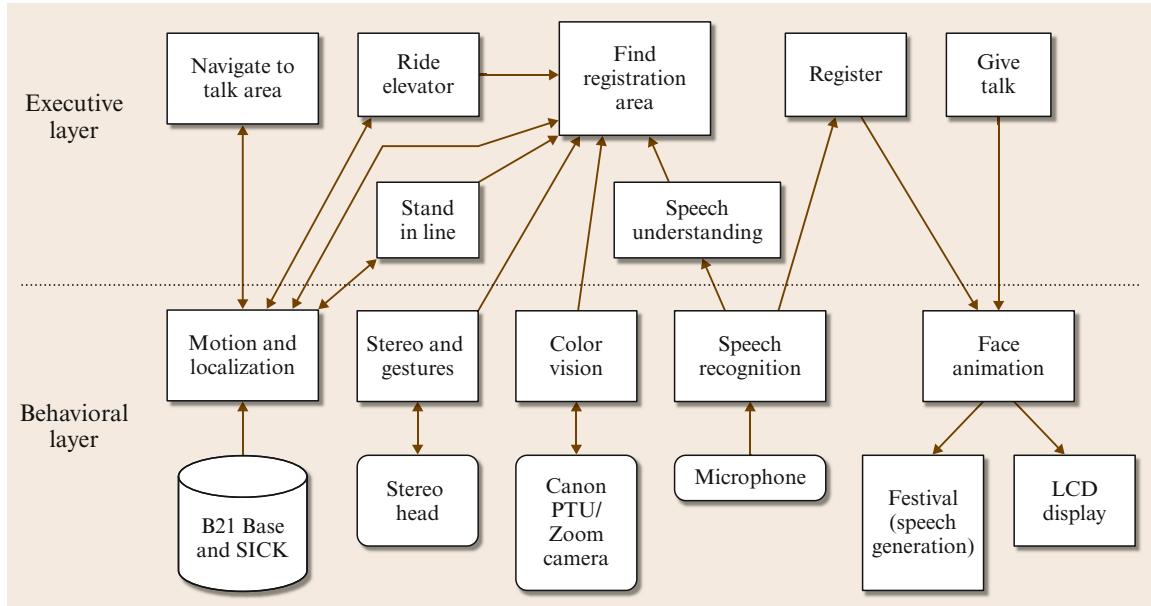

Fig. 8.10 GRACE's architectural structure

sensors. To accommodate the different coding styles of the various groups involved, both synchronous, blocking and asynchronous, nonblocking calls were supported by most of the interfaces (for the nonblocking calls, the interfaces allowed programmers to specify a callback function to be invoked when data was returned). Interfaces at the behavioral level included robot motion and localization (this interface also provided laser information), speech recognition, speech generation, facial animation, color vision, and stereo vision (Fig. 8.10).

The architecture used individual processes for each of the behavioral capabilities, mainly because the underlying code had been developed by different organizations. While having a large number of processes run concurrently is somewhat inefficient, trying to integrate everything into a monolithic process was thought to be too difficult. In addition, the use of separate processes facilitated development and debugging, since one needed to run only those aspects of the system that were being tested.

The executive layer consisted of separate programs for achieving each subtask of the challenge – finding the registration desk, riding the elevator, standing in line, interacting with the person at the desk, navigating to the talk, and giving the talk (Fig. 8.10). As is common in many implemented robotic systems, the GRACE architecture did not have a planning layer – since the high-level plan was fixed and relatively straightforward,

it was coded explicitly. Several of the executive-layer programs were written using TDL (see Sect. 8.3.3),

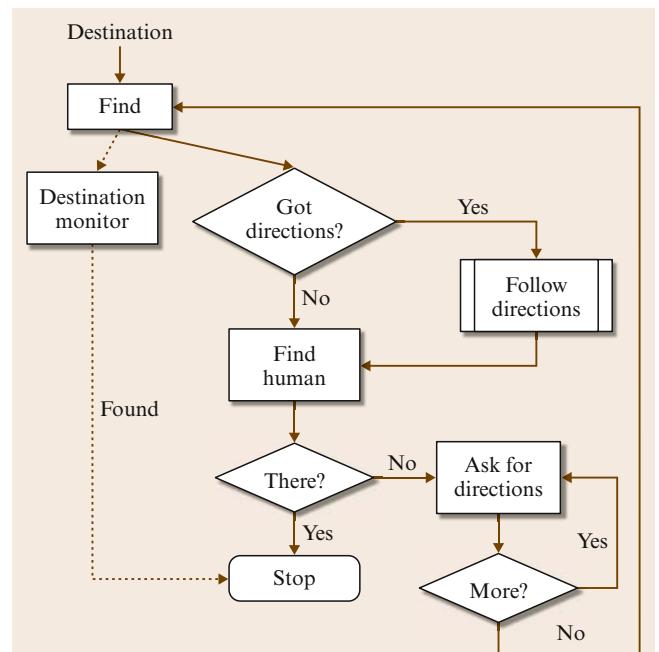

Fig. 8.11 Finite-state machine for GRACE's task for following directions to the registration booth

which facilitated concurrent control and monitoring of the various tasks.

One particularly involved task was finding the registration desk (recall that **GRACE** had no idea where the booth was, or even what the convention center looked like). **TDL** was used to create a finite-state machine that allowed **GRACE** to maintain multiple goals, such as using an elevator to get to a particular floor and following directions to find the elevator (Fig. 8.11). The top-level goal was to find the registration desk. Intermediate subgoals were created as **GRACE** interacted with people to determine the directions to the desk. If there were no directions to follow, **GRACE** performed a random walk until a person was detected using its laser scanner. **GRACE** then engaged in conversation with the person to obtain directions. **GRACE** could handle simple commands, such as *turn left* and *go forward five meters*, as well as higher-level instructions, such as *take the elevator* and *turn left at the next intersection*. In addition, **GRACE** could ask questions, such as *am I at the registration desk?* and *is this the elevator?* The **TDL**-based finite-state machine was used to determine which interactions were appropriate at various times and to prevent the robot from getting confused.

Communication between processes used the inter-process communication (**IPC**) messaging package [8.9, 77]. **IPC** supports both publish–subscribe and client–

server messaging, and enables complex data structures to be passed transparently between processes. One side benefit of using **IPC** to communicate between processes was the ability to log all message traffic (both message name and data content). This proved invaluable, at times, in determining why the system failed to act as expected – did a process send out a message with invalid data? Did it fail to send out a message in a timely fashion? Was the receiving process blocked, for some reason? Was there a timing issue? While wading through the message traffic was often tedious, in some cases it was the only way to catch intermittent bugs.

In July 2002, **GRACE** successfully completed the challenge at the Shaw Convention Centre in Edmonton, Canada. The processes at the behavioral level generally worked as anticipated – this was largely attributed to the fact that those modules were ported from previously developed (and hence well-tested) systems. While generally functional, the executive-level processes had more problems with off-nominal situations. This is largely attributed to problems in sensor interpretation, as well as mistaken assumptions about what the convention center was going to look like (for instance, it turned out that some of the barriers were made of glass, which is largely invisible to the laser). Overall, however, the architecture itself worked as expected, enabling a large body of complex software to be integrated rather quickly and operate together effectively.

8.5 The Art of Robot Architectures

Designing a robot architecture is much more of an art than a science. The goal of an architecture is to make programming a robot easier, safer, and more flexible. Thus, the decisions made by a developer of a robot architecture are influenced by their own prior experiences (e.g., what programming languages they are familiar with), their robot and its environment, and the tasks that need to be performed. The choice of a robot architecture should not be taken lightly, as it is the authors' experiences that early architectural decisions often persist for years. Changing robot architectures is a difficult proposition and can set back progress while a great deal of code is reimplemented.

The art of designing a robotic architecture starts with a set of questions that the designer needs to ask. These questions include:

- What are the tasks the robot will be performing? Are they long-term tasks? Short-term? User-initiated?

Robot-initiated? Are the tasks repetitive or different across time?

- What actions are necessary to perform the tasks? How are those actions represented? How are those actions coordinated? How fast do actions need to be selected/changed? At what speed do each of the actions need to run in order to keep the robot safe?
- What data is necessary to do the tasks? How will the robot obtain that data from the environment or from the users? What sensors will produce the data? What representations will be used for the data? What processes will abstract the sensory data into representations internal to the architecture? How often does the data need to be updated? How often can it be updated?
- What computational capabilities will the robot have? What data will these computational capabilities produce? What data will they consume? How will

the computational capabilities of a robot be divided, structured, and interconnected? What is the best decomposition/granularity of computational capabilities? How much does each computational capability have to know about the other capabilities? Are there legacy computational capabilities (from other robots, other robot projects, etc.) that will be used? Where will the different computational capabilities reside (e.g., onboard or offboard)?

- Who are the robot's users? What will they command the robot to do? What information will they want to see from the robot? What understanding do they need of the robot's computational capabilities? How will the user know what the robot is doing? Is the user interaction peer to peer, supervisory, or as a bystander?
- How will the robot be evaluated? What are the success criteria? What are the failure modes? What is the mitigation for those failure modes?
- Will the robot architecture be used for more than one set of tasks? For more than one kind of robot? By more than one team of developers?

Once designers have answers to all (or most) of these questions, they can then begin building some *use cases* for the types of operations they want the robot to perform and how they want users to interact with it. These use cases should specify the outward behavior of the robot with respect to its environment and its users. From the use cases, an initial partitioning of robot functionality can be developed. This partitioning should be accompanied by a *sequence diagram* that shows the transfer of information and control over time amongst the various components of the robot architecture [8.78]. After this, a more formal specification of the interfaces

between architectural components can be developed. This may be done using a language such as the interface definition language ([IDL](#)) of [CORBA](#) or by defining the messages to be distributed in a publish-subscribe protocol. This is an important step, as once implementation begins it is very costly to change interfaces. If an interface does change, all stakeholders need to be notified and need to agree to the change. The most common integration problems in robot architectures are mismatches between what components expect and what they are receiving in the way of data.

An advantage of tiered architectures with clear interface definitions is that the different layers can be developed in parallel. The behavioral control layer can be implemented and tested on the robot using a human as an executive. The executive can be implemented and tested using state machine *stubs* for the expected behaviors on the robot. The planning layer can be implemented and tested using *stubs* for the tasks in the executive. The *stubs* merely acknowledge that they were called and report back appropriately. Then, the tiers can be integrated to test timing and other runtime issues. This parallel approach speeds up the development of a robot architecture, but is possible only if the roles and interfaces between components are clearly defined and respected. There is still considerable real-time debugging necessary during integration. In our experiences, most of the development time in robot architectures is still spent on the behavioral control layer – that is, sensing and acting are still the hard parts of robot control, as compared to execution and planning. Having a good, robust behavioral control layer goes a long way towards having a competent robot architecture.

8.6 Conclusions and Further Reading

Robot architectures are designed to facilitate the concurrent execution of task-achieving behaviors. They enable systems to control actuators, interpret sensors, plan, monitor execution, and deal with unexpected contingencies and opportunities. They provide the conceptual framework within which domain-dependent software development can take place, and they often provide programming tools that facilitate that development.

While no single architecture has proven to be best for all applications, researchers have developed a variety of approaches that can be applied in different

situations. While there is not yet a specific formula for determining which architecture will be best suited for a given application, this chapter provides some guidelines to help developers in selecting the right architecture for the job. That being said, layered architectures have proven to be increasingly popular, due to their flexibility and ability to operate at multiple levels of abstraction simultaneously.

The book [AI and Mobile Robots](#) [8.79] has several chapters on architectures that have influenced this chapter. Most text books in robotics [8.19, 80, 81] have

sections on robot architectures. For many years in the mid 1990s, the [AAAI](#) Spring Symposia on Artificial Intelligence had sessions devoted to robot architec-

tures, although proceedings from those symposia are not widely available. More information on [GRACE](#) can be found in [8.82–84].

AI Reasoning

9. AI Reasoning Methods for Robotics

Joachim Hertzberg, Raja Chatila

Artificial intelligence ([AI](#)) reasoning technology involving, e.g., inference, planning, and learning, has a track record with a healthy number of successful applications. So, can it be used as a toolbox of methods for autonomous mobile robots? Not necessarily, as reasoning on a mobile robot about its dynamic, partially known environment may differ substantially from that in knowledge-based pure software systems, where most of the named successes have been registered.

This Chapter sketches the main robotics-relevant topics of symbol-based [AI](#) reasoning. Basic methods of knowledge representation and inference are described in general, covering both logic- and probability-based approaches. Then, some robotics-related particularities are addressed specially: issues in logic-based high-level robot control, fuzzy logics, and reasoning under time constraints. Two generic applications of reasoning are then described in some detail: action planning and learning.

General reasoning is currently not a standard feature onboard autonomous mobile robots. Beyond sketching the state of the art in robotics-related [AI](#) reasoning, this Chapter points to the involved research problems that remain to be solved towards that end.

The Chapter first reviews knowledge representation and deduction in general (Sect. 9.1), and

then goes into some detail regarding reasoning issues that are considered particularly relevant for applications in robots (Sect. 9.2). Having presented reasoning *methods*, we then enter the field of generic reasoning *applications*, namely, action planning (Sect. 9.3) and machine learning (Sect. 9.4). Section 9.5 concludes.

Historical debates about the necessity and wisdom of employing symbolic reasoning in autonomous mobile robots notwithstanding, there now seems to be agreement that some part or layer in the control system of such robots should or could include reasoning. Hybrid control architectures (Chap. 8) would be typical software structures for solving the difficult problem of amalg-

mating their contributions with those of other parts of the controller, while guaranteeing sufficiently short control cycle times, so that the robot can act safely in a dynamic environment.

Symbolic reasoning is understood here in the classical sense of artificial intelligence ([AI](#)), i.e., deliberation based on symbols as in first-order predicate logic

(FOPL) or Bayesian probability theory, but typically with restrictions and/or extensions thereof, which have

to be traded off against each other to achieve a suitable combination of expressivity and inference speed.

9.1 Knowledge Representation and Inference

Reasoning requires that the reasoner – in our case, a robot – has an explicit representation of parts or aspects of its environment to reason about. Two questions come up immediately: what are suitable formats for such an explicit representation, and where does the represented knowledge come from?

The second question refers to the problem of generating and maintaining in real time a symbolic description of the robot's environment, or at least of some part of it, based on a previous symbolic description and on recent environment information obtained from sensors and communication with other agents. In full generality, this problem is currently unsolved, involving AI fundamentals such as *symbol grounding* [9.1] and *object anchoring* [9.2]. So practical symbolic reasoning in a robot is restricted to that part of its knowledge that can be kept sufficiently recent. This includes, obviously, static knowledge about the environment, such as the topological elements and their relations in a building; transient knowledge available in symbolic forms, such as in facility management databases; and, most challenging, symbolic data that has to be distilled from sensor data. Object recognition from camera data (Chap. 23) is a relevant method here.

This section deals with answers to the first question, i.e., formalisms suitable for representing knowledge. Suitability has two aspects here that are to be treated as two sides of one coin. One is *epistemological adequacy*: does the formalism allow the targeted aspects of the environment to be expressed compactly and precisely? The other is *computational adequacy*: does the formalism allow typical inferences to be drawn effectively and efficiently? There is a tradeoff between these two adequacies, given that very rich, expressive, and hence epistemologically appealing formalisms are typically accompanied by intractable or even undecidable inference problems, and vice versa. Knowledge representation (KR), then,

is the field of AI that focuses on the design of formalisms that are both epistemologically and computationally adequate for expressing knowledge about a particular domain. [9.3, p. xiii]

In this section, we focus on two families of formalisms, namely, logic and probability theory, and respective inference procedures. For introductions to the field of KR and for sources for recent results, we refer to the general AI and KR literature as given at the end of this chapter. In addition, there is the *International Conference on Knowledge Representation* (KR), held biannually every even year.

9.1.1 Logic

First-order predicate logic (FOPL) is the archetype of KR formalisms in AI. Having said this, let us add immediately that it does not qualify for such a formalism in the aforementioned sense of being both epistemologically and computationally adequate for typical application domains – in many cases, it is neither of the two. However, it is the background for conceptually and mathematically understanding formalisms for representing and reasoning with definite knowledge.

We assume familiarity with the basic notions of FOPL, and rather than giving another sketch here, we refer to the substantial body of textbooks and introductions. Every typical AI textbook introduces FOPL, and [9.4, 5] are no exceptions. [9.6] is a principled introduction to logics; [9.7] a practical one, and [9.8] a concise mathematical one.

Representing knowledge in some variant of logic facilitates drawing inferences from that knowledge using provably sound and complete calculi. Automated deduction is a subfield of logic and AI that offers a healthy number of very powerful implemented deduction systems that can readily be used. (See [9.4, Chap. 9] for an introduction; [9.9] is a recent, comprehensive source book.)

Relying on logical inference, a robot could deduce a large number of facts that might otherwise be hard or impossible to obtain. For example, assume that a robot perceives by acquiring and interpreting sensor data, that the door D_{509} in an office building is currently closed: $Closed(D_{509})$ expressed in some ad hoc FOPL language, assuming intuitive interpretations of symbols. Let us further assume that the robot's base of static knowledge

about the building contains the sentences

$$\begin{aligned}
 & \text{Connects}(D_{509}, C_5, R_{509}), \\
 & \text{Connects}(D_{508}, C_5, R_{508}), \\
 & \text{Connects}(D_{508a}, R_{508}, R_{509}), \\
 & \forall d, l_1, l_2 [\text{Connects}(d, l_1, l_2) \\
 & \quad \leftrightarrow \text{Connects}(d, l_2, l_1)], \\
 & \forall d. [\text{Closed}(d) \leftrightarrow \neg \text{Open}(d)], \\
 & \forall l. [\text{At}(l) \rightarrow \text{Accessible}(l)], \\
 & \forall l_1, l_2. [\text{Accessible}(l_1) \\
 & \quad \rightarrow (\exists d. [\text{Connects}(d, l_1, l_2) \wedge \text{Open}(d)] \\
 & \quad \rightarrow \text{Accessible}(l_2))]
 \end{aligned}$$

Constants D_i and variable d denote doors; R_i denote rooms; C_i corridors; variables l, l_i denote locations, i.e., rooms and corridors. Assume that the robot's localization tells it its current room or corridor location as $\text{At}(\cdot)$.

Then, assuming the robot knows itself to be $\text{At}(C_5)$, observing $\text{Closed}(D_{509})$ entails $\neg \text{Open}(D_{509})$, and, more interesting, $\text{Accessible}(R_{509})$ only if $\text{Open}(D_{508}) \wedge \text{Open}(D_{508a})$ is true. So, performing, for example, a delivery task to room R_{509} , the robot may replan its route through R_{508} , unless at least one of D_{508} and D_{508a} is known to be closed. If the status of one or both of them is unknown (neither $\text{Open}(\cdot)$ nor $\text{Closed}(\cdot)$ is entailed by the current knowledge base), then accessibility of R_{509} can be neither proven nor disproven. That would leave open the option of planning the route through D_{508} and D_{508a} , gathering their required statuses on site.

So, as this little example shows, **FOPL** is a powerful representation and reasoning tool. Moreover, its theory is very well understood. In particular, it is well known that consequence in **FOPL** is in general undecidable, which means that a sound and complete deduction algorithm cannot even guarantee termination for some particular inference attempt, let alone speedy results.

However, that does not mean logic as a representation and inference tool needs to be completely disposed of. Many applications do not require the full expressivity of **FOPL**. Moreover, there are many interesting language subsets of **FOPL** that are decidable and can be handled by algorithms that are efficient in most practical cases. So some effort by the **KR** community has gone into identifying **FOPL** subsets and fitting inference procedures that qualify for being both epistemologically and computationally adequate for a broad number of applications. We will consider two of these in more detail: propositional logic and description logics.

Propositional Theories

In quite a number of practical cases, **FOPL** theories (sets of formulas) in fact represent finite domains. Logically speaking, they have finite Herbrand universes or can at least be recast in a form such that they have. In this case, it may still be handy to express the domain theory in **FOPL** syntax, but all that goes beyond a purely propositional theory is just for notational convenience. For example, an axiom stating that a robot can only be in one location (room or corridor) at a time

$$\forall l_1, l_2. [\text{At}(l_1) \rightarrow (\neg \text{At}(l_2) \vee l_1 = l_2)]$$

can be *flattened* for a finite building into the, clumsy but equivalent, form handling all locations explicitly, for example in a six-storey building

$$\begin{aligned}
 \text{At}(R_{001}) \rightarrow & [\neg \text{At}(R_{002}) \wedge \neg \text{At}(R_{003}) \wedge \dots \\
 & \neg \text{At}(R_{514}) \wedge \neg \text{At}(C_{0a}) \wedge \\
 & \neg \text{At}(C_{0b}) \wedge \dots \wedge \neg \text{At}(C_5)], \\
 \text{At}(R_{002}) \rightarrow & [\neg \text{At}(R_{001}) \wedge \neg \text{At}(R_{003}) \wedge \dots \\
 & \neg \text{At}(R_{514}) \wedge \neg \text{At}(C_{0a}) \wedge \\
 & \neg \text{At}(C_{0b}) \wedge \dots \wedge \neg \text{At}(C_5)], \\
 & \dots
 \end{aligned}$$

where every ground (variable-free) instance of a predicate, such as the At instances above, are to be considered as propositional variables, regarding textual identity.

The good news here is that the corresponding *flat* theory to a **FOPL** theory over a finite Herbrand universe is propositional; hence, it is decidable. Moreover, under some practical conditions – e.g., if the variables in the **FOPL** theory are sorted (that is, the information is available that the variables l_1, l_2 , e.g., range over rooms and corridors) – it can even be generated mechanically from a more compact **FOPL** syntax.

The potentially bad news is that the now propositional theory may of course consist of a huge number of propositional sentences: In general, as all combinations of variable substitutions in all **FOPL** sentences need to be generated, the growth is multi-exponential in terms of the domain sizes of the **FOPL** variables.

However, the technology for propositional satisfiability checking or model checking is making considerable progress, allowing propositional theories with thousands or even tens of thousands of variables to be handled in the order of seconds of computation time on regular hardware. These methods are particularly efficient if many models exist for a satisfiable propositional formula or if the truth or falsity of many ground facts is

known a priori (such as $At(C_5)$ for a robot by independent localization). Both are often the case in practical KR.

[9.4, Chap. 7] gives an introduction to model checking. One family of methods is based on the classical Davis–Putnam (DPLL) algorithm [9.10]. It attempts to construct systematically a propositional model of a given theory, efficiently propagating interpretation constraints for variables. Another family of algorithms applies local search techniques, attempting to generate interpretations using random (Monte Carlo) variable assignments. [9.11] is a recent collection of papers summarizing the state of the art, including a paper about the results of the SAT2002 competition that discusses in detail the performance of recent satisfiability checkers on synthetic (i.e., typically unnaturally hard) problems.

Description Logics

Description logics (DL) have emerged as a rigorous formalization of somewhat intuitive KR forms of the AI of the 1970s, namely, semantic networks and frame systems. Logically speaking, DLs, of which there is a considerable variety, form a certain family of decidable subsets of FOPL.

There are two parts of representing knowledge about a particular domain using a DL language. First, the *upper ontology* of the domain is formulated. It introduces the general domain concepts as well as relations between these concepts. A particularly interesting type of relations occurring in all ontologies is the superclass–subclass relation. Given that DLs – as part of the means for enforcing decidability – strictly disallow cyclic relations between concepts to be specified, the superclass relation imposes a hierarchical taxonomy on concepts, which serves to define property inheritance, much like in object-oriented programming. This first part of a DL-based domain representation is, for historical reasons, often called the *TBox* (or *terminological knowledge*).

A concept in the DL language corresponds to a unary predicate. To give an example, an ontology of robot navigation domains might include concepts like *Door*, *Location*, and so on. The concept hierarchy is built by defining concept equality = or a subconcept property, e.g., $Room \sqsubseteq Location$, and $Corridor \sqsubseteq Location$. Concepts can be combined using concept conjunction, disjunction and, negation (\sqcap , \sqcup , \neg , respectively), allowing, e.g., concept definitions such as $Location = Room \sqcup Corridor$, $Door = Closed \sqcup Open$, and $Open = \neg Closed$.

Roles in a DL language correspond to binary predicates, such as *leadsTo* for a door and a location. Inversity, intersection, and union of roles are defined as expected, where $leadsTo = leadsFrom^{-1}$ is an example for defining inverse roles. Roles can be composed, such as in defining $adjacent = leadsFrom \circ leadsTo$ (location l is adjacent to m if and only if some door leads from l to m). Finally, concepts and roles can be combined for defining new concepts and roles. In particular, it is possible to quantify over *role-fillers*, i.e., the individual objects (see below) that can be consistently substituted for role arguments, for example, one could define $BlockedLoc = Location \sqcap \neg \exists leadsFrom . Open$ (assuming the intuitive binding rules of the operators). Different variants of DLs differ in what other operators they make available. See [9.3] for details.

As the second part of domain representation using DLs, individual objects have to be introduced into the language of concepts and roles. This part of the domain representation is called *ABox* or *assertional knowledge*, for example, $Room(R_{509})$, $leadsTo(D_{509}, R_{509})$, and $Closed(D_{509})$ could be asserted.

DLS have a number of reasoning services to offer, which are based on logical inference in a given TBox and ABox. They include consistency of the concept definition, subsumption and disjointness of concepts, consistency of the ABox with respect to the TBox, concept and role instances, all of which are decidable in a DL. Given the TBox and ABox rudiments above, it would, e.g., be concluded that everything is consistent and that $BlockedLoc(R_{509})$ (note that only door D_{509} is known here to lead to R_{509}). These DL inferences are theoretically intractable, but run very efficiently in most practical cases.

Reference [9.3] provides a comprehensive overview of the state of the art in DL. In 2004, the WWW consortium (W3C) defined the web ontology language (OWL) [9.12] as a technical basis for the semantic web. Part of the language is OWL-DL, a classical DL in the sense just described. OWL-DL ontologies are starting to become publicly available over the web; see [9.13] for a tutorial introduction.

9.1.2 Probability Theory

KR formalisms based on logics are worth considering whenever factual knowledge is to be represented, from which deductions are to be made. Part of the knowledge that a robot might use about its environment does, however, not really have this character. Choosing among KR

formalisms is – just like choosing among programming languages – to some degree a matter of taste, experience, familiarity, or system integration considerations. In KR terms the epistemological adequacy of a formalism for some domain is not an issue that can be judged with precision.

However, logic, at least its classical variants, has a number of weak spots in terms of KR requirements for some application types. Handling *uncertainty* is one, or rather, a whole family of them, as uncertainty is in itself an overloaded concept. *Lack of knowledge* is one of its aspects. Logics can handle this insofar as truth or falsity of some facts may remain undetermined. However, if too much is undetermined in a knowledge base, logics will no longer be able to make interesting deductions, as *everything is possible* logically. However, intuitively the different possibilities may differ considerably in likelihood.

The field of KR has adopted Bayesian probability as a means of representing and reasoning with this type of uncertainty, using correlations between facts rather than strict implications. Note that this approach amalgamates different sources of lack of precise and complete knowledge. Some piece of knowledge may be unknown because it is in principle unknowable, or because it was judged too costly to build a precise theory or determine all information relevant for making a sound deduction. In either case, working with probabilities rather than binary truth values can serve as an approximation. Note that the conception of truth is still the same here as in classical logics: *objectively*, a fact is supposed to be either true or false; probability just models the subjective degree of belief that the fact is true. Note that this is a difference from fuzzy logics, which will be addressed briefly below (Sect. 9.2.2).

In analogy to Sect. 9.1.1, we here assume familiarity with the basic notions of probability theory. Reference [9.4, Chap. 13] gives an excellent basic introduction; for a more comprehensive treatment, there are a large variety of introductory textbooks around, of which [9.14] is a recent example.

Inference in Bayesian probability theory basically means to infer the probability of some event of interest, given other prior and dependent relevant probabilities. Practically, an important type of probabilistic inference is *diagnostic reasoning*: reasoning from observed effects back to hidden causes, given causal rules that specify conditional probabilities from causes to effects. So the problem is, for a potential cause C and an observed effect E : given prior probabilities $P(C)$ and $P(E)$ and the conditional probability $P(E|C)$, determine the posterior

$P(C|E)$. The solution is of course given by the Bayes rule as

$$P(C|E) = \frac{P(E|C)P(C)}{P(E)}.$$

However, as in logical reasoning, this theoretically appealing principle turns out to be impractical if applied naively. Consider that not just one effect E may be observed, but n of them; moreover, not all of these are conditionally independent. A generalized form of the Bayes rule to calculate the correct posterior is straightforward, but who can specify all the conditional probabilities involved – in the worst case $O(2^n)$ of them, where n may easily range in the hundreds in practical cases?

Until the late 1980s, this problem has more or less been circumvented. One way is to treat the E_i in bad faith as independent, simply use the n individual conditional probabilities $P(E_i|C)$ and use them straightforwardly to approximate the full joint probability distributions. Reference [9.4, Chap. 14.7] reviews this and other alternative approaches.

The solution used ever since it has appeared [9.15] is *Bayes networks (BNs)*. The idea is to represent the random variables in a directed acyclic graph, where a node is directly preceded by a set of parent nodes iff it is directly conditionally dependent on the corresponding parent variables. So the huge full joint probability distribution is broken down into many, typically very small, *local joint probability distributions* without loss of information, the trick being to use the typically many known conditional independencies among variables to reduce the representational and inferential effort drastically.

Figure 9.1 shows a simple BN expressing that D can be caused by B or C , with probabilities given by a conditional probability table that specifies locally the joint probability distribution. In addition, the structure says

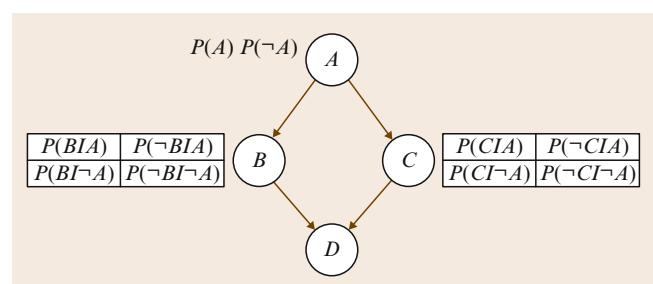

Fig. 9.1 Structure of a simple Bayesian network associated with conditional probability tables. (The ones for D , dependent on B and on C , are omitted.)

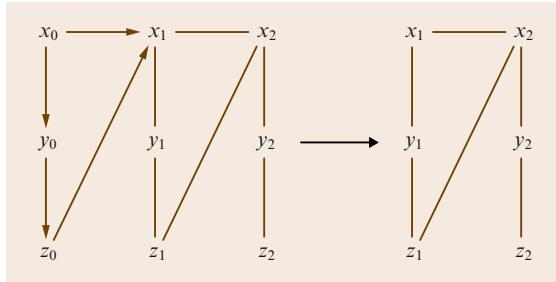

Fig. 9.2 Example of a dynamic Bayesian network at two successive time steps. The structure is invariant over time

that D is independent from A knowing B and C (a node is independent from its ancestors knowing its parents), and that B is independent from C knowing A , i.e., that $P(C|A, B) = P(C|A)$ and $P(B|A, C) = P(B|A)$. The

network can be exploited in both directions. Bottom up, it enables one to explain an observed phenomenon using the known conditional probabilities (diagnostic). For example, if D is observed, its more probable cause (B or C) can be inferred. Top down, it enables one to propagate evidence to compute the probability of a phenomenon, e.g., to compute the probability of D given A (causation).

For systems evolving over time, it is important to use an invariant structure of the Bayes network in order to update the values of the variables while using the same reasoning process. Such networks are called dynamic Bayesian networks (DBNs). Figure 9.2 shows such a network at time T , then at time $T + 1$.

In Sect. 9.3.3 we shall see specific probabilistic techniques for planning under uncertainty such as Markov decision processes.

9.2 KR Issues for Robots

The reasoning methods and generic applications in the rest of this chapter all make use, to some degree, of variants of the basic formalisms of logic or Bayesian probability theory. Both formalisms, in particular if variants are included, are so general and powerful that they can contribute to any KR application.

However, reasoning in a robot control system differs from reasoning in other knowledge-based systems in a number of aspects. A knowledge-based robot is an embedded system, working in closed-loop control, typically in a dynamic environment with quite limited resources; it has to interpret itself its sensor input, and should execute at least some of the actions autonomously that it has judged appropriate. Accordingly, knowledge-based robot control has special needs that are not present in, say, an offline expert system, which gets its input by prompting an experienced human in its domain of expertise and writes its output into some document for more experienced humans to deliberate about and possibly act accordingly if they feel it right. Naturally, this difference poses particular demands of robot control on the side of KR that may not be of interest for many other KR customers and that lie outside the mainstream of the field. In this section, we very briefly address three topics.

Before doing so, a word about the role of representation in designing *intelligent* or *smart* robots. It has been convincingly demonstrated that some forms of *intelligence without representation* [9.16] can be achieved in robots; Chap. 38 provides the background to this.

Clearly, the most sophisticated representation and inference system is of no help for a robot, if the reasoning in terms of symbols cannot be grounded in real sensor data and actuator control. On the other hand, representation and inference have much to offer for improving the performance, the software design, and the user interface of robots, for example in field, service, and intervention applications (Part F). Hybrid robot control systems (Chap. 8) are currently the means for amalgamating instances of KR technology with reactive control elements in a robot.

9.2.1 Logics for High-Level Robot Control

Robot domains are dynamic by nature, including at least one physical agent, namely, the robot. Capturing this in a logic-based formalism poses some conceptual and technical problems, which are introduced in [9.4, Chap. 10.3].

Very briefly, one of these comes from the requirement of expressing concisely and reasoning efficiently with logical models of action. Logically speaking, an individual action changes the truth value of a limited number of facts, leaving everything else as it was. For example, modeling on some abstract level the action of going from one location to another as atomic, it changes the robot's current location before and after; depending on the modelization, it may also change the battery state and the mileage count; but it does not change the lay-

out of the building or the name of the president. The problem of formalizing actions concisely in a logical language so that they allow facts that may or may not have changed after applying a sequence of actions to be inferred efficiently, has been termed the *frame problem*. It has received much attention in the literature; there are now a number of practical solutions to it.

Another problem concerns knowledge-base update, made necessary by independently changing facts. Consider, for example, a robot sitting – as it is told by its self-localization – in front of some door D , which is believed to be open, but the robot perceives a closed door. Logically, this is a contradiction. Now there are in theory several ways to make the knowledge and the perception consistent. One is to assume that D got closed since learning that it was open – probably the most intuitive explanation. Logically just as good would be, e.g., that the perception is faulty, or that the robot has been teleported in front of a door that is known to be closed. Among these *explanations*, some are more intuitively plausible than others; logically, some would require less formulas of the knowledge-base to be withdrawn and should therefore be preferred. Ideally, after replacing an old information by a new one, one would have to make sure that the consequences of a retracted formula are no longer believed.

Theoretically, these problems are arbitrarily difficult. Practically, they can be sufficiently restricted to allow solutions within a neat logical framework. Typical solutions would introduce some notion of situation or holding period for formulas, following the classical example of the situation calculus [9.17]. This allows change to be tracked. Typical solutions would also give up completeness of inference, resorting to a PROLOG-like inference engine. Three examples for such solutions with reported applications in robot control are GOLOG [9.18], event calculus [9.19], and FLUX [9.20].

9.2.2 Fuzzy Logic Approaches

For historical reasons, a number of methods and techniques dealing with classical AI questions have been living outside the *inner circle* of AI, sometimes under the different field names of *soft computing* or *computational intelligence*. This relates in particular to *fuzzy logic*, which is clearly a symbolic reasoning method. Moreover, it shares its fundamentals with fuzzy control, which gets used, in one way or another, in quite a number of robot controllers, so it is certainly a formalism to consider for KR on a robot.

To start with, the ontological basis of fuzzy logic is different to that of FOPL and probability theory. The latter assume that predicates are *objectively* either true or false; the truth may not be known, but it is in fact there. Fuzzy logic assumes that truth *objectively* comes in degrees. Many natural language categories have a fuzzy flavor, e.g., the statement that some person is *big* could be interpreted as objectively true or false in some extreme cases – but what should one *objectively* say about a male of 185 cm and 80 kg?

Fuzzy logic is conceived as a generalization of propositional logic (often called *crisp* logic in the field). Consequently, fuzzy logic uses the regular junctors \wedge , \vee , \neg etc., but generalizes their truth functional definitions from the set $\{0, 1\}$ to the interval $[0, 1]$. There are several plausible ways of doing this; a frequent one is to define

$$\begin{aligned}\text{value}(\neg P) &= 1 - \text{value}(P) \\ \text{value}(P \vee Q) &= \max\{\text{value}(P), \text{value}(Q)\}.\end{aligned}$$

The other junctors can be defined in the same spirit, where a number of differing definitions are in use.

Fuzzy deduction then typically has a different purpose, and hence a different machinery than propositional deduction – satisfiability of some fuzzy logic theory is normally not an interesting question as it too would come in degrees, so most fuzzy theories would normally be at least *a bit satisfiable*. Fuzzy logic knowledge bases are normally applied in a forward chaining manner over sets of fuzzy inference rules, inferring fuzzy values of fuzzy variables from other known fuzzy values. This is how fuzzy knowledge bases are successfully used in robot controllers, e.g., in the Saphira control architecture [9.21]. For example, it would make sense to determine the steering angle of a mobile robot using rules like

```
if (freeRange right is_narrow) ∧
(freeRange front is_medium) ∧
(freeRange left is_wide) ∧
then set angle medium_left
```

where the italicized components (*right*, *is_narrow* etc.) are fuzzy variables. The fuzzy truth values of the antecedent variables at a particular instance in time would be determined, e.g., from the readings of a distance sensor via definitions of the variables mapping, e.g., *is_medium* to a normal distribution with mean of 2 m; the set angle *medium_left* might be mapped to a normal distribution with mean 30° to the left. The actual

set angle to apply would finally be calculated by *defuzzification* of the combined fuzzy set values of the best applicable rule or rules; a plausible scalar value would be the center of gravity of the resulting fuzzy value.

Weltanschauung debates between soft computing and *core AI* notwithstanding, fuzzy reasoning components and other *AI* components can live together well in a robot controller, each contributing their respective strengths. The Saphira architecture is an example.

9.2.3 Reasoning under Time Constraints

Unlike many usual *AI* systems, robots have to take decisions in real time based on sensory data, in order to cope with the dynamics of their environments. Hence their decisions should be produced in limited time. If these decisions require some lookahead and anticipation, i. e., if planning is required, a problem arises: real-time decision-making is indeed incompatible with the unbounded nature of planning, which in its general form is an intractable problem, and being based on *FOPL* inference mechanisms, is in addition only semi-decidable.

In order to take real-time constraints into account, approaches such as reactive planning have been proposed [9.22], which actually abandons to plan too much ahead (only one step at a time). However, the solution

to time constraints usually comes from the *architectural design* of the robot system (Chap. 8), which integrates a decision-making level and a reactive level that would react within a bounded time. The decision-making level often includes a planner and a supervisory control system that ensures task execution supervision using predefined procedures or scripts, with explicit triggering conditions. This supervisory component has to be both goal and event driven: goal driven to accomplish the task and event driven to be reactive to environment changes. An example of such a system is the procedural reasoning system (*PRS* [9.23, 24]), which includes a set of procedures, a database updated by sensing and by the evolution of system state, and an interpreter that decides to launch the applicable procedures according to the contents of the database.

Anytime algorithms [9.25, 26] were developed as a possible response to time constraints. The basic idea is that the longer the algorithm can operate, the closer to optimal its solution will be. However, if time is shortened, the algorithm will still produce an answer, which may be far from optimal, but will enable the system to act instead of being blocked awaiting a decision. Anytime algorithms evaluate the quality of their results and a performance profile enables one to predict how this quality can be improved over time.

9.3 Action Planning

For the rest of this Chapter, we turn from reasoning *methods* to two generic reasoning *applications*, namely action planning and learning.

Planning, in the traditional *AI* sense, means deliberating about a course of action for an agent to take for achieving a given set of goals. *Scheduling* means allocating time and potentially other resources to a set of actions such that given deadlines are met and resource constraints respected. The two activities are conceptually different and have historically often been treated in a cascaded way: plan first, then schedule. Recently, with the advent of more efficient temporal reasoning methods and more efficient planning algorithms, there is a tendency to deal with them in an integrated way. The rationale is that generating an optimal plan according to some metric first, and then designing an optimal schedule for that plan, may not lead to a time- and resource-optimal schedule. It does still also make sense, however, to consider the two in isolation as their combi-

nation is not always required. In this overview, we skip the integration of scheduling. Reference [9.27, Part IV] provides a comprehensive overview.

Robot control has been among the first intended applications of planning: the STRIPS system [9.28, 29] was used to generate plans, i. e., sequences of abstract high-level actions to execute, for the robot SHAKEY [9.30]. However, it has turned out to be nontrivial to design a robot control architecture in which plans containing abstract actions are broken down into physical operation that is flexible enough to follow the plan but cope with contingency, serendipity, and failure as one would intuitively expect from an *intelligent* usage of plans.

This overview starts with how to model planning domains for planners. In Sect. 9.3.2, we sketch planning algorithms that work efficiently under a number of simplifying assumptions. Section 9.3.3 relaxes these assumptions, dealing with uncertainty such as lack of

observability. We close with a brief discussion of robot planning Sect. 9.3.4.

For comprehensive coverage of the topic, we refer to [9.27]. Introductions to the topic can be found in AI textbooks, such as [9.4, Chap. 11,12,16,17]. Reference [9.31] concisely reviews the more recent developments in planning. The *International Conference on Automated Planning and Scheduling* (ICAPS) is currently the main international conference of the field, held annually. The PLANET online research database [9.32, Service.Repositories] contains a set of continually updated links to state-of-the-art planners, schedulers, and related tools. Reference [9.33] contains an application-oriented perspective of the current state and perspectives of the field as of the end of 2003.

9.3.1 Planning Domain Descriptions

Deliberating about the course of action of an agent requires representing its possible actions, including their effects, keeping track of changes in the environment over time, and dealing rationally with any remaining uncertainty or lack of information. In this sense, planning combines the reasoning methods described previously in this Chapter.

The extreme form of deliberation would be to simulate in advance the environment, including the agent's possible actions, and then do what seems best. In practice, that is impossible for at least two reasons. First, typically not all information that would be needed for a truthful simulation is available. Planning is meant for real environments in which many parameters are unknown or unknowable and which are not under the agent's control. Second, even if everything for a complete simulation were known, then it would very likely be so computationally intensive that the real world would run ahead of the simulation all the time. In consequence, planning domain representations deliberately abstract away many, or most, details, to make effective planning possible. As in all forms of KR, precision and completeness of domain models need to be traded off against reasoning speed.

Exactly how many or how few details, and which, are represented, is an engineering decision to take when a planning system is built. Accordingly, a number of simplifying assumptions on the domain may or may not be made, including

- *finiteness* (the domain has only finitely many objects, actions, and states)

- *information completeness* (the planner has all relevant information at planning time)
- *determinism* (actions have deterministic effects)
- *instantaneousness* (actions have no relevant duration)
- *idleness* (the environment does not change during planning)

As usual, restrictive assumptions lead to efficient algorithms, but may cause problems when a simplified solution makes contact with the real world – in this case at execution time. Note that using a simplifying domain model does *not* mean assuming that the world objectively *is* that way. It may, e.g., make sense to plan only for standard cases, assuming maximal simplicity, and handle any occurring exceptions at execution time if and when they occur. In robot planning, this philosophy goes back as far as SHAKEY [9.29].

Currently, two main families of domain representations are used. The PDDL-type description is described next. In Sect. 9.3.3, a representation for nondeterministic domains will be sketched. In addition, there are various forms of deductive planning orthogonal to these two that use variants of *pure* logical representations. See [9.27, Chap. 12] for an introduction.

PDDL-Type Descriptions

Remaining on the simple side of all the above assumptions, a *domain description* contains mainly two parts. First, a specification of a restricted first-order language \mathcal{L} from predicate symbols and constants representing the relations and objects considered relevant in modeling the environment; and, second, a set \mathcal{A} of *action descriptions*. These consist for each action $a \in \mathcal{A}$ of $\text{pre}(a)$, the preconditions, i. e., a set of facts in \mathcal{L} that need to be true to execute a ; and $\text{post}(a)$, the postconditions, i. e., a set of (positive or negative) facts in \mathcal{L} that become true by executing a .

To give a very simple example (taken from [9.27, p. 35]), Table 9.1 shows an *action schema* for moving a robot r between adjacent locations l and m . Action schemata are instantiated in the planning process to ac-

Table 9.1

```
(:action move
  :parameters (?r - robot ?l ?m - location)
  :precondition (and (adjacent ?l ?m) (at ?r ?l)
    (not (occupied ?m)))
  :effect (and (at ?r ?m) (occupied ?m)
    (not (occupied ?l)) (not (at ?r ?l))))
```

tions occurring in plans, by substituting variables by constant objects.

A specific *planning problem*, given a domain, is then specified by the following components over \mathcal{L} :

- I , the *initial situation*, a set of all facts in \mathcal{L} true of the environment before execution starts
- G , the *goal conditions*, a set of facts in \mathcal{L} to bring about by executing a plan

Plans in this framework are typically *partially ordered* sets of ground (variable-free) actions to be executed in accordance with the ordering.

The *planning domain description language* (PDDL, [9.34]) is the current de facto standard for describing planning domains. In fact, PDDL stands for a whole family of languages, allowing or disallowing features such as argument typing, equality handling, conditional action effects, and some restricted form of FOPL statements. To give an example of a conditional effect, consider that the robot in the move action may or may not be loaded with some container $?c$, then we specify as an *additional effect* that $?c$ would move with the robot:

```
(when (loaded ?r ?c)
      % condition
      (and (at ?c ?m) (not(at ?c ?l)))
            % effect.)
```

Beyond such variants, there are extensions to the original PDDL of which PDDL2.1 [9.35] is most notable, allowing information to be expressed for temporal planning, e.g., allowing actions to have durations.

Planning is computationally hard. For propositional variants of PDDL-type problems, i.e., those with a finite \mathcal{L} , plan existence is of course decidable. However, solving planning problems is PSPACE-complete [9.36].

9.3.2 Partial-Order Plan Generation

Many planning systems and their underlying planning algorithms accept the aforementioned restrictive assumptions of information completeness, determinism, instantaneousness, and idleness. In consequence, the definition of a planning problem just given applies. The sort of plan to find, then, is a set of actions whose execution transforms the initial situation into a situation with the goal conditions true. (Goal situations need not be unique.) Finiteness need not be assumed for this planning model, but let us do so for simplicity, meaning that all action instances can be assumed to be ground.

Normally, actions in a plan cannot be executed in arbitrary sequence, but have to obey an ordering, making sure that all preconditions of each action are true at

the time of its execution. This order need not be total or linear, but may be partial or nonlinear. The corresponding type of plan is called a *nonlinear* or *partial-order plan*, which is, in sum, defined as a pair $\langle A, \prec \rangle$ of a set A of action instances and an ordering relation \prec on A . Unordered actions may be executed in either sequence. With some care in the action modeling, they may also be executed *concurrently*, which, assuming instantaneousness, means within the same atomic *time step*.

For a plan to be a *solution* of the given planning problem, every action $a \in A$ needs to have its preconditions true in every possible execution sequence compatible with \prec , and the goal conditions must be true at the end of any such execution.

Starting from the first partial-order planning approaches in the 1970s and 1980s, culminating in the SNLP (systematic nonlinear planning) algorithm [9.37] and its descendants, algorithms that tried to achieve efficiency by systematic, backward-chaining, least-commitment, relatively reasoning-intensive assembly of partial-order plans were developed. Reference [9.4, Sec. 11.3] provides an introduction and references. This line of work is often called *classical planning*.

Here is the algorithmic idea to generate a solution plan: start with the empty plan containing only the initial facts and the goal conditions; iteratively check any condition occurring in the current plan, whether it is true under all \prec -admissible execution sequences; if some condition c is found open, fix it by inserting a new action generating c as an effect or by ordering an existing action in the plan so that c becomes true at the time needed. This would work efficiently if all actions were independent of each other, but usually they are not: a c once achieved in a plan may be threatened later by some action with $\neg c$ in its effects. Much of the algorithmic or heuristic effort in classical planning systems has gone into preventing or handling subgoal interactions in plans efficiently.

A technique employed in many application systems is using predefined subplans as *macros*, which induce a hierarchical structure in plans, motivating their name *hierarchical task networks* (HTNs). Reference [9.27, Chap. 11] gives an introduction. Formally, a subplan can be expressed as a *task*, i.e., an action with preconditions and postconditions, that can be expanded at planning time into its underlying subplan. Tasks may be layered hierarchically. A plan is unfinished as long as it contains unexpanded tasks. The rationale for using HTNs is that the planning domain modeler knows typically – in fact, in all real applications – recurring subplans that the planner need not reinvent every time from scratch.

Moreover, the hierarchical nature of HTNs allows even large plans to be displayed in a way that is manageable for humans. HTNs have been used for a long time, with good results. SIPE (system for interactive planning and execution monitoring) [9.38] was among the first planners used for real applications. More recently, SHOP (simple hierarchical ordered planner) [9.39] is among the top-performing planners.

Starting with GRAPHPLAN [9.40], the field has focused on a set of techniques for partial-order planning algorithms (dubbed *neoclassical planning* by [9.27]), which deviate from the classical algorithms and keep generating top-performance planners. We will elaborate on two of their ingredients, namely, planning graphs and translation into satisfiability problems.

Much of the performance improvement of recent planners is owed to the formulation of planning as a particular family of search problems, for which powerful heuristics exist. For details, see [9.27, Part III].

Planning Graphs

One of GRAPHPLAN's key ideas is to start plan construction with a preprocessing phase, that:

1. determines a necessary criterion for solvability in n time steps (where n is incremented until some answer is found), and
2. yields a structured representation, based on which an n -time-step partial-order plan can be extracted relatively efficiently, if it does exist.

This structure is the *planning graph* (PG), i.e., a bipartite, layered DAG of ground fact nodes and ground action nodes, where layers of fact nodes and action nodes

occur alternately. Figure 9.3 sketches three subsequent layers.

The first layer F_0 consists of all fact nodes to represent completely the initial situation of the problem. The last layer is also a fact layer. An edge connects a fact node with an action node iff the corresponding fact is among the action preconditions. An action node is connected with a fact node iff the fact is in the action effects. In addition to the actions \mathcal{A} of the domain description, PGs contain pseudo-actions serving to copy each and every fact of a fact layer to the next fact layer. (Syntactically, a pseudo-action for f has exactly f as its precondition and its effect.) A PG contains in any layer A_i the action nodes corresponding to all actions that are applicable, given the facts of F_{i-1} , and F_i contains all facts contained in all A_i action postconditions.

For a given finite planning problem, the PG is unique up to node sequence within layers. It can be expanded without search by forward-chaining from the last fact layer, inserting all applicable actions in the next action layer and their effects in the next fact layer. The sets of actions and facts grow monotonically over layers, so PG generation terminates for finite domains.

A necessary condition for solvability of the planning problem is the existence of a fact layer containing all goal facts. If such a layer is found at time step n , PG expansion is suspended and *plan extraction* is attempted, assembling a solution plan backwards. A set of actions is selected from each A_i that generate the facts needed in F_i , starting with the goal facts in F_n and needing the preconditions of the A_i actions in F_{i-1} .

Plan extraction is not guaranteed to succeed, as needed actions may be mutually exclusive in a common action layer – the analog to subgoal interaction in classical planning. So, occurrence of the goal conditions in some F_n is a necessary, but not sufficient, criterion for solvability. In general, search is involved in plan extraction from a PG, yet in a much smaller search space than in classical planning algorithms, which typically outweighs by far the effort for constructing the PG first.

The main drawback of PGs is that they require domains to be finite (i.e., propositional), and, moreover, their languages \mathcal{L} have to be limited in size, as all fact and action ground instances are explicitly constructed for expanding the PG.

Planning as Satisfiability

From the early history of planning, researchers have been tempted to express the problem of plan generation as one of inference in classical logic [9.41]. This might be useful for two reasons. First, existing efficient

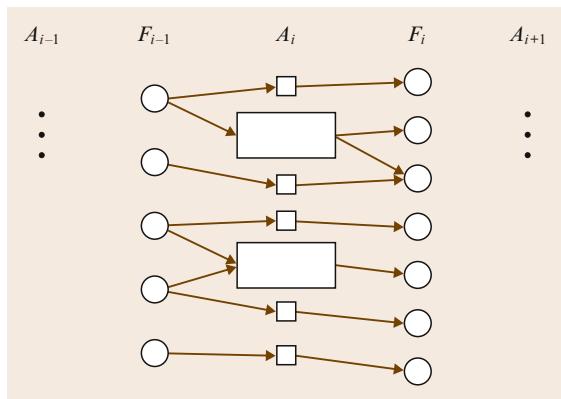

Fig. 9.3 Structure of a planning graph. Circles represent fact nodes, boxes represent action nodes, and small square boxes represent pseudo-operators

logical reasoners might be used for planning, saving the effort of inventing dedicated planning algorithms. Second, logical reasoning within the domain would be seamlessly integrated into planning, obtaining powerful domain representations for free.

Expressing change and inertia efficiently in **FOPL** has turned out to be problematic due to the *frame problem*; see [9.4, Sec. 10.3] for an introduction. Meanwhile there are several methods to represent planning problems in different logical formalisms, with some *deductive* planners under the top performers of their times. For example, *TALplanner* [9.42] uses a representation in a temporal logic; *Blackbox* [9.43] uses an encoding in propositional logic, its planning algorithm incorporating PGs. A propositional logic encoding offers the option of using an efficient model checker (Sect. 9.1) for inference. This is applicable whenever PGs are. Reference [9.27, Chap. 7] provides an introduction.

A propositional representation of a finite planning problem can be derived relatively schematically from a given domain and problem description, as developed for *Blackbox*. Facts are given an additional situation argument, with actions transiting between situations. The propositional logic representation of initial facts, goal facts, and action effects is straightforward. The interesting part (Sect. 9.2.1) consists of the *explanatory frame axioms*, i. e., a set of axioms formalizing that any change of the truth of a fact between two situations needs to be *explained* by applying an action that has the changed fact values among its effects.

9.3.3 Planning Under Uncertainty

While information completeness, determinism, and idleness are often useful approximations for planning domains at some abstract level, they may not help in other cases. However, that does not mean that all their exact opposites are true (in which case planning would hardly make sense). Many domains show aspects of ignorance, randomness or dynamics, but still offer some degree of information or control. Exploiting this to compensate for any lacking information or control is the point of planning under uncertainty. According to different aspects and grades of imperfection in domain models, it comes in different forms. We sketch one of these forms here and refer to [9.27, P. V] and [9.4, Chaps. 12, 16, 17] for comprehensive introductions. Reference [9.44, P. IV] introduces probabilistic planning techniques in a robotics context. Reference [9.45] develops a unifying view of classical planning as previously described and planning under various forms of uncertainty.

MDPs

Assume that some actions may have nondeterministic effects, and information (which may be approximate or estimated) is available about the relative frequencies of these effects. In this case, representation in a probabilistic framework, such as *Markovian decision processes* (**MDPs**) is natural. An **MDP** represents the domain by a finite set of states S , a finite set of actions A , and an action model, which specifies for each $a \in A$ the conditional probability distribution $P_a(s' | s)$ of ending in state s' when executing a in s . For example, assume that the robot's current location is part of the state description; the high-level action of moving from its current location l to an adjacent, free location m (Sect. 9.3.1) produces the standard effect of being at m in 95% of cases; unspecified, maybe unknown, conditions cause the robot to stay at location l in the remaining 5% of cases.

States have associated utilities, where action cost may be modeled as negative utility of the resulting states. Planning in this framework means finding a course of action that takes not only a unique standard outcome for every operator into account, but regards all likely outcomes, including those that are unlikely but would produce very costly effects (think of the possible motion errors of a wheeled platform in the vicinity of a steep staircase).

A plan in this framework is a *policy* as in decision theory, i. e., a function from states into actions. The basic planning algorithms are value iteration (**VI**) and policy iteration (**PI**, see [9.4, Chap. 17]), both of which converge to the optimal policy for finite state sets. The difference is that **VI** does so by approximating the true utility of an optimal policy in a given state, whereas **PI** finds just the optimal policy, saving the effort of determining its precise utility value.

MDPs still make an assumption that may be inconvenient in some robotic applications, namely that state is observable at execution time, i. e., the agent can precisely determine in which state it is, and can pick the corresponding branch in its policy with certainty. Further skipping the observability assumption leads to *partially observable MDPs* (**POMDPs**). A **POMDP** adds to an **MDP** an observation model consisting of a finite set O of possible observations for the agent to make and of the conditional probabilities $P(o | s)$ of observing o in s . **POMDPs** are also used as the formal model in mobile robot localization and mapping (see Chap. 37).

Optimal policies for **POMDPs** are defined in analogy to **MDPs**, but finding them is computationally hard. A standard approach is to consider the *belief space* rather

than the state space, i.e., the space of probability distributions over the state space, which correspond to the agent's belief of where in state space it probably is after performing an action or an observation. Belief space is fully observable (the agent knows its beliefs with certainty); hence a POMDP can be translated into a belief space MDP and the VI and PI algorithms applied. The belief space is exponentially larger than the state space, and it is continuous. As a consequence, only POMDPs over small state spaces can be effectively handled in this way. Approximation approaches exist, see [9.4, Chap. 17].

9.3.4 Robot Planning

The term *robot planning*, or *plan-based robot control*, in AI refers to the usage of the planning methods just described in the control software of a robot, typically an autonomous mobile robot. It is not meant to replace existing motion or path-planning methods in robotics (Chaps. 5, 26, and 35), but to complement them for more general action planning. There are several purposes for using plans in robot control – be they automatically generated online by the robot or taken from a plan library. Offering a highly granular description of the robot's operation, they can be useful for *optimizing* the overall behavior, for *interacting* with humans as in task-level teleoperation, for *communicating* with fellow robots as in multirobot coordination (Chap. 40), for *learning* complex action structures in highly granular chunks, for *adapting* the behavior to environment changes, and, on a different scale of usefulness, for *engineering* the robot control code by providing a meaningful abstraction level for the programmer. Reference [9.27, Chap. 20] elaborates on these purposes; [9.46] is a collection of research papers spanning them. Reference [9.33, Chap. 5] presents a recent application-oriented perspective on the field.

Corresponding to the multiplicity of purposes and abstraction levels where action planning can be of help,

there is no single method, formalism or approach for robot planning; rather, any of the planning methods can be of use. As a consequence, the term *robot plan* is mostly used in the broad sense formulated in [9.47], namely *that part of the robot's program whose future execution the robot reasons about explicitly*. The specificity of robot planning from the viewpoint of planning methodology comes from the requirement for closed-loop execution and monitoring of whatever plan the robot adopts. Technically, this poses constraints on robot planning, in particular on the domain language, on the action formalism, and on the robot control architecture.

The *domain language* \mathcal{L} for a given planning domain is normally carefully handcrafted, as bad design decisions may make the difference between short and unacceptable planning time of the same planner. For robot planning, there is another issue: the propositions (at least those that need to be observed for plan generation and execution monitoring) need to be effectively determined based solely on sensor data. In general, this is the fundamental *symbol grounding* problem in AI [9.1, 2] (Sect. 9.1). The current pragmatic approach to this is to restrict the dynamic part of the domain language to propositions that can be effectively monitored.

The *action formalism* should ideally support both plan generation and execution monitoring. So it should be expressive enough to resemble, e.g., real-time programming languages, but restricted enough to make reasoning about plans effective. Reference [9.48] discusses these issues and reviews the relatively small range of existing approaches.

Finally, the *robot control architecture* has to make sure that planning and plans are integrated appropriately into the overall robot control. In particular, the advice coming from the recent plan (if any) has to be effectively negotiable with any activity coming from other control components, such as concurrent reactive behaviors; see Chap. 8 for details.

9.4 Robot Learning

Machine learning has been one of the first concerns of AI research, the link between learning and intelligence appearing to be so obvious. One of the first instances of a learning program was Samuel's Checkers program in 1959. The definition of learning is itself as general as the definition of intelligence. It can be basically stated

as *the ability to improve the system's own performance or knowledge based on its experience*. In AI, the main classical learning schemes are based on manipulating symbolic representations to produce new knowledge either by deduction, by induction or by analogy. Statistical learning covers methods that enable the classification

of data, i.e., to deduce models from samples, which is a widespread learning scheme used in robotics and other domains. When the representations are probabilistic, Bayesian reasoning is used. Neural networks, based on formal models of the biological neurons, cover techniques for data classification related to statistical learning.

Another popular learning scheme in robotics is *reinforcement learning*, which is closely related to **MDPs** and dynamic programming. It is mainly based on a reinforcement signal (a reward) associated to each robot action that is used to reinforce a correct response.

Learning can also be classified as being *supervised* or *unsupervised* depending on whether there is a teacher able to provide the correct answer explicitly after the system's action, i.e., to reward the system, or only the system's own performance is available for this.

This section overviews the most important learning schemes of interest to robotics. Applications of learning in robot control appear throughout this Handbook, e.g., for learning maps in Chap. 37, learning intricate motor coordination patterns in Chap. 60, and evolutionary learning in Chap. 61.

9.4.1 Inductive Logic Learning

One of the main supervised symbolic learning schemes is *inductive logic programming* (**ILP**) [9.49]. This process is based on logic representations and first-order logic inference, and uses contextual knowledge, i.e., already acquired knowledge. The purpose of **ILP** is to synthesize (or learn) logic programs given a set of variables for which they return true or false values, and so-called background knowledge. The programs form an explanation of the observations. These programs are of course not unique. Therefore the difficulty is to find a minimal (necessary and sufficient) program that is compatible with the data, i.e., that returns true for the positive variables and false for the negative ones. This program must also be able to generalize, i.e., to produce the correct answer when applied to new instances. In general, **ILP** is not tractable. Reference [9.4, Sect. 19.5] provides an introduction.

9.4.2 Statistical Learning and Neural Networks

Statistical learning is very widely used in robotics and computer vision. It covers several techniques such as *Bayesian learning*, *kernel methods*, and *neural networks* that classify patterns into categories with the purpose of

learning models from data considered as random variables, the values of which provide a sampling of the model. First there is a training period during which the algorithm is presented with a set of data and associated labels (supervised learning). Then the algorithm will label the data on its own. The purpose of the training phase is to minimize the classification error (or risk or expected loss). We refer to [9.4, Chap. 20] for a general introduction.

Bayesian learning is the application of the Bayes rule to compute the probability of given hypotheses – which are the labels of the classes to which the data belong – given the data. The training period provides the likelihood of the data for each class $P(d|C_i)$. The classification also requires a knowledge of the prior class distribution $P(C_i)$ to apply the Bayes rule. There are several variations of Bayesian learning including *maximum likelihood* (**ML**) and *expectation maximization* (**EM**). Bayes techniques have medium computational cost and are easy to implement, but they are not online.

Neural networks (**NN**) are composed of elementary computational units (neurons) linked by weighted connections. Each unit computes the weighted sum of its inputs and activates or fires if the input is larger than a given threshold (a sigmoid function is often used). Hence this provides for the base of a classifier. The basic structure of a feedforward network, the most commonly used, includes an input layer, one or more hidden layers, and an output layer. Through the connection weights, the output of a **NN** is a function of its inputs. The training of the **NN** consists of adjusting the weight to classify the data correctly (supervised learning). Contrary to Bayesian learning, neural networks give no insight into the classifier, but they can be used online.

9.4.3 Reinforcement Learning

Reinforcement learning (**RL**) is unsupervised learning through acting in the environment, which returns a reward signal. A main reference for **RL** is [9.50], while [9.4, Chap. 21] gives a general introduction. In **RL**, the purpose of the robot or the agent is to learn the best *policy*, i.e., sequence of actions to reach a given goal. To do this it has to maximize the cumulated reward. The formal framework of **RL** is therefore the same as that of **MDPs**. The robot perceives (in some cases partially) environment states in a set S and is able to accomplish actions in a set A , the sequence of which forms a policy π . There are transition probabilities from a state to the

next upon performing a given action $P(s_{t+1} = s' | s_t, a_t)$. The robot attempts to maximize a value function V expressing the expected cumulated rewards r_t over time. The basic equation expressing the value function and enabling learning of the optimal policy π^* is the Bellman equation

$$V^{\pi^*}(s) = \max_a \left[r(s, a) + \gamma \sum_s' P(s'|s, a) V^{\pi^*}(s') \right], \quad (9.1)$$

where $r(s, a)$ is the immediate reward, and the discount factor γ enables future anticipated rewards to be taken into account. A variant to compute the optimal policy is Q-learning [9.51], the idea of which is to learn values of actions rather than those of states.

Most **RL** work assumes that the action space is discrete, and the application to continuous action spaces is not straightforward given the formulation of the learning process itself. To apply **RL** to continuous spaces, one usually resorts to sampling.

9.5 Conclusions and Further Reading

From its early days, autonomous robots have been included on the **AI** research agenda. The first experiments took place in many laboratories in the 1990s, when mobile robot platforms became widely available and affordable. **AI**'s motivation for dealing with robotics is clear: it provides a useful test bed for computational models of agents that include perception, reasoning, and action, as robots allow them to be examined in full integration.

This is similar to **AI**'s *long-term* perspective for robotics: to develop methods and tools that will contribute to closed-loop controllers for smart autonomous robots. But what is the contribution of **AI** reasoning methods to robotics *today*?

Two lessons have been learned here. First, the described reasoning methods are sufficiently well understood and efficient that they can be applied safely and profitably as ingredients in closed-loop control of robotic agents today. Mid-size league matches in RoboCup soccer are spectacular examples of this; the autonomous control features in the National Aeronautics and Space Administration (**NASA**) Remote Agent mission [9.52] are another.

Second, the full closed-loop integration of perception, (symbol-based) reasoning, and action would require the symbol-grounding problem [9.1], or a substantial part of it, to be solved. That is, we would have to understand how a robot could perceive its environment in terms of the semantic categories that it uses for reasoning and for planning actions. Understanding the symbol-grounding process fully is among the big problems of **AI**, and of all of cognitive science for that matter. So robotics had better not wait for **AI** to find the general solution first. In the meantime, robots can profitably use **AI** reasoning methods wherever the required data are available in closed-loop control.

To conclude this chapter, let us return to the issue of the robot control architecture to highlight an essential point of functional and physical integration. For the purpose of this overview, we have treated reasoning as a method or set of methods that has to rely on information given by, first, a (human) domain modeler, second, online perception for delivering up-to-date information in symbol form about the current state of the domain, and/or, possibly third, a learner that helps with the recognition or the reasoning itself by generalizing past experience. This view is in fact short-sighted. A fully integrated robot reasoner should help other modules by providing hypotheses, e.g., about what the perception module might currently look for in its sensor data. (*If you tell me you have identified a sink and a dishwasher, then I tell you we might be in a kitchen, and you could watch out for a fridge.*) A two-way integration of reasoning and perception is currently beyond the state of the art in robotics, but is moving into focus. A source of inspiration might be related work from *cognitive vision*, of which [9.53] contains a collection of recent papers.

Further Reading

For a more complete coverage of the methods described here, as well as the of the rest of **AI**, we refer to **AI** textbooks, of which the book by *Russell and Norvig* [9.4] is currently most widely used. Reference [9.5] is to be recommended as a recent introduction specifically to knowledge representation and its issues. Among the sources for first-hand material, let us mention the two journals *Artificial Intelligence* and the *Journal of Artificial Intelligence Research (JAIR)* [9.54], both of which cover the topics addressed here well. The main international conference, the *International Joint Conferences on Artificial Intelligence (IJCAI)*, is held biannually every odd year.

The chapters contained in **Part B**, Robot Structures, are concerned with the design, modeling, motion planning, and control of the actual physical realizations of a robot. Some of the more obvious mechanical structures that come to mind are arms, legs, and hands; to this list we can add wheeled vehicles and platforms, and robot structures at the micro- and nanoscales. Even for that most basic robotic device, the arm, an incredibly diverse set of structures is possible, depending on the number and types of joints and actuators, and the presence of closed loops in the kinematic structure, or flexibility in the joints and links. Constructing models, and planning and control algorithms for these diverse structures represents an even greater set of challenges.

The topics addressed in these chapters are essential to creating not only the physical robot itself, but also to creating and controlling movements, and manipulating objects in desired ways. As such the connections with the chapters on Robot Foundations (Part A) — particularly the chapters on Kinematics (Chap. 1), Dynamics (Chap. 2), and Mechanisms and Actuation (Chap. 3) — are self-evident. What ultimately distinguishes robotics from other disciplines that study intelligence is that, by definition, robots require a physical manifestation, and by extension must physically interact with the environment. In this regard the topics addressed in these chapters can be said to constitute the most basic layer of this endeavor.

Just as it is difficult to examine human intelligence from a purely abstract perspective, remotely detached from the physical body, so it is difficult to separate the contents of the remaining parts without including in the discussion the actual medium of interaction with the physical world, the (physical) robots themselves. For example, the question of how to coordinate sensing and perception with action (Part C), how to grasp and manipulate objects (Part D), and how to teach multiple robots to cooperate (Part E), must inevitably consider the physical structure of the robot. Robots specialized to various applications and environments (Part F), particularly those intended for direct interaction with humans (Part G), naturally must also consider the robot's physical structure.

With this overview of Part B, we now provide a brief synopsis of each chapter.

Chapter 10, Performance Evaluation and Design Criteria, provides a concise overview of the robot design process, and surveys some of the criteria and tools used in the mechanical design and performance evaluation of robots. Criteria such as workspace volume, local and global dexterity, and elastostatic and elastodynamic

performance are not only applicable to determining the topological structure and physical dimensions of the robot, but can also be useful for, e.g., workpiece placement and kinematic redundancy resolution.

Chapter 11, Kinematically Redundant Manipulators, addresses the motion generation and control of manipulators with redundant kinematic degrees of freedom. Kinematic redundancy affords a robot with an increased level of dexterity that may be used to, e.g., avoid singularities, joint limits and workspace obstacles, and also to minimize joint torques, energy, or other suitable performance criteria. The chapter discusses inverse kinematic redundancy resolution schemes for manipulators ranging from those with just a few degrees of kinematic redundancy, to hyperredundant manipulators that can be kinematically modeled as continuous curves.

Chapter 12, Parallel Mechanisms and Robots, presents an introduction to the kinematics and dynamics of parallel mechanisms such as the well-known Stewart–Gough platform. Parallel mechanisms contain closed loops in their kinematic structure, and as such methods for their analysis differ considerably from those for their serial counterparts. This chapter discusses topics ranging from type synthesis and forward and inverse kinematic solutions of parallel mechanisms, to an investigation of their singularity behavior, workspace characterization, static and dynamic analysis, and practical issues in their design.

Chapter 13, Robots with Flexible Elements, addresses the dynamic modeling and control of robots with flexibility in the joints and links. Because the control methods developed to compensate for joint versus link flexibility are structurally different, the chapter is organized such that these two types of flexibility are examined independently. The methods, however, can be extended to the case when both joint and link flexibilities are present, possibly even dynamically interacting at the same time. The chapter also examines the typical sources of flexibility in industrial robots.

Chapter 14, Model Identification, discusses methods for determining the kinematic and inertial parameters of robot manipulators. For kinematic calibration, the primary aim is to identify the geometric Denavit–Hartenberg parameters or equivalent, typically by sensing a combination of joint and endpoint positions. Inertial parameters in turn are estimated through the execution of a trajectory while additionally sensing one or more components of joint forces or torques. The chapter is organized such that both kinematic and inertial parameter identification are cast into a common framework of

least-squares parameter estimation; common features relating to the identifiability of the parameters, adequacy of the measurement sets, and numerical robustness are identified and emphasized for both the kinematic and inertial parameters.

Chapter 15, Robot Hands, investigates the principal issues behind the design, modeling, and control of robot hands. Beginning with a discussion of levels of anthropomorphism, and the characterization of robot hand dexterity, the chapter investigates the relevant design issues for robot hands, actuation and transmission architectures, and available sensing technologies. The dynamic modeling and control of robot hands are made challenging not only by the complex kinematic structure, but also by the flexible transmission elements, and the chapter devotes particular attention to these issues.

Chapter 16, Legged Robots, discusses the myriad issues involved in the design, analysis, and control of legged robots. Beginning with a history of legged robot research, the chapter provides an analysis of cyclic walking, and the control of biped robots based on the forward dynamics and the zero-moment point (ZMP). Multi-legged robots, such as dynamic quadrupeds inspired by mammals and behavior-based multilegged robots, are also discussed, as are hybrid leg–wheel–arm robots,

tethered walking robots, and even legged robots capable of climbing walls.

Chapter 17, Wheeled Robots, provides a general and comprehensive description of wheeled mobile robots. The chapter begins with a discussion of robot mobility based on the types of wheels and the nature of the kinematic constraints, followed by a discussion of kinematic and dynamic state space models, and structural properties of wheeled robot models such as controllability, nonholonomy, and stabilizability. The chapter also discusses feedback linearizability in the context of nonlinear control, and concludes with a detailed classification of the possible robot structures based on the number and types of wheels.

Chapter 18, Micro/Nanorobots, provides an overview of the state of the art in micro- and nanorobotics. The former entails robotic manipulation of objects with dimensions in the millimeter to micron range, as well as the design and fabrication of autonomous robotic agents within this size range (nanorobotics is defined in the same way, but for dimensions smaller than a micron). The chapter outlines scaling effects, actuation, and sensing and fabrication at these scales, and also applications to microassembly, biotechnology, and the construction and characterization of micro- and nano-electromechanical systems.

10. Performance Evaluation and Design Criteria

Performance

Jorge Angeles, Frank C. Park

This chapter is devoted to the design of robots, with a focus on serial architectures. In this regard, we start by proposing a stepwise design procedure; then, we recall the main issues in robot design. These issues pertain to workspace geometry, the kinetostatic, the dynamic, the elastostatic, and elastodynamic performance. In doing this, the mathematics behind the concepts addressed is briefly outlined to make the chapter self-contained.

We survey some of the tools and criteria used in the mechanical design and performance evaluation of robots. Our focus is limited to robots that are (a) primarily intended for manipulation tasks and (b) supplied with serial kinematic chains. The kinematics of parallel robots is addressed in detail in Chap. 12. Wheeled robots, walking robots, multifingered hands, and other similar specialized structures are studied in their own chapters.

The most obvious application of the criteria and tools described in this chapter is in the mechanical design of a robot. Robot design differs from the design of single-degree-of-freedom machinery in that the latter is intended for one specific task, e.g., picking up a workpiece from a belt conveyor and placing it on a magazine. Moreover, the conveyor is synchronized with the manipulating machine and the magazine is stationary, with well-defined locations where each workpiece is to be placed. Manipulation robots, in contrast, are not in-

tended for one specific task, but rather for a *family of tasks* falling within one class of workpiece motions, e.g., planar, spherical, translational, or motions produced by systems of the Selective Compliance Assembly Robot Arm (**SCARA**) type, also known as *Schönflies displacements* [10.1]. The challenge that robot designers face is therefore one of *uncertainty* in the specific task that the robot will be required to execute. Design criteria have been devised to help the designer cope with uncertainty, as discussed herein.

10.1 The Robot Design Process

Given a family of tasks that constitute the *functional requirements* in the design process, besides more-detailed *design specifications*, the role of the designer consists in

producing a robot that will meet all the requirements and specifications. The various stages in the robot design job at hand are intended to:

1. determine the *topology* of the kinematic chain underlying the mechanical structure. Under this item we consider first the robot type: serial, parallel or hybrid. Then, a decision is to be made on the layout of the various *subchains* in terms of the type of joints, most commonly, revolute and prismatic. Recently, one additional type has been recognized to be equally useful, the Π -joint, coupling two links under relative translation by means of two other links undergoing identical angular displacements, although about different parallel axes. The four links form a parallelogram four-bar linkage [10.2];
2. determine the *geometric dimensions* of the various links defining the *robotic architecture*, as required to fill a table of *Denavit–Hartenberg parameters* [10.3] so as to satisfy workspace requirements. Although these parameters are usually understood to include the joint variables, these variables do not affect the *robot architecture*; they determine instead the *robot posture*;
3. determine the structural dimensioning of the various links and joints, as needed to meet static load requirements, where load includes both forces and moments – wrenches – under either the most demanding or the most likely operation conditions, depending on the design philosophy adopted at the outset;
4. determine the structural dimensioning of the various links and joints, as needed to meet dynamic load requirements, where loads are inertia effects of links and manipulated object;
5. determine the elastodynamic dimensioning of the overall mechanical structure, including the actuator dynamics, to avoid a specific spectrum of excitation frequencies under either the most demanding or the most likely operation conditions;
6. select the actuators and their mechanical transmissions for the operation conditions adopted at the outset to cope with task uncertainty.

The above stages can be performed sequentially, in the order given above: (i) first, the topology is determined based on the family of tasks specified at the outset and the *shape* of the workspace, as discussed in Sect. 10.2.2; (ii) the link geometry is defined based on the workspace requirements, which include the *maximum reach*, and the topology defined in stage 1; (iii) with the link geometry thus defined, the structural dimensioning of links and joints (unless the robot under design is parallel, which does not fall within the scope of this chapter, all joints are actuated) is undertaken, so as to support the static loads assumed at the outset; (iv)

with the links and joints dimensioned for static-load conditions, the link centers of mass and link inertia matrices are determined for a preliminary evaluation of the motor torque requirements (this evaluation is preliminary in that it does not consider the dynamic load brought about by the actuators; this load can be significant, even in the case of parallel robots, which can have all their motors fixed to the robot base); (v) with the links assumed rigid, joint stiffness is assumed, based on experience or using data from a similar robot, which then leads to an elastodynamic model whose natural modes and frequencies can be determined at a selected set of robot postures (dynamic behavior of the structure is dependent on robot posture) by means of scientific code such as Matlab or computer-aided engineering (CAE) code such as Pro/Engineer or ANSYS; and (vi) if the frequency spectrum of the robot structure is acceptable, the designer can continue to motor selection; otherwise, a redimensioning is required, which means returning to stage 3.

Even though a design cycle can be completed as outlined above, the designer must now incorporate into the elastodynamic model the structural and inertial data provided by the motor manufacturer. This requires a return to stage 5 and a new elastodynamic analysis. It is thus apparent that the robot design process has one element in common with engineering design in general: both are iterative and open-ended [10.4]. Remarkably, however, the various items driving each design stage are, to a large extent, independent of each other, e.g., topology and geometry can be determined independently from motor selection. Obviously, all issues interact in the overall design process, but, within certain design specifications, the various items do not contradict each other, as to warrant a multiobjective design approach. That is, the optimum design of serial robots can be accomplished fairly well by means of a sequence of single-objective optimization jobs. Again, the results of the last stage, motor selection, must be integrated into an overall mathematical model to test the overall performance. One reference addressing practical optimization issues in the conceptual design of industrial robots is [10.5].

Only when the physical limits of components have been exhausted may a radical redesign requiring a return to stage 1 be warranted. This is the case with **SCARA** systems. Current industrial topologies of these robots are usually of the serial type, with some exceptions, like the *Konig* and *Hartman RP-AH* series robots with parallel architecture [10.6], which feature two serial **SCARA** systems sharing one common end-effector. The quest for shorter cycle times, as for an industry test cycle (see Sect. 10.2.1), has prompted the industry to look for

alternatives to serial architectures. This is how ABB Robotics is currently marketing a parallel robot, the *FlexPicker*, built upon *Clavel's* Delta robot [10.7], to which a fourth axis has been added in series with the first three. The latter are laid out in a symmetric, parallel architecture that enables Delta to produce pure translations of its moving platform. The shortest cycle time reported by Adept Technology is 420 ms for a payload of 2 kg (with the Adept Cobra s600, a serial robot) but other manufacturers claim even shorter times.

This chapter is organized according to the various stages of the robot design process outlined earlier. Noting that topology selection and geometric dimensioning are tightly coupled in the kinematic design process, we

first begin with an examination of workspace criteria: we review methods for determining the topology of the kinematic chain, followed by the geometric dimensions so as to satisfy workspace requirements. We then review in detail the various criteria developed for characterizing a robot's manipulating capability, focusing on quantitative notions of dexterity based on both kinematic and dynamic models. We then examine methods for structural dimensioning of the links and joints so as to meet both static and dynamic load requirements. Finally, we discuss elastodynamic dimensioning, and actuator and gear sizing, taking into account properties such as the natural frequency of the robot, and force and acceleration capability requirements.

10.2 Workspace Criteria

The most obvious consideration in designing a robot is that its workspace has a set of *required characteristics*. This is a fundamental problem in classical mechanism design, and raises the obvious question of how a user can specify those characteristics.

Issues to consider here pertain, mostly, to what *Vijaykumar et al.* [10.8] termed the *regional structure* of a manipulator. This applies to manipulators with a *decoupled architecture*, whose last three revolutes have concurrent axes, thereby forming a *spherical wrist*, the point of concurrency being the *wrist center*. The manipulation task of architectures of this kind thus allows for a *decoupling* of the positioning and the orientation subtasks: the regional structure, consisting of the first three joints, is first postured so as to locate the center of its wrist at a specified point $C(x, y, z)$; then, the *local structure*, i. e., the wrist, is postured so as to make the end-effector (EE) attain a specified orientation with respect to a frame fixed to the base, given by a rotation matrix.

Most algorithms reported in the literature to determine the workspace of a given robot refer to the workspace of the regional structure. Here, we should distinguish between the workspace of the kinematic chain, regardless of the physical implementation of the chain, and that of the physical robot. In the former, all revolute joints are capable of unlimited rotations about their axes; in the latter, joint limits are needed, for example, to avoid wire entanglement. In the early stages of robot design, joint limits need not be considered, the workspace thus exhibiting symmetries that are proper of the type of joints of the regional structure. If the first joint is a revo-

lute, the workspace has an axis of symmetry, namely, the axis of this revolute joint; if the first joint is prismatic, the workspace has an extrusion symmetry, with the direction of extrusion given by the direction of motion of this joint. As prismatic joints are infinitely extensive, so is the kinematic workspace of a robot with a prismatic joint. The kinematic workspaces of robots with prismatic joints are usually displayed for a finite portion of this workspace.

In the case of parallel robots, to be studied in full detail in Chap. 14, the regional structure is elusive, in general. The usual practice when displaying the workspace for these robots is to assume a constant orientation of the moving plate, the counterpart of the EE of serial robots [10.9]. A common architecture of parallel robots, which arises quite naturally in the design process, entails identical legs symmetrically placed both on the base platform and on the moving platform. Each leg is, in turn, a serial kinematic chain with one or two active joints, all others being passive. The workspace of this kind of robots also exhibits certain symmetries, but no axial symmetry. The symmetries are dictated by the number of legs and the types of actuated joints.

Coming back to serial robots, the workspace can be defined by an envelope that is essentially of one of two types, either a manifold or a surface that is smooth *almost everywhere*, i. e., smooth everywhere except for a set of points of *measure zero* in the Lebesgue sense [10.10]. Broadly speaking, a set of measure zero on a surface is a curve, e.g., a meridian on a sphere, or a set of isolated points on a line, e.g., the set of rational numbers on the real line. A paradigm for this second kind of workspace

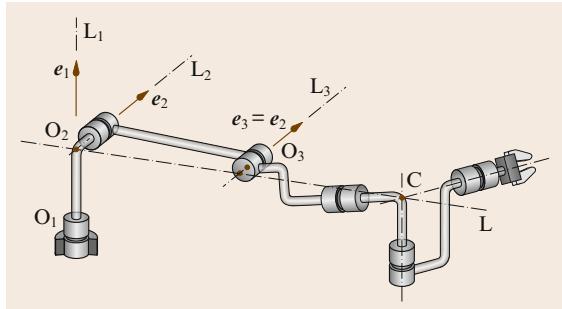

Fig. 10.1 A Puma robot in a fully stretched posture (after [10.11])

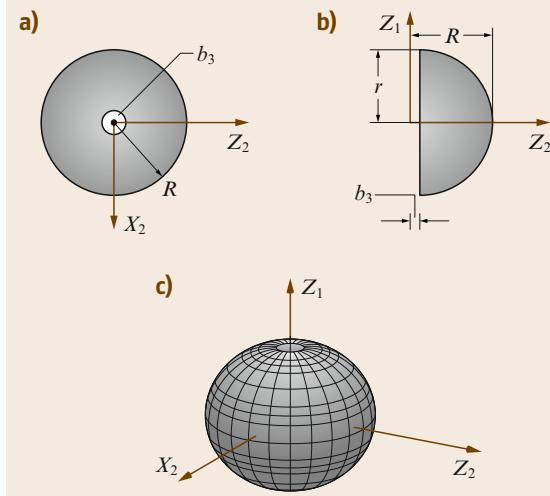

Fig. 10.2a–c The workspace of a Puma robot (after [10.11])

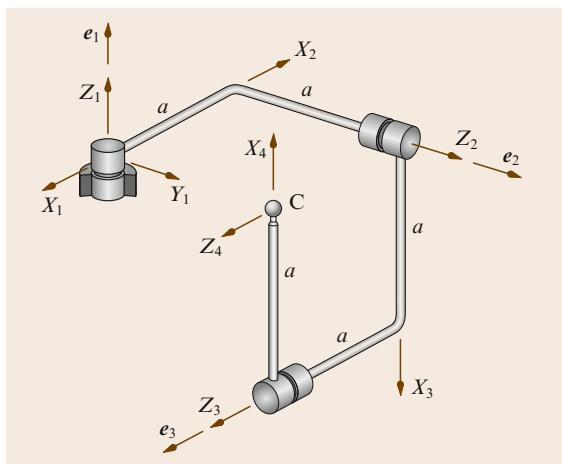

Fig. 10.3 An orthogonal three-revolute robot (after [10.11])

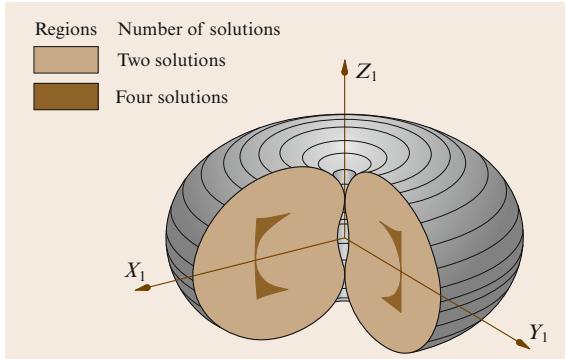

Fig. 10.4 The workspace of the orthogonal robot of Fig. 10.3 (after [10.11])

is that of the Puma robot, whose kinematic chain is displayed in Fig. 10.1. In this figure, the regional and the local structures are clearly distinguished, the former being *fully extended*. The workspace of this robot is obtained upon locking all joints but the second, when the robot is in the posture shown in Fig. 10.1. Then, the second joint is fully rotated about its axis, the center C of the wrist then describing a circle of radius R equal to the distance of C from the line L_2 , the plane of the circle being normal to this line and lying a distance b_3 from the axis L_1 of the first joint. This distance is known as the *shoulder offset*. Now, with all joints locked again, but this time with the first joint unlocked, the robot is turned as a rigid body about L_1 . The result is the toroid of Fig. 10.2. Notice that the solid enclosed by this surface is the result of the Boolean operation $\delta - \mathcal{C}$, where δ is the sphere of radius R centered at point O_2 of Fig. 10.1, while \mathcal{C} is the infinite cylinder of radius b_3 and axis L_1 , which appears as Z_1 in Fig. 10.2. It is noteworthy that, although this workspace can be readily generated by a simple Boolean operation, it cannot possibly be generated by an implicit function of the form $f(x, y, z) = 0$ because the surface is not a manifold.

Robots with manifold workspaces are not common in industry. We display in Fig. 10.3 an architecture for the regional structure of a six-axis decoupled robot, with its neighboring axes mutually orthogonal and at the same distance a from each other. The common normals to the two pairs of axes, X_2 and X_3 , also lie at the same distance a , as do X_4 from X_3 and C from Z_3 . Point C is the center of the spherical wrist, the latter not being included in the figure. The workspace of this robot admits a representation of the form $f(x, y, z) = 0$ [10.11], which produces the manifold workspace of Fig. 10.2. The shaded internal region

of the workspace includes all points admitting four real inverse-kinematics solutions, all other points admitting only two.

Given that any point of the workspace boundary represents a positioning singularity – different from an orientation singularity – manipulators with workspace boundaries that are not manifolds exhibit double singularities at the edges of their workspace boundary, which means that at edge points the rank of the robot Jacobian becomes deficient by two. At any other point of the workspace boundary the rank deficiency is by one.

Design rules based on the *shape* of the workspace can now be drawn.

1. If the workspace required is axially symmetric and finite, use a serial robot with a regional structure composed of revolute joints only.
2. If the workspace required is prismatic and *infinite*, use a serial robot with regional structure having one first joint of the prismatic type. Here, *infinite* is used in a restricted sense, meaning much larger in one direction than the others. Moreover,
 - if one direction is required to be much larger than the others, then practical implementations of prismatic joints are available in the form of rails either overhead, thereby giving rise to *gantry* robots, or on the floor.
 - if two directions are required to be much larger than the other, then use a wheeled mobile robot carrying a manipulator on top. A famous realization of this concept is the National Aeronautical and Space Agency's (**NASA**) *Sojourner* used in the *Pathfinder* mission to Mars in 1997.
3. If axial symmetry is not required, but rather a workspace with various coplanar axes of symmetry, similar to those of regular polygons, use a parallel robot.

10.2.1 Reaching a Set of Goal Frames

Closely related to the problem of workspace specification is that of task specification. In mechanism design it is customary to specify a set of coordinate frames in space, and to design a mechanism with an a priori specified topology that can visit these frames. An order in which the frames must be reached may be given. In the event that not all of the frames are reachable, then one may seek a mechanism that comes *closest*, in some suitable sense, to the specified frames. The lit-

erature on this classical mechanism design problem is vast – see, e.g., [10.1, 12, 13] and the references cited therein. Some further remarks in connection with this goal-frame approach to robot dimensioning are noteworthy.

1. Reaching *exactly* the desired frames may not always be desired or possible: in some cases it is better to use an optimization approach that allows for solutions that will visit the desired poses within a minimum error (provided that an error norm can be suitably engineered, of course).
2. It has been claimed [10.9] that interval analysis allows not only a discrete set of desired poses but also a full six-dimensional (6-D) workspace to be met while taking into account manufacturing errors.
3. The branching problem occurring in single-degree-of-freedom mechanisms may also occur in robot design: a design solution based on via points may indeed visit the prescribed poses, but not all of these may be reachable within the same assembly mode. This problem is exacerbated in the design of serial robots, as a six-degree-of-freedom, revolute-coupled robot may admit up to 16 distinct postures – branches – for one given EE pose [10.14, 15].
4. While a robot designed to visit a set of prescribed poses via its end-effector will be able to visit that set, we should not forget that the purpose of using robots is first and foremost to be able to perform not one single task, but rather a family of tasks. In this light, the set of poses for which a robot is designed might as well be a task that is *representative* of that family.

In connection with remark 4 above, we can cite the design or evaluation of **SCARA** systems. A **SCARA** system is a four-degree-of-freedom serial robot capable of tasks that lie within the *Schönflies* subgroup of the group of rigid-body displacements [10.16, 17], namely the set of three-dimensional displacements augmented with a rotation about an axis of fixed direction. In these systems, the task at hand is given by two vertical segments joined by one horizontal segment. Moreover, the length of the vertical segments is 25.0 mm, that of the horizontal segment being 300.0 mm. While the end-effector is traversing the horizontal segment, moreover, it should rotate about a vertical axis through an angle of 180°. This task specification, which has been adopted by **SCARA** manufacturers, does not indicate how to negotiate the corners, which is left to the imagination of the robotics engineer.

10.2.2 Workspace Volume and Topology

Reachable and Dexterous Workspace

Beginning with the early work of *Roth* [10.18], there have been many studies on the relationship between manipulator kinematic geometry and its workspace. Most studies have focused on a classification of the workspace into two components, the *reachable* and the *dexterous* workspace [10.19]. Given a reference point P attached to a manipulator end-effector, such as the center of the spherical wrist, or a point on the EE, the reachable workspace is defined to be the set of points in physical space that can be reached by P . The dexterous workspace, on the other hand, is the set of points that can be reached by P with arbitrary EE orientations.

The early literature on workspace focuses on numerical and algebraic methods to characterize these workspaces. Reachable and dexterous workspaces have been analyzed using numerical techniques by *Kumar* and *Waldron* [10.19], *Yang* and *Lee* [10.20], and *Tsai* and *Soni* [10.21], among others. The advantage of these schemes over algebraic approaches is that kinematic constraints can be readily included. More-general design principles or insights, however, are more difficult to come by using these techniques. Among the algebraic approaches to workspace characterization, a topological analysis of robot workspace is given by *Gupta* and *Roth* [10.22] and *Gupta* [10.23]; here the concept of workspace holes and voids is defined, and conditions for their existence are identified. The shape of the reachable and dexterous workspaces is also analyzed as a function of P .

Further studies of workspace analysis were reported by *Freudenstein* and *Primrose* [10.24] and by *Lin* [10.25], where precise relationships between kinematic and workspace parameters are developed, and a class of three-joint manipulators is optimized for workspace volume. A more general analysis of workspace optimization is given in *Vijaykumar* et al. [10.8]. Performance criteria for manipulators are defined here in terms of the dexterous workspace; given that a manipulator satisfies certain constraints on its Denavit–Hartenberg parameters, it is shown that the optimal 6R design is the elbow manipulator.

A typical design of robot regional architecture is of the *orthogonal type*, consisting of one revolute of the vertical axis and two revolutes of the horizontal axes, one of which intersects the vertical axis. Moreover, the most common architecture includes intermediate and distal links of identical lengths. The workspace

of this architecture is thus a sphere of radius equal to twice that common link length. The volume of this workspace is thus determined by the length in question. As shown by *Yoshikawa* [10.26], the workspace of the two-link planar manipulator defined by the last two links of the foregoing regional architecture is of maximum area for a prescribed reach and equal link lengths. As a result, the volume of the same regional architecture is similarly of maximum volume for a prescribed reach.

Differential-Geometric Workspace Characterization

Workspace can also be approached from a differential-geometric perspective, by regarding the configuration space of a robotic end-effector frame as a subset of the special Euclidean group $\text{SE}(3)$. An important physical consideration in defining the workspace volume of spatial mechanisms is that it should not depend on the choice of fixed reference frame. Less obvious but just as important is the requirement that the volume should not depend on which point of the last link the end-effector frame is fixed to. This last condition has the following physical significance: if the EE were enlarged or shrunk, then the robot would have the same workspace volume. The workspace volume of a robot therefore depends only on the joint axes.

The workspace volume of a robot is defined by regarding $\text{SE}(3)$ as a Riemannian manifold, so that the workspace volume is simply the volume of the image of the forward kinematic map f with respect to the volume form on $\text{SE}(3)$. It is known that $\text{SE}(3)$ has a bi-invariant volume form, that is, the notion of volume is invariant with respect to the choice of both the fixed (base) and moving (end-effector) frames – see, e.g., *Loncaric* [10.27]. *Paden* and *Sastry* [10.28] provide the following visualization for this volume form: Suppose an airplane is restricted to move within a cube of airspace of length 1 km on a side. At each point within this cube the airplane can point itself anywhere in a 4π solid angle and roll 2π about the direction it is pointing. The orientation volume at such a point is $4\pi \times 2\pi = 8\pi^2 \text{ rad}^3$. Multiplying by the positional volume one obtains $8\pi^2 \text{ rad}^3 \text{ km}^3$ for the volume of the free configuration space of the aircraft.

This depiction is the notion of workspace volume used for robots; it has the advantage of being able to trade off orientation freedom for positional freedom smoothly, unlike the popular notion of dexterous workspace. Note that the actual numerical value one obtains will depend on the choice of length scale for physical space; this

in itself does not pose a serious problem for workspace volumes, as long as the same length scale is maintained when comparing different workspaces.

In [10.28] Paden and Sastry show that the optimal 6R manipulator that maximizes the workspace volume subject to a kinematic length constraint is the

elbow manipulator. This result is consistent with the earlier finding of Vijaykumar et al. [10.8], but the authors employ the geometric framework outlined above. Moreover, the results are obtained without some of the a priori assumptions on the kinematic structure made by Vijaykumar.

10.3 Dexterity Indices

10.3.1 Local Dexterity for Open Chains

Dexterity can be defined as the ability to move and apply forces and torques in arbitrary directions with equal ease, the concept thus belonging to the realm of *kinetostatics*, which is the study of the interplay between *feasible twists* and *constraint wrenches* in multibody mechanical systems under *static conservative conditions*. Here, twist is the six-dimensional array of velocity variables of a rigid body, involving three components of a landmark-point velocity and three of angular velocity; wrench, in turn, is the six-dimensional array of static variables acting on a rigid body, three accounting for the resultant force applied at the same landmark point and three for the concomitant moment acting on the same body.

Salisbury and Craig [10.29] introduced the concept of dexterity when working on the design of articulated hands. At issue is the way in which input joint velocity errors propagate to the output velocities of each fingertip. To illustrate this concept, let $\mathbf{J}(\boldsymbol{\theta})$ denote the Jacobian of the forward kinematic map, i. e.,

$$\mathbf{t} = \mathbf{J}(\boldsymbol{\theta})\dot{\boldsymbol{\theta}} \quad (10.1)$$

in which $\boldsymbol{\theta}$ and $\dot{\boldsymbol{\theta}}$ denote the vectors of joint variables and joint rates, respectively, while \mathbf{t} is the EE *twist*, defined, in turn, as,

$$\mathbf{t} = \begin{pmatrix} \boldsymbol{\omega} \\ \dot{\mathbf{p}} \end{pmatrix} \quad (10.2)$$

with $\boldsymbol{\omega}$ denoting the angular velocity of the EE and $\dot{\mathbf{p}}$ the velocity of the *operation point* P of the EE, at which the task is specified.

Let n and m be the dimensions of the joint space \mathcal{J} and of the end-effector configuration space \mathcal{G} , respectively, where $n \geq m$. Now, the image under $\mathbf{J}(\boldsymbol{\theta})$ of the unit hypersphere $\{\boldsymbol{\theta} \mid \|\dot{\boldsymbol{\theta}}\| = 1\}$ is an ellipsoid in the space of twists \mathbf{t} . Indeed, if we assume for concreteness that $n = m$ – the more general case $n \neq m$ can also be accommodated, but we refrain from including it here in

order to streamline the discussion that follows – then the *polar decomposition* [10.30] of \mathbf{J} takes the form

$$\mathbf{J} = \mathbf{R}\mathbf{U} = \mathbf{V}\mathbf{R}, \quad (10.3)$$

where \mathbf{R} is an orthogonal matrix, whether proper or improper – if proper, then \mathbf{R} represents a rotation; if improper, then a reflection – while \mathbf{U} and \mathbf{V} are symmetric and at least positive-semidefinite matrices. Moreover, if \mathbf{J} is nonsingular, then \mathbf{U} and \mathbf{V} are both positive-definite and the decomposition is *unique*. In any event, these two matrices are related by a similarity transformation, namely,

$$\mathbf{V} = \mathbf{R}\mathbf{U}\mathbf{R}^\top \quad (10.4)$$

which means that the two matrices have identical real nonnegative eigenvalues. These eigenvalues are nothing but the *singular values* of \mathbf{J} . Indeed, if $\boldsymbol{\Sigma}$ denotes the diagonal representation of \mathbf{U} , with its i -th diagonal entry σ_i denoting the i -th eigenvalue of \mathbf{U} , or of \mathbf{V} for that matter, then the *eigenvalue decomposition* of \mathbf{U} is

$$\mathbf{U} = \mathbf{E}\boldsymbol{\Sigma}\mathbf{E}^\top \quad (10.5)$$

in which \mathbf{E} is the orthogonal matrix whose i -th column \mathbf{e}_i represents the i -th eigenvector of \mathbf{U} , while $\mathbf{R}\mathbf{e}_i$ denotes the i -th eigenvector of \mathbf{V} . Now, if we substitute the above decomposition of \mathbf{U} into the polar decomposition of \mathbf{J} , (10.3), we obtain

$$\mathbf{J} = \mathbf{R}\mathbf{E}\boldsymbol{\Sigma}\mathbf{E}^\top \quad (10.6)$$

which is nothing but the *singular-value decomposition* of \mathbf{J} , the diagonal entries of $\boldsymbol{\Sigma}$ being the *singular values* of \mathbf{J} .

Now we can provide a geometric interpretation of the forward kinematic mapping of (10.1), for we can rewrite this mapping in the form

$$\mathbf{t} = \mathbf{R}\mathbf{U}\dot{\boldsymbol{\theta}}. \quad (10.7)$$

At nonsingular postures, the Jacobian is invertible, and hence so is \mathbf{U} , whence the foregoing expression leads to

$$\dot{\boldsymbol{\theta}} = \mathbf{U}^{-1}\mathbf{R}^\top\mathbf{t}. \quad (10.8)$$

Furthermore, if we assume that all the components of both the twist array \mathbf{t} and the joint-rate array $\dot{\theta}$ have the same physical units, which is the case for purely positioning or purely orienting manipulators with only revolute joints, then we can take the Euclidean norm of both sides of (10.8), thereby obtaining

$$\|\dot{\theta}\|^2 = \mathbf{t}^\top \mathbf{R} \mathbf{U}^{-2} \mathbf{R}^\top \mathbf{t}. \quad (10.9)$$

Moreover, if we substitute \mathbf{U} by its eigenvalue decomposition, (10.5), in the above equation, we obtain

$$\|\dot{\theta}\|^2 = \mathbf{t}^\top \mathbf{R} \mathbf{E} \boldsymbol{\Sigma}^{-2} \mathbf{E}^\top \mathbf{R}^\top \mathbf{t}$$

and, if we let

$$\mathbf{v} = \mathbf{E}^\top \mathbf{R}^\top \mathbf{t} \quad (10.10)$$

then the above expression for $\|\dot{\theta}\|^2$ becomes

$$\mathbf{v}^\top \boldsymbol{\Sigma}^{-2} \mathbf{v} = \|\dot{\theta}\|^2. \quad (10.11)$$

Now, if the i -th component of \mathbf{v} is denoted by v_i , for $i = 1, \dots, n$, and we look at the mapping of the unit ball in \mathcal{J} , $\|\dot{\theta}\|^2 = 1$, (10.11) leads to

$$\frac{v_1}{\sigma_1^2} + \frac{v_2}{\sigma_2^2} + \dots + \frac{v_n}{\sigma_n^2} = 1 \quad (10.12)$$

which is the canonical equation of an ellipsoid of semiaxes $\{\sigma_i\}_1^n$ in the \mathcal{J} -space, i. e., the space of Cartesian velocities, or twists of the EE. Notice that the ellipsoid in question takes its canonical form when represented in a coordinate frame of axes oriented in the directions of the eigenvectors of \mathbf{U} . The equation of the ellipsoid along the original axes in \mathcal{J} -space is, of course,

$$\mathbf{t}^\top \mathbf{R} \mathbf{E} \boldsymbol{\Sigma}^{-2} \mathbf{E}^\top \mathbf{R}^\top \mathbf{t} = 1. \quad (10.13)$$

In summary the unit ball in joint space is mapped by the Jacobian-inverse \mathbf{J}^{-1} into an ellipsoid whose semiaxes are the singular values of \mathbf{J} . That is, \mathbf{J} *distorts* the unit ball in the joint-rate space into an ellipsoid in the EE-twist space. Hence, a measure of the quality of motion and force transmission of the robotic architecture from the joints to the EE is given by the above distortion; *the smaller the distortion, the higher the quality of the transmission.*

A measure of the Jacobian-induced distortion can thus be defined as the ratio of the largest σ_M to the smallest σ_m singular values of \mathbf{J} , which is nothing but the *condition number* κ_2 of \mathbf{J} based on the matrix 2-norm [10.31], i. e.,

$$\kappa_2 = \frac{\sigma_M}{\sigma_m}. \quad (10.14)$$

Actually, (10.14) is only one possibility of computing the condition number of \mathbf{J} , or of any $m \times n$ matrix for that matter, and certainly not the most economical. Notice that this definition requires knowledge of the singular values of the Jacobian. However, computing the singular values of a matrix is as computationally intensive as computing eigenvalues, with the added cost of the polar decomposition; the combined operation is slightly less expensive than the singular-value decomposition [10.32]. The most general definition of condition number, for $n \times n$ matrices, is [10.31]

$$\kappa(\mathbf{A}) = \|\mathbf{A}\| \|\mathbf{A}^{-1}\|. \quad (10.15)$$

As stated above, the expression (10.14) is obtained when the matrix 2-norm is adopted in (10.15). The matrix 2-norm is defined as

$$\|\mathbf{A}\|_2 \equiv \max_i \{\sigma_i\}. \quad (10.16)$$

If, on the other hand, the *weighted matrix Frobenius norm* is adopted, which is defined as

$$\|\mathbf{A}\|_{\text{F}} \equiv \sqrt{\frac{1}{n} \text{tr}(\mathbf{A} \mathbf{A}^\top)} \equiv \sqrt{\frac{1}{n} \text{tr}(\mathbf{A}^\top \mathbf{A})} \quad (10.17)$$

then, apparently, the computation of the singular values can be obviated. When the weight $1/n$ is omitted in the above definition, the standard Frobenius norm is obtained. Notice, however, that the weighted Frobenius norm is more significant in engineering, for it does not depend on the number of rows and columns of the matrix at hand. The weighted Frobenius norm, in fact, yields the root-mean-square (rms) value of the set of singular values.

The *Frobenius condition number* κ_{F} of the Jacobian \mathbf{J} , based on the matrix Frobenius norm, is then

$$\begin{aligned} \kappa_{\text{F}}(\mathbf{J}) &= \frac{1}{n} \sqrt{\text{tr}(\mathbf{J} \mathbf{J}^\top)} \sqrt{\text{tr}[(\mathbf{J} \mathbf{J}^\top)^{-1}]} \\ &= \frac{1}{n} \sqrt{\text{tr}(\mathbf{J}^\top \mathbf{J})} \sqrt{\text{tr}[(\mathbf{J}^\top \mathbf{J})^{-1}]} . \end{aligned} \quad (10.18)$$

One more important difference between the two forms of computing the matrix condition number is worth pointing out: $\kappa_2(\cdot)$ is not an *analytic function* of its matrix argument, while $\kappa_{\text{F}}(\cdot)$ is. Hence, the condition number based on the Frobenius norm can be applied to great advantage in robot architecture design, as $\kappa_{\text{F}}(\cdot)$ is differentiable and lends itself to gradient-dependent optimization methods, which are much faster than direct methods based only on function evaluations. In robot control, which requires real-time computations, $\kappa_{\text{F}}(\cdot)$ also offers practical advantages, for its computation

obviates the knowledge of the singular values, only requiring a matrix inversion, which is a rather simple task.

The significance of the condition number in robot design and control can be best understood if we recall that the concept stems from numerical analysis in connection with the solution of the linear system of equations (10.1) for $\dot{\theta}$. Given that J is a function of both the architecture parameters and the posture variables θ , J is known only to within the error with which those quantities are known. Further, let the architecture parameters, namely, the constant values in the Denavit–Hartenberg parameter list, be stored in an array p . Both p and θ are known up to measurement errors δp and $\delta\theta$, respectively. Moreover, the twist t is input into the control software of the robot with an unavoidable error δt .

In solving (10.1) for $\dot{\theta}$ with floating-point arithmetic, the computed value is contaminated with a roundoff error $\delta\dot{\theta}$. The *relative error* in the computed $\dot{\theta}$ is related to the relative errors in the architecture parameters and posture variables by the relation [10.31]

$$\frac{\|\delta\dot{\theta}\|}{\|\dot{\theta}\|} \leq \kappa(J) \left(\frac{\|\delta p\|}{\|p\|} + \frac{\|\delta\theta\|}{\|\theta\|} + \frac{\|\delta t\|}{\|t\|} \right), \quad (10.19)$$

where p and θ represent the (unknown) actual values of these vectors and t the nominal value of the twist.

Nevertheless, the foregoing discussion applies to tasks involving either positioning or orientation, but not both. Most frequently, robotic tasks involve both positioning and orientation, which leads to Jacobian matrices with entries bearing disparate physical units, the consequence being that the Jacobian singular values have disparate units as well. Indeed, singular values associated with positioning bear units of length, whereas those associated with orientation are dimensionless. As a consequence, it is impossible to either order all singular values from smallest to largest or to add them all.

To cope with the issue of disparate units in the Jacobian entries, and to allow for the computation of the Jacobian condition number, the concept of *characteristic length* has been proposed [10.11]. The characteristic length L has been defined as the length by which the entries of the Jacobian with units of length are to be divided to render the Jacobian condition number a minimum at an optimum posture. This definition, while sound, lacks an immediate geometric interpretation, which has made its adoption in the robotics community difficult. In order to provide for a geometric interpretation, the concept of *homogeneous space* was recently introduced [10.33]. Using this concept, the robot architecture is designed in a *dimensionless space*, with points whose coordinates are dimensionless real numbers. In this way, the

six Plücker coordinates [10.34] of lines are all dimensionless, and hence the columns of the robot Jacobian matrix, comprising the Plücker coordinates of the revolute axes, are dimensionless as well. As a consequence, the Jacobian singular values are all dimensionless, and the Jacobian condition number can be defined. Once the robotic architecture has been designed for minimum condition number, under geometric constraints on link-length ratios and angles between neighboring revolute axes, for example, the maximum reach of the robot can be calculated. The maximum reach r will thus be a dimensionless quantity. When this quantity is compared with the prescribed maximum reach R , with units of length, the characteristic length is computed as the ratio $L = R/r$.

10.3.2 Dynamics-Based Local Performance Evaluation

Since motions are caused by forces and torques acting on rigid bodies, it seems reasonable to formulate performance indices that take into account the inertial properties of the mechanism. *Asada* [10.35] defines the *generalized-inertia ellipsoid* (GIE) as the ellipsoid defined by the product $G = J^{-T} MJ^{-1}$, where M denotes the inertia matrix of the manipulator. This ellipsoid is that with semiaxes given by the singular values of the foregoing product. *Yoshikawa* [10.36], in turn, defines a corresponding dynamic manipulability measure as $\det[J M^{-1} (J M^{-1})^T]$. Physically these concepts represent two distinct phenomena. Suppose the robot is viewed as an input–output device which, given a joint torque, produces an acceleration at the end-effector. Yoshikawa’s index measures the uniformity of this torque–acceleration gain, whereas Asada’s GIE characterizes the inverse of this gain. If a human operator were holding the end-effector and attempting to move it about, the GIE would measure the resistance of the robot to this end-effector motion.

Other measures that attempt to capture robot performance as a function of the dynamics can be cited: *Voglewede* and *Ebert-Uphoff* [10.37] propose performance indices based on joint stiffness and link inertia, with the aim of establishing a distance to singularity for any robot posture, while *Bowling* and *Khatib* [10.38] propose a general framework for capturing the dynamic capability of a general robot manipulator that includes the velocity and acceleration characteristics of the end-effector, taking into account factors such as torque and the velocity limits of the actuators.

10.3.3 Global Dexterity Measures

The above measures are local in the sense that they characterize the dexterity of a robot at a given posture. Local measures are useful for applications ranging from redundancy resolution to workpiece positioning, but for design applications a global measure may be more desirable. One straightforward way of extending local measures to global ones is to integrate them over the allowable joint space. In [10.39] *Gosselin* and *Angeles* integrate the Jacobian condition number over the workspace to define a global measure, thereby producing a *global conditioning index*. For the simpler cases of planar positioning and spherical manipulators, the global conditioning index was found to coincide with its local counterpart.

10.3.4 Closed-Chain Dexterity Indices

The formulation of dexterity for closed chains presents a number of subtleties. The first obvious difference is that the joint configuration space of a closed chain will no longer be a flat space; in the general case it will be a curved multidimensional surface embedded in a higher-dimensional (typically flat) space. Also, dual to the open chain case, the forward kinematics for closed chains is generally more difficult to solve than the inverse kinematics, with the possibility of multiple solutions. Another important difference is that only a subset of the joints may be actuated, and that the number of actuated joints may even exceed the mechanism's kinematic degrees of freedom.

Several coordinate-based formulations for closed-chain dexterity have been proposed for specific mechanisms [10.40] and for cooperating robot systems whose joints are all assumed to be actuated [10.41, 42], at least some of which have led to apparently paradoxical results [10.43, 44]. Because of the nonlinear characteristics unique to closed-chain mechanisms discussed above, particular care must be exercised in formulating coordinate-based dexterity measures.

Another recent line of work has attempted a coordinate-invariant differential-geometric formulation of

dexterity for closed chains. In this framework the joint and end-effector configuration spaces are regarded as Riemannian manifolds with an appropriate choice of Riemannian metric, with the choice of joint space metric reflecting the characteristics of the joint actuators. The previous notions of ellipsoid developed for serial chains can be extended to general closed chains, containing both passive and active joints, and possibly redundantly actuated [10.45, 46].

10.3.5 Alternative Dexterity-Like Measures

The various definitions of dexterity discussed above all refer to the same qualitative feature of the ability of a robot to move and apply forces in arbitrary directions. A different viewpoint is taken in the work of *Liégeois* [10.47] and *Klein* and *Huang* [10.48], where dexterity is quantified in terms of joint-range availability. The driving motivation here lies in that most robots have joint limits; therefore, one should minimize the possibility of a joint reaching a stop.

Hollerbach [10.49] takes an alternative approach to designing a redundant 7R manipulator, by considering: (a) elimination of internal singularities, (b) ability to avoid obstacles in the workspace; (c) the solvability of the kinematic equations, and (d) mechanical constructability. Based on these four criteria, he derived a particular 7R design with the morphology of the human arm, i. e., composed of two spherical joints defining the shoulder and the wrist plus an intermediate revolute playing the role of the elbow. Now, while a redundant architecture should remain fully capable of performing six-DOF tasks upon locking one joint, the architecture reported in this reference may end up by losing this capability if the elbow joint is locked.

From a control perspective, *Spong* [10.50] shows that, if the inertia matrix of a manipulator has a vanishing Riemannian curvature, there exists a set of coordinates in which the equations of motion assume a particularly simple form. The curvature of the inertia matrix also reflects the sensitivity of the dynamics to certain robot parameters. Minimizing the curvature, therefore, is another possible criterion for robot design.

10.4 Other Performance Indices

10.4.1 Acceleration Radius

Another measure that attempts to capture the dynamic capabilities of a robotic manipulator is the *accelera-*

tion radius. Initially proposed by *Graettinger* and *Krogh* in [10.51], the acceleration radius measures the minimum acceleration capability of the end-effector, in arbitrary directions, for the given torque bounds on the

actuators. Specifically, given the dynamics equations for a serial chain in the form

$$\tau = M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} \quad (10.20)$$

in which M is the robot *mass matrix* – also known as the *inertia matrix* – in *joint space*, and $C(\theta, \dot{\theta})$ is the matrix mapping the joint-rate vector to the vector of Coriolis and centrifugal forces in the same space. Moreover, the actuators are assumed to have joint torque limits of the form

$$\tau_{\min} \leq \tau \leq \tau_{\max}, \quad (10.21)$$

where the lower and upper limits $\tau_{\min}, \tau_{\max} \in \mathbb{R}^n$ are constant or functions of the manipulator posture θ . The end-effector *twist rate*, denoted by \dot{t} , can be expressed as

$$\dot{t} = J(\theta)\ddot{\theta} + J(\theta, \dot{\theta})\dot{\theta}, \quad (10.22)$$

where $J(\theta, \dot{\theta})$ is the Jacobian time-derivative. The Jacobian J was introduced in (10.1).

Under the assumption that $J(\theta)$ is nonsingular, one can write

$$\ddot{\theta} = J(\theta)^{-1}\dot{t} - J(\theta)^{-1}J(\theta, \dot{\theta}). \quad (10.23)$$

Substituting the above expression into the dynamic equations (10.20) leads to

$$\tau(\theta, t, \dot{t}) = M'(\theta)\dot{t} + C'(\theta, t), \quad (10.24)$$

where

$$M'(\theta) = M(\theta)J(\theta)^{-1}$$

$$C'(\theta, t) = [C(\theta, t) - M(\theta)J(\theta)^{-1}J(\theta, t)]J^{-1}(\theta).$$

For a given state $(\theta, \dot{\theta})$, the linear torque bounds (10.21) now define a polytope in the twist-rate space. *Graettinger* and *Krogh* [10.51] define the acceleration radius to be the largest sphere centered at the origin that is contained in this polytope; the radius reflects the minimal guaranteed EE acceleration in arbitrary directions. This concept is applied to measure the EE acceleration capability of a manipulator, as well as to determine the actuator sizes for achieving a desired acceleration radius. *Bowling* and *Khatib* [10.38] generalize this concept to capture both force and acceleration capabilities of the end-effector, with a view to quantifying the worst-case dynamic performance capability of a manipulator.

10.4.2 Elastostatic Performance

Elastostatic performance refers to the robotic system's response to the applied load – force and moment, i. e.,

wrench – under static equilibrium. This response may be measured in terms of the *stiffness* of the manipulator, which determines the translation and angular deflections when the EE is subjected to an applied wrench.

Robot deflections have two sources: link and joint deflection. In the presence of long links, as in the space robot Canadarm2, link compliance is a major source of deflection. However, in the majority of today's serial robots, the main source of deflection occurs at the joints.

In this chapter, we assume that the manipulator links are rigid, and model the joints as linearly elastic torsional springs. The more complex problem of link flexibility is studied in detail in Chap. 13. That is, for the elastostatic model we base our analysis on the assumption that, under a positioning task, the joints are locked at a certain posture θ_0 , while the EE is subject to a perturbation wrench Δw that is balanced by an elastic joint torque $\Delta \tau$. Under these conditions, $\Delta \theta$ and $\Delta \tau$ obey the well-known linear relation

$$K \Delta \theta = \Delta \tau \quad (10.25)$$

in which K is the *stiffness matrix* in joint space at the given posture. Moreover, the matrix K is diagonal, with its entries equal to the torsional stiffnesses of the corresponding joints, K is therefore *posture independent*, i. e., constant throughout the whole robot workspace. Moreover, since all joints exhibit a finite, nonzero stiffness, K is invertible, its inverse C being termed the *compliance matrix*. We can thus express the inverse relation of (10.25) as

$$\Delta \theta = C \Delta \tau. \quad (10.26)$$

It should be apparent that $\Delta \theta$ and $\Delta \tau$ have an *incremental* nature, for both are measured from the equilibrium posture, at which $\Delta \tau$ and $\Delta \theta$ vanish.

On the issue of stiffness matrix, *Grifflis* and *Duffy* [10.52] proposed a mapping from an incremental rigid-body displacement Δx into an incremental wrench Δw that turned out to be nonsymmetric. The concept behind this mapping was formalized by *Howard* et al. [10.53] by means of Lie algebra. However, in the foregoing papers, Δx and Δw turn out to be incompatible in the sense that their reciprocal product does not yield incremental work – the point at which Δx is defined is distinct from that at which Δw is applied. For this reason, the array representation of the same mapping cannot be, properly speaking, termed a stiffness matrix.

For a constant magnitude of $\Delta \tau$, the deflection attains its maximum value in the direction of the eigenvector associated with the maximum eigenvalue of C

or, equivalently, with the minimum eigenvalue of \mathbf{K} , denoted by κ_{\min} . In terms of elastostatic performance, we aim to (a) make the maximum deflection a minimum, i.e., we want to maximize κ_{\min} , and (b) make the magnitude of the deflection $||\Delta\boldsymbol{\theta}||$ as insensitive as possible to changes in the direction of the applied load $\Delta\boldsymbol{\tau}$. This can be done by rendering κ_{\min} as close as possible to κ_{\max} . The first aim is associated with the stiffness constants, i.e., the higher the constants the lower the deflections. The latter, however, is associated with the concept of isotropy, the ideal case being when all the eigenvalues of \mathbf{K} are identical, which means that \mathbf{K} is isotropic. Due to the *pyramidal effect* of serial robots, in which downstream motors carry their upstream counterparts, the joint stiffness is bound to be largest for the proximal joints. Hence an isotropic stiffness matrix is impossible for serial robots.

Notice that (10.25) and (10.26) may also be formulated in the task space, i.e.,

$$\mathbf{K}_C \Delta\mathbf{x} = \Delta\mathbf{w}, \quad (10.27)$$

where $\Delta\mathbf{x} \equiv t\Delta t$, with Δt denoting a *small* time interval producing a correspondingly *small* change $\Delta\mathbf{x}$ in the pose of the EE. That is,

$$\Delta\mathbf{x} = \mathbf{J}\dot{\boldsymbol{\theta}}\Delta t = \mathbf{J}\Delta\boldsymbol{\theta} \quad (10.28)$$

which is a linear transformation of the joint-vector increment into the pose-increment vector. We show next that *the stiffness matrix is not frame invariant*. This means that, under the linear transformation from joint to Cartesian coordinates, *the stiffness matrix does not obey a similarity transformation*. For quick reference, we recall below the definition of similarity transformation: if $\mathbf{y} = \mathbf{L}\mathbf{x}$ is a linear transformation of \mathbb{R}^n into itself, and we introduce a change of vector basis, $\mathbf{x}' = \mathbf{A}\mathbf{x}$, $\mathbf{y}' = \mathbf{A}\mathbf{y}$, then \mathbf{L} changes to \mathbf{L}' , which is given by

$$\mathbf{L}' = \mathbf{A} \mathbf{L} \mathbf{A}^{-1}. \quad (10.29)$$

The above transformation of any vector of \mathbb{R}^n into another one of the same space, and of a matrix \mathbf{L} into \mathbf{L}' , as given by (10.29), is termed a *similarity transformation*. Notice that \mathbf{A} is guaranteed to be invertible, as it represents a change of coordinate frame.

Now, under the change of coordinates given by (10.28), (10.27) leads to

$$\mathbf{K}_C \mathbf{J} \Delta\boldsymbol{\theta} = \mathbf{J}^{-T} \Delta\boldsymbol{\tau}, \quad (10.30)$$

where we have used the kinetostatic relation [10.11]

$$\mathbf{J}^T \Delta\mathbf{w} = \Delta\boldsymbol{\tau}.$$

The exponent $-T$ denotes the transpose of the inverse or, equivalently, the inverse of the transpose. Upon multiplication of both sides of (10.30) by \mathbf{J}^T from the left, we end up with

$$\mathbf{J}^T \mathbf{K}_C \mathbf{J} \Delta\boldsymbol{\theta} = \Delta\boldsymbol{\tau}. \quad (10.31)$$

If we now compare (10.25) with (10.31), we can readily derive the relations between the stiffness matrix \mathbf{K} in joint space and the stiffness matrix \mathbf{K}_C in Cartesian space:

$$\mathbf{K} = \mathbf{J}^T \mathbf{K}_C \mathbf{J} \quad \text{and} \quad \mathbf{K}_C = \mathbf{J}^{-T} \mathbf{K} \mathbf{J}^{-1} \quad (10.32)$$

which apparently is not a similarity transformation between \mathbf{K} and \mathbf{K}_C . What this means is that the two matrices do not share the same set of eigenvalues and their eigenvectors are not related by the linear relation (10.28). As a matter of fact, if the robot is revolute-coupled, the entries of its stiffness matrix \mathbf{K} all have units of Nm, i.e., of *torsional stiffness*, while the entries of \mathbf{K}_C have disparate units. To show this, the Jacobian matrix, the inverse Jacobian and the two stiffness matrices are partitioned correspondingly into four 3×3 blocks, i.e., as

$$\mathbf{J} = \begin{pmatrix} \mathbf{J}_{11} & \mathbf{J}_{12} \\ \mathbf{J}_{21} & \mathbf{J}_{22} \end{pmatrix}, \quad \mathbf{J}^{-1} = \begin{pmatrix} \mathbf{J}'_{11} & \mathbf{J}'_{12} \\ \mathbf{J}'_{21} & \mathbf{J}'_{22} \end{pmatrix},$$

$$\mathbf{K} = \begin{pmatrix} \mathbf{K}_{11} & \mathbf{K}_{12} \\ \mathbf{K}_{12}^\top & \mathbf{K}_{22} \end{pmatrix}, \quad \mathbf{K}_C = \begin{pmatrix} \mathbf{K}_{C11} & \mathbf{K}_{C12} \\ \mathbf{K}_{C12}^\top & \mathbf{K}_{C22} \end{pmatrix}.$$

Furthermore, in light of the definition of the twist, (10.2), the two upper blocks of \mathbf{J} are dimensionless, while its two lower blocks have units of length [10.11]. As a consequence, the two left blocks of \mathbf{J}^{-1} are dimensionless, while its two right blocks have units of inverse length. Now, the blocks of \mathbf{K}_C are computed from the corresponding relation in (10.32), thereby obtaining

$$\begin{aligned} \mathbf{K}_{C11} &= \mathbf{J}'_{11}^T (\mathbf{K}_{11} \mathbf{J}'_{11} + \mathbf{K}_{12} \mathbf{J}'_{21}) \\ &\quad + \mathbf{J}'_{21}^T (\mathbf{K}_{12}^\top \mathbf{J}'_{11} + \mathbf{K}_{22} \mathbf{J}'_{21}) \\ \mathbf{K}_{C12} &= \mathbf{J}'_{11}^T (\mathbf{K}_{11} \mathbf{J}'_{12} + \mathbf{K}_{12} \mathbf{J}'_{22}) \\ &\quad + \mathbf{J}'_{21}^T (\mathbf{K}_{12}^\top \mathbf{J}'_{12} + \mathbf{K}_{22} \mathbf{J}'_{22}) \\ \mathbf{K}_{C21} &= \mathbf{K}_{C12}^\top \\ \mathbf{K}_{C22} &= \mathbf{J}'_{12}^T (\mathbf{K}_{11} \mathbf{J}'_{12} + \mathbf{K}_{12} \mathbf{J}'_{22}) \\ &\quad + \mathbf{J}'_{22}^T (\mathbf{K}_{12}^\top \mathbf{J}'_{12} + \mathbf{K}_{22} \mathbf{J}'_{22}). \end{aligned}$$

It is now apparent that: \mathbf{K}_{C11} has entries with units of Nm, i.e., of torsional stiffness; \mathbf{K}_{C12} and \mathbf{K}_{C21} have entries with units of N; and \mathbf{K}_{C22} has entries with units of N/m, i.e., of translational stiffness.

The outcome of the foregoing discussion is that a norm for \mathbf{K} is possible, but not one for \mathbf{K}_C , unless of course a characteristic length is introduced to render all the entries of \mathbf{K}_C dimensionally homogeneous. A norm of a matrix is useful as it indicates *how large* the entries of the matrix are. We would like to characterize how stiff a robot is in both joint and Cartesian spaces. In joint space we could adopt any norm, but notice that the 2-norm, introduced in (10.3), would be misleading, as this norm would assign the value of the strongest joint to the overall robot stiffness. A more suitable norm would be the weighted Frobenius norm, introduced in (10.17), which would assign the rms value of the joint stiffnesses to the overall robot stiffness.

To design a robot optimally, we would therefore aim to maximize the Frobenius norm of its stiffness matrix in joint space, while observing constraints on the robot weight, as stiffer joints lead to heavier joints if the same material is used for all joints.

10.4.3 Elastodynamic Performance

For a general design problem, not only the kinetostatic and elastostatic performances, but also the elastodynamic performance have to be considered. In this regard, we introduce the assumptions of Sect. 10.4.2, with the added condition that inertia forces due to the link masses and moments of inertia are now taken into consideration.

The linearized model of a serial robot at the posture given by θ_0 , if we neglect damping, is

$$\mathbf{M}\Delta\ddot{\boldsymbol{\theta}} + \mathbf{K}\Delta\boldsymbol{\theta} = \Delta\boldsymbol{\tau} \quad (10.33)$$

in which \mathbf{M} is the $n \times n$ positive-definite mass matrix introduced in Sect. 10.4.1, while \mathbf{K} was defined in Sect. 10.4.2 as the $n \times n$ positive-definite stiffness matrix in joint space. Both \mathbf{K} and \mathbf{M} were defined in joint-space coordinates, $\Delta\boldsymbol{\theta}$, representing the vector of joint-variable elastic displacements, as in Sect. 10.4.2. These displacements are produced when, as the joints are all locked at a value θ_0 and thereby become ideal linear springs, the robot is subject to a perturbation $\Delta\boldsymbol{\tau}$, to nonzero initial conditions, or to a combination of both.

Under *free vibration*, i.e., under a motion of the system (10.33) caused by nonzero initial conditions and a zero excitation $\Delta\boldsymbol{\tau}$, the foregoing equation can be

solved for $\Delta\ddot{\boldsymbol{\theta}}$:

$$\Delta\ddot{\boldsymbol{\theta}} = -\mathbf{D}\Delta\boldsymbol{\theta}, \quad \mathbf{D} \equiv \mathbf{M}^{-1}\mathbf{K} \quad (10.34)$$

in which the matrix \mathbf{D} is known as the *dynamic matrix*. This matrix determines the behavior of the system under consideration, as its eigenvalues are the *natural frequencies* of the system and its eigenvectors the *modal vectors*. Let $\{\omega_i\}_1^n$ and $\{f_i\}_1^n$ denote the sets of eigenvalues and the corresponding eigenvectors of \mathbf{D} , respectively. Under the initial conditions $[\Delta\boldsymbol{\theta}(0), \Delta\dot{\boldsymbol{\theta}}(0)]^\top$, in which $\Delta\boldsymbol{\theta}(0)$ is proportional to the i -th eigenvector of \mathbf{D} and $\Delta\dot{\boldsymbol{\theta}}(0) = \mathbf{0}$, the ensuing motion is of the form $\Delta\boldsymbol{\theta}(t) = \Delta\boldsymbol{\theta}(0) \cos \omega_i t$ [10.54].

Furthermore, under the change of variables given by (10.28), the model (10.33) changes to

$$\mathbf{M}\mathbf{J}^{-1}\Delta\ddot{\boldsymbol{x}} + \mathbf{K}\mathbf{J}^{-1}\Delta\boldsymbol{x} = \mathbf{J}^\top\Delta\boldsymbol{w}.$$

If we now multiply both sides of the above equation by $\mathbf{J}^{-\top}$, we obtain the elastodynamic model (10.33) in Cartesian coordinates, namely

$$\mathbf{J}^{-\top}\mathbf{M}\mathbf{J}^{-1}\Delta\ddot{\boldsymbol{x}} + \mathbf{J}^{-\top}\mathbf{K}\mathbf{J}^{-1}\Delta\boldsymbol{x} = \Delta\boldsymbol{w}$$

in which the first matrix coefficient is the mass matrix \mathbf{M}_C in Cartesian coordinates, and the second is identified as \mathbf{K}_C , which was introduced in (10.32), i.e.,

$$\mathbf{M}_C \equiv \mathbf{J}^{-\top}\mathbf{M}\mathbf{J}^{-1}. \quad (10.35)$$

The elastodynamic model in Cartesian coordinates thus takes the form

$$\mathbf{M}_C\Delta\ddot{\boldsymbol{x}} + \mathbf{K}_C\Delta\boldsymbol{x} = \Delta\boldsymbol{w}. \quad (10.36)$$

Again, by virtue of the transformation (10.35), it is apparent that the mass matrix, like its stiffness counterpart, is not invariant under a change of coordinates. Moreover, in a revolute-coupled robot, all the entries of \mathbf{M} have units of kg m^2 ; however, the entries of \mathbf{M}_C have disparate units. An analysis similar to that conducted in Sect. 10.4.2 for the stiffness matrix in Cartesian space reveals that, if \mathbf{M}_C is partitioned into four 3×3 blocks, then its upper-left block has units of moment of inertia, its lower-right block has units of mass, while its off-diagonal blocks have units of kg m .

Correspondingly, the dynamic matrix in Cartesian coordinates becomes

$$\mathbf{D}_C = \mathbf{M}_C^{-1}\mathbf{K}_C. \quad (10.37)$$

It is now a simple matter to prove that the *dynamic matrix is invariant under a change of coordinates*. Indeed,

if we substitute transformations (10.32) and (10.35) into (10.37), we obtain

$$\mathbf{D}_C = \mathbf{J} \mathbf{M}^{-1} \mathbf{J}^\top \mathbf{J}^{-\top} \mathbf{K} \mathbf{J}^{-1} = \mathbf{J} \mathbf{M}^{-1} \mathbf{K} \mathbf{J}^{-1},$$

in which the dynamic matrix \mathbf{D} in joint coordinates can be readily identified in the final expression, and hence,

$$\mathbf{D}_C = \mathbf{J} \mathbf{D} \mathbf{J}^{-1}, \quad (10.38)$$

which shows that \mathbf{D}_C is indeed a similarity transformation of \mathbf{D} . As a consequence, the dynamic matrix is indeed invariant under a change of coordinates, the two matrices thus sharing the same sets of eigenvalues, their eigenvectors being related by the same similarity transformation. That is, if the modal vectors in joint space – the eigenvectors of \mathbf{D} – are denoted by $\{f_i\}_1^n$ and the modal vectors in Cartesian space are denoted by $\{g_i\}_1^n$, then these two sets are related by

$$\mathbf{g}_i = \mathbf{J} \mathbf{f}_i, \quad i = 1, \dots, n. \quad (10.39)$$

Therefore, the natural frequencies of the elastodynamic model are the same, regardless of the space in which they are calculated, while their natural modes of vibration change under a similarity transformation.

Under an excitation of the form $\Delta \boldsymbol{\tau} = \theta_0 \cos \omega t$ and zero initial conditions, the system is known to respond

with a harmonic motion of frequency ω and magnitude that depends on both ω and the system *frequency spectrum* $\{\omega_i\}_1^n$ [10.54]. When ω equals one of the natural frequencies of the system, the response magnitude grows unbounded, a phenomenon known as *resonance*. For this reason, when designing a robot, it is imperative that its frequency spectrum does not involve any of the expected operation frequencies, which can be achieved by designing the robot with stiffness and mass matrices that yield a frequency spectrum outside of the frequency range of the operation conditions.

This design task is not straightforward. Indeed, while the stiffness matrix in joint space is constant, the mass matrix is posture dependent, i.e., $\mathbf{M} = \mathbf{M}(\boldsymbol{\theta})$. Because of this feature, the elastodynamic design of a robot is bound to be iterative: the design can be conducted for a *straw-man task*, i.e., a typical task in the target applications, thus defining a set of postures that lead in turn to a set of mass-matrix values. Then, the frequency spectrum for all these postures can be designed to lie above the frequency range of the straw-man task. Since the robot will eventually be commanded to execute other tasks than the straw-man task, simulation of alternative tasks is required to ensure that the design is safe from a resonance viewpoint.

11. Kinematically Redundant Manipulators

Stefano Chiaverini, Giuseppe Oriolo, Ian D. Walker

This chapter focuses on redundancy resolution schemes, i.e., the techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem. This is obviously an issue of major relevance for motion planning and control purposes.

In particular, task-oriented kinematics and the basic methods for its inversion at the velocity (first-order differential) level are first recalled, with a discussion of the main techniques for handling kinematic singularities. Next, different first-order methods to solve kinematic redundancy are arranged in two main categories, namely those based on the optimization of suitable performance criteria and those relying on the augmentation of the task space. Redundancy resolution methods at the acceleration (second-order differential) level are then considered in order to take into account dynamics issues, e.g., torque minimization. Conditions under which a cyclic task motion results in a cyclic joint motion are also discussed; this is a major issue, e.g., for industrial applications in which a redundant manipulator is used to execute a repetitive task. The special class of hyperredundant manipulators is analyzed in detail. Suggestions for further reading are given in a final section.

A kinematically redundant manipulator possesses more joints than those strictly required to execute its task. This provides the robot with an increased level of dexterity that may be used to avoid singularities, joint limits, and

workspace obstacles, but also to minimize joint torque, energy or, in general, to optimize suitable performance indexes.

11.1 Overview

Kinematic redundancy occurs when a robotic manipulator has more degrees of freedom than those strictly

required to execute a given task. This means that, in principle, no manipulator is inherently redundant; rather,

there are certain tasks with respect to which it may become redundant. Since it is widely recognized that a general task consists of following an end-effector motion trajectory requiring six degrees of freedom, a robot arm with seven or more joints is considered as the typical example of inherently redundant manipulator. However, even robot arms with fewer degrees of freedom, like conventional six-joint industrial manipulators, may become kinematically redundant for specific tasks, such as simple end-effector positioning without constraints on the orientation.

The motivation for introducing kinematic redundancy in the mechanical structure of a manipulator goes beyond that for using redundancy in traditional engineering design, namely, increasing robustness to faults so as to improve reliability (e.g., redundant processors or sensors). In fact, endowing robotic manipulators with kinematic redundancy is mainly aimed at increasing dexterity.

The minimal-complexity approach which characterized early manipulator design had the objective of minimizing cost and maintenance, for example, this led to the development of selective compliance assembly robot arm (**SCARA**) robots for pick-and-place operations. However, giving a manipulator the minimum number of joints required to execute its task results in a serious limitation in real-world applications where, in addition to the singularity problem, joint limits or workspace obstacles are present. All of these give rise to forbidden regions in the joint space that must be avoided during operation, thus requiring a carefully structured (and static) workspace in which the motion of the manipulator can be planned in advance; this is the case of workcells in traditional industrial applications.

On the other hand, the presence of additional degrees of freedom besides those strictly required to execute the

Fig. 11.1 The 7-DOF DLR Lightweight Robot

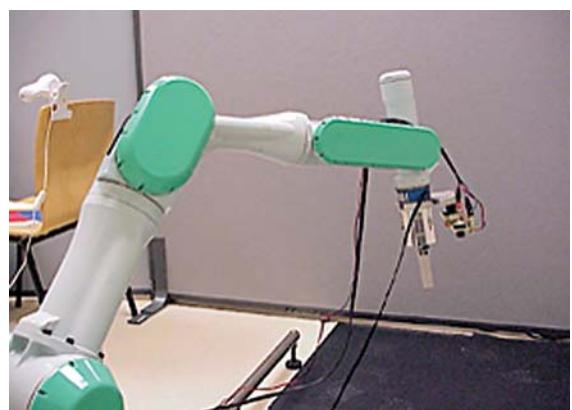

Fig. 11.2 The 7-DOF Mitsubishi PA-10 manipulator

Fig. 11.3 The 8-DOF DEXTER by Scienzia Machinale

task allows motions of the manipulator which do not displace the end effector (the so-called self-motions or internal motions); this implies that the same task at the

end-effector level can be executed in several ways at the joint level, giving the possibility of avoiding the forbidden regions and ultimately resulting in a more versatile mechanism. Such a feature is key to allowing operation in unstructured or dynamically varying environments that characterize advanced industrial applications and service robotics scenarios.

In practice, if properly managed, the increased dexterity characterizing kinematically redundant manipulators may allow to avoid singularities, joint limits, and workspace obstacles, but also to minimize torque/energy over a given task, ultimately meaning that the robotic manipulator can achieve a higher degree of autonomy.

The biological archetype of kinematically redundant manipulator is the human arm, which, not surprisingly, also inspires the terminology used to characterize the structure of serial-chain manipulators. In fact, the human arm has three degrees of freedom at the *shoulder*, one degree of freedom at the *elbow* and three degrees of freedom at the *wrist*. The available redundancy can be easily verified by locking one's wrist, e.g., on a table and moving the elbow while keeping the shoulder still. The kinematic arrangement of the human arm has been replicated in a number of

robots often termed as *human-arm-like* manipulators. This family of 7-DOF manipulators includes the DLR Lightweight Robot (Fig. 11.1) and the Mitsubishi PA-10 robot (Fig. 11.2). An example of an 8-DOF robot is the DEXTER by Scienzia Machinale (Fig. 11.3). Manipulators with a larger number of joints are often called *hyperredundant* robots, and include many snake-like robots described in the literature.

The use of two or more robotic structures to execute a task (as in the case of cooperating manipulators or multifingered hands) also gives rise to kinematic redundancy. Redundant mechanisms also include vehicle-manipulator systems; in this case, however, the possible presence of nonholonomic constraints on the motion of the base must be properly taken into account in order to determine the actual degree of redundancy.

Although the realization of a kinematically redundant structure raises a number of issues from the point of view of mechanical design, this chapter focuses on redundancy resolution schemes, i.e., techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem. This is an issue of major relevance for motion planning and control purposes.

11.2 Task-Oriented Kinematics

The relationship between the variables representing the configuration of an articulated manipulator and those describing an assigned task in the appropriate space can be established at the position, velocity or acceleration level. In particular, consideration of the first-order task kinematics brings up the task Jacobian matrix, which is a central object in redundancy resolution techniques.

11.2.1 Task-Space Formulation

A manipulator consists of a chain of rigid bodies articulated by joints. If q_i denotes the variable characterizing the relative displacement of body i with respect to body $i-1$, the vector $\mathbf{q} = (q_1 \dots q_N)^\top$ uniquely describes the configuration of an N -joint serial-chain manipulator. Joint i may be either prismatic or revolute, in which case q_i measures the relative translation or rotation of the attached links, respectively.

While the manipulator is naturally described and actuated in the *joint space*, its operation is conveniently

specified in terms of the vector $\mathbf{t} = (t_1 \dots t_M)^\top$, which typically defines the location of the manipulator end-effector in a suitably defined *task space*. In the general case, it is $M=6$ and \mathbf{t} is chosen so that its first three components represent the position of the end effector, while its last three components represent a minimal description of the end-effector orientation (such as Euler angles or the roll-pitch-yaw representation), i.e.,

$$\mathbf{t} = [p_x \ p_y \ P_z \ \alpha \ \beta \ \gamma]^\top.$$

Typically, one has $N \geq M$, so that the joints can provide at least the number of degrees of freedom required for the end-effector task. If $N > M$ strictly, the manipulator is *kinematically redundant*.

The relationship between the joint-space coordinate vector \mathbf{q} and the task-space coordinate vector \mathbf{t} is expressed by the *direct kinematics* equation

$$\mathbf{t} = \mathbf{k}_t(\mathbf{q}), \quad (11.1)$$

where \mathbf{k}_t is a nonlinear vector function.

Task Jacobian and Geometric Jacobian

It is useful to consider the *first-order differential kinematics* [11.1]

$$\dot{\boldsymbol{t}} = \mathbf{J}_t(\boldsymbol{q}) \dot{\boldsymbol{q}}, \quad (11.2)$$

that can be obtained by differentiating (11.1) with respect to time. In (11.2), $\dot{\boldsymbol{t}}$ is the task-space velocity vector, $\dot{\boldsymbol{q}}$ is the joint-space velocity vector, and $\mathbf{J}_t(\boldsymbol{q}) = \partial \boldsymbol{k}_t / \partial \boldsymbol{q}$ is the $M \times N$ task Jacobian matrix (also called the *analytic* Jacobian).

Remarkably, the components of $\dot{\boldsymbol{t}}$ relative to the end-effector orientation express the rate of change of the parameters characterizing the adopted minimal representation; they are not the components of the angular velocity vector of the end-effector. Indeed, denoting by \boldsymbol{v}_N the 3×1 translational velocity vector and by $\boldsymbol{\omega}_N$ the 3×1 angular velocity vector of the end-effector, and defining the end-effector spatial velocity \boldsymbol{v}_N as

$$\boldsymbol{v}_N = \begin{pmatrix} \boldsymbol{v}_N \\ \boldsymbol{\omega}_N \end{pmatrix}, \quad (11.3)$$

the following relationship holds

$$\dot{\boldsymbol{t}} = \mathbf{T}(\boldsymbol{t}) \boldsymbol{v}_N, \quad (11.4)$$

where \mathbf{T} is an $M \times 6$ transformation matrix that is a function of \boldsymbol{t} only. In the case $M=6$, the transformation matrix \mathbf{T} takes the form

$$\mathbf{T} = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{R} \end{pmatrix}, \quad (11.5)$$

where \mathbf{I} and $\mathbf{0}$ are, respectively, the identity and null matrix of proper dimensions, and \mathbf{R} is a 3×3 matrix that specifically depends on the minimal representation used to describe the end-effector orientation.

For a given manipulator, the mapping

$$\boldsymbol{v}_N = \mathbf{J}(\boldsymbol{q}) \dot{\boldsymbol{q}} \quad (11.6)$$

relates a joint-space velocity to the corresponding end-effector velocity through the $6 \times N$ geometric Jacobian matrix \mathbf{J} . The geometric Jacobian matrix is of major concern in the kinematic analysis of a manipulator since it allows description of the motion capabilities of the end-effector (in terms of its free rigid-body spatial velocity) as a result of the velocity commands at the joints in the current configuration.

By comparing (11.2), (11.4), and (11.6), the relation between the geometric Jacobian and the task Jacobian can be found as

$$\mathbf{J}_t(\boldsymbol{q}) = \mathbf{T}(\boldsymbol{t}) \mathbf{J}(\boldsymbol{q}). \quad (11.7)$$

Second-Order Differential Kinematics

While the first-order differential kinematics (11.2) relates task-space to joint-space velocities, further differentiation with respect to time provides an analogous relationship between accelerations

$$\ddot{\boldsymbol{t}} = \mathbf{J}_t(\boldsymbol{q}) \ddot{\boldsymbol{q}} + \mathbf{J}_t(\boldsymbol{q}, \dot{\boldsymbol{q}}) \dot{\boldsymbol{q}}. \quad (11.8)$$

This equation is also known as the *second-order differential kinematics*.

11.2.2 Singularities

In this section the occurrence of singular configurations is considered to properly analyze their effect on inverse kinematics solutions.

Representation and Kinematic Singularities

A robot configuration \boldsymbol{q} is *singular* if the task Jacobian matrix \mathbf{J}_t is rank-deficient there. Considering the role of \mathbf{J}_t in (11.2) and (11.8), it is easy to realize that at a singular configuration it is impossible to generate end-effector task velocities or accelerations in certain directions. Further insight can be gained by looking at (11.7), which indicates that a singularity may be due to a loss of rank of the transformation matrix \mathbf{T} and/or of the geometric Jacobian matrix \mathbf{J} .

Rank deficiencies of \mathbf{T} are only related to the mathematical relationship established by \mathbf{R} between the angular velocity vector of the end-effector and the components of $\dot{\boldsymbol{t}}$ relative to the end-effector orientation; since the expression of \mathbf{R} depends on the adopted minimal representation of the orientation, a configuration at which \mathbf{T} is singular is then referred to as a *representation singularity*. Remarkably, any minimal description of the end-effector orientation experiences the occurrence of representation singularities. Furthermore, a given configuration may or may not yield a representation singularity depending on which description of orientation is used.

A representation singularity is not directly related to the true motion capabilities of the manipulator structure, which can instead be inferred by the analysis of the geometric Jacobian matrix. Rank deficiencies of \mathbf{J} are in fact related to loss of mobility of the manipulator end-effector; indeed, end-effector velocities exist in this case which are unfeasible for any velocity commanded at the joints. A configuration at which \mathbf{J} is singular is referred to as a *kinematic singularity*.

Since this chapter focuses on the inversion of the task differential kinematics (11.2) and (11.8), in the following the task Jacobian matrix and its singularities

(which include representation and kinematic singularities) are studied in detail. The case $N \geq M$ is considered, which encompasses conventional as well as redundant manipulators.

Singular Value Decomposition of the Jacobian

To analyze the linear mapping (11.2), the *singular value decomposition* (SVD) of the Jacobian matrix is adopted; remarkably, this powerful numerical tool is the sole reliable method to compute the rank of a matrix and to study near-singular linear mappings. The classic *Golub–Reinsch* algorithm [11.2], which is the most efficient and numerically stable algorithm to compute the SVD of an arbitrary matrix, may however be computationally demanding in view of real-time applications. A faster algorithm that takes advantage of the nature of robotic matrix calculations has been proposed [11.3]; this makes it possible to improve real-time kinematic control techniques.

The SVD of the task Jacobian matrix can be written in the form

$$\mathbf{J}_t = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^\top = \sum_{i=1}^M \sigma_i \mathbf{u}_i \mathbf{v}_i^\top, \quad (11.9)$$

where \mathbf{U} is the $M \times M$ orthonormal matrix of the output singular vectors \mathbf{u}_i , \mathbf{V} is the $N \times N$ orthonormal matrix of the input singular vectors \mathbf{v}_i , and $\boldsymbol{\Sigma} = (\mathbf{S} \ \mathbf{0})$ is the $M \times N$ matrix whose $M \times M$ diagonal submatrix \mathbf{S} contains the singular values σ_i of the matrix \mathbf{J}_t . It is worth noticing that the SVD is a continuous and well-behaved function of its matrix argument; therefore, the input and output singular vectors as well as the singular values do not change much in the neighborhood of the current configuration. Letting $\text{rank}(\mathbf{J}_t) = R$, the following hold:

- $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_R > \sigma_{R+1} = \dots = 0$;
- $\mathcal{R}(\mathbf{J}_t) = \text{span}\{\mathbf{u}_1, \dots, \mathbf{u}_R\}$;
- $\mathcal{N}(\mathbf{J}_t) = \text{span}\{\mathbf{v}_{R+1}, \dots, \mathbf{v}_N\}$.

If the task Jacobian is full-rank ($R=M$), all the singular values are nonzero, the range space of \mathbf{J}_t is the entire \mathbb{R}^M , and the null space of \mathbf{J}_t has dimension $N-M$. In a singular configuration, instead, it is $R < M$; thus, the last $M-R$ singular values are zero, the range space of \mathbf{J}_t is an R -dimensional subspace of \mathbb{R}^M , and the dimension of the null space of \mathbf{J}_t increases to $N-R$. An interpretation of this from a kinematic viewpoint is presented in the following.

Feasible Velocities. At each configuration, the range space of \mathbf{J}_t is the set of task-space velocities that can

be obtained as a result of all possible joint-space velocities $\dot{\mathbf{q}}$; therefore, it constitutes the so-called subspace of *feasible velocities* for the end-effector task. A base of $\mathcal{R}(\mathbf{J}_t)$ is given by the first R output singular vectors, which represent independent linear combinations of the single components of the task velocities. Accordingly, the effect of a singularity is to decrease the dimension of the range space of \mathbf{J}_t by eliminating a linear combination of task velocity components from the space of feasible velocities.

Null-Space Velocities. At each configuration, the null space of \mathbf{J}_t is the set of joint-space velocities which yield zero task velocity; these are thus shortly called *null-space velocities*. A base of $\mathcal{N}(\mathbf{J}_t)$ is given by the $N-R$ last input singular vectors, which represent independent linear combinations of the velocities at each joint. From this viewpoint, the effect of a singularity is to increase the dimension of the null space of \mathbf{J}_t by introducing a further independent linear combination of joint velocities which produces a zero task velocity.

According to (11.2) and (11.9), a joint velocity along the i -th input singular vector results in a task velocity which lies along the i -th output singular vector:

$$\forall \rho \in \mathbb{R} \quad \dot{\mathbf{q}} = \rho \mathbf{v}_i \quad \Rightarrow \quad \mathbf{t} = \sigma_i \rho \mathbf{u}_i.$$

Thus, the i -th singular value of \mathbf{J}_t can be viewed as a gain factor relating motion along the \mathbf{v}_i direction of the joint velocity space to the resulting motion along the \mathbf{u}_i direction of the task velocity space. When a singularity is approached, the R -th singular value σ_R tends to zero and the task velocity produced by a fixed joint velocity along \mathbf{v}_R is decreased proportionally. At a singular configuration, the joint-space velocity along \mathbf{v}_R belongs to the null-space velocities and task velocities along \mathbf{u}_R become unfeasible for the manipulator.

In the generic case, the joint-space velocity $\dot{\mathbf{q}}$ is an arbitrary linear combination of individual joint velocities with nonzero components along all the \mathbf{v}_i . Its effect can be analyzed by combining the single effects of the above components. Remarkably, the components of $\dot{\mathbf{q}}$ in the null space of \mathbf{J}_t produce a change in the configuration of the manipulator without affecting its task velocity. This can be exploited to achieve additional goals – such as obstacle or singularity avoidance – in addition to the realization of a desired task motion, and constitutes the core of redundancy resolution approaches.

Distance from Singularities

Clearly, the effect of a singularity is experienced not only at the singular configuration itself but also in its

neighborhood (see also Sect. 11.3.2). For this reason, it is important to be able to characterize the distance from singularities through suitable measures; these can then be exploited to counteract undesirable effects.

Since each singularity is associated to a rank loss of \mathbf{J}_t , one conceptually simple possibility in the case of a square Jacobian matrix ($M=N$) is to compute its determinant. A generalization of this idea that works also for nonsquare Jacobians is the *manipulability measure* [11.4], defined as

$$\mu = \sqrt{|\mathbf{J}_t \mathbf{J}_t^\top|}.$$

It can be recognized that the manipulability measure is equal to the product of the singular values of \mathbf{J}_t , i.e.,

$$\mu = \prod_{i=1}^M \sigma_i,$$

and thus its zeros coincide with the singularities.

Another possible measure of distance from a singular configuration is the *condition number* of the Jacobian matrix [11.5], defined as

$$\kappa = \frac{\sigma_1}{\sigma_M}.$$

The condition number has values ranging from 1, at configurations in which all the singular values are equal,

to ∞ , at singular configurations. Note that when $\kappa=1$ all the singular values are equal and thus the end-effector has the same motion capability in all task space directions – i.e., the arm is at an *isotropic configuration* – whereas at a singularity it loses mobility in some task-space direction.

An even more direct measure of the distance from singular configurations is the *smallest singular value* of the Jacobian matrix [11.5], i.e.,

$$\sigma_{\min} = \sigma_M.$$

A computationally light estimate of the smallest singular value can be obtained either via numerical methods [11.3, 6, 7] or based on a kinematic analysis of the robot structure [11.8].

It must be noted that the manipulability measure may remain constant even in the presence of significant variations of either the condition number or the smallest singular value of \mathbf{J}_t . On the other hand, since the smallest singular value changes more radically near singularities than the other singular values, it dominates there the behavior of the determinant and the condition number of the Jacobian matrix; therefore, the most effective measure of distance from singular configurations is the smallest singular value of \mathbf{J}_t [11.5].

11.3 Inverse Differential Kinematics

In order to accomplish a task, a proper joint motion must be commanded to the manipulator; therefore, it is necessary to derive mathematical relations which allow to compute joint-space variables corresponding to the assigned task-space variables. This is the objective of the inverse kinematics problem.

The inverse kinematics problem can be solved by inverting either the direct kinematics equation (11.1), the first-order differential kinematics (11.2) or the second-order differential kinematics (11.8). If the task is time-varying (i.e., if a desired trajectory $\mathbf{t}(t)$ is assigned), it is convenient to solve the differential kinematic relationships because these represent linear equations with the task Jacobian as the coefficient matrix [11.9].

11.3.1 The General Solution

Under the assumption that the manipulator is kinematically redundant (i.e., $M < N$), the general solution of (11.2) or (11.8) can be expressed by resorting to the pseudoinverse \mathbf{J}_t^\dagger of the task Jacobian matrix [11.1, 10];

this is the unique matrix satisfying the Moore–Penrose conditions [11.11–13]

$$\begin{aligned} \mathbf{J}_t \mathbf{J}_t^\dagger \mathbf{J}_t &= \mathbf{J}_t \\ \mathbf{J}_t^\dagger \mathbf{J}_t \mathbf{J}_t^\dagger &= \mathbf{J}_t^\dagger \\ (\mathbf{J}_t \mathbf{J}_t^\dagger)^\top &= \mathbf{J}_t \mathbf{J}_t^\dagger \\ (\mathbf{J}_t^\dagger \mathbf{J}_t)^\top &= \mathbf{J}_t^\dagger \mathbf{J}_t. \end{aligned} \quad (11.10)$$

If \mathbf{J}_t is low-rectangular and full-rank, its pseudoinverse can be computed as

$$\mathbf{J}_t^\dagger = \mathbf{J}_t^\top (\mathbf{J}_t \mathbf{J}_t^\top)^{-1}. \quad (11.11)$$

If \mathbf{J}_t is square, expression (11.11) reduces to the standard inverse matrix.

The general solution of (11.2) can be written as

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \dot{\mathbf{q}}_0. \quad (11.12)$$

Here, $\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t$ represents the orthogonal projection matrix in the null space of \mathbf{J}_t , and $\dot{\mathbf{q}}_0$ is an arbitrary

joint-space velocity; the second part of the solution is therefore a null-space velocity. Equation (11.12) provides all least-squares solution to the end-effector task constraint (11.2), i.e., it minimizes $\|\dot{\mathbf{t}} - \mathbf{J}\dot{\mathbf{q}}\|$. In particular, if \mathbf{J}_t is low-rectangular and full-rank, all joint velocities in the form (11.12) exactly realize the assigned task velocity. By acting on $\dot{\mathbf{q}}_0$, one can still obtain different joint velocities that give the same end-effector task velocity; therefore, as will be discussed later in detail, the solution in the form (11.12) is typically used in the context of redundancy resolution.

The particular solution obtained by setting $\dot{\mathbf{q}}_0 = 0$ in (11.12)

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} \quad (11.13)$$

provides the least-squares solution of (11.2) with minimum norm, and is known as the *pseudoinverse solution*. In terms of the inverse differential kinematics problem, the least-squares property quantifies the accuracy of the end-effector task realization, while the minimum norm property may be relevant for the feasibility of the joint-space velocities.

As for the second-order kinematics (11.8), its least-squares solutions can be expressed in the general form

$$\ddot{\mathbf{q}} = \mathbf{J}_t^\dagger (\dot{\mathbf{t}} - \mathbf{J}_t \dot{\mathbf{q}}) + (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \ddot{\mathbf{q}}_0, \quad (11.14)$$

where $\ddot{\mathbf{q}}_0$ is an arbitrary joint-space acceleration. As above, choosing $\ddot{\mathbf{q}}_0 = 0$ in (11.14) gives the minimum-norm acceleration solution:

$$\ddot{\mathbf{q}} = \mathbf{J}_t^\dagger (\dot{\mathbf{t}} - \mathbf{J}_t \dot{\mathbf{q}}). \quad (11.15)$$

11.3.2 Singularity Robustness

We now investigate the kinematics aspects involved by the first-order inverse mappings (11.12) and (11.13) with respect to the handling of singularities. With reference to the SVD of \mathbf{J}_t in (11.9), let us consider the following decomposition of the matrix \mathbf{J}_t^\dagger

$$\mathbf{J}_t^\dagger = \mathbf{V} \boldsymbol{\Sigma}^\dagger \mathbf{U}^\top = \sum_{i=1}^R \frac{1}{\sigma_i} \mathbf{v}_i \mathbf{u}_i^\top, \quad (11.16)$$

where, as above, R denotes the rank of the task Jacobian matrix. Analogously to (11.9), the following hold:

- $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_R > \sigma_{R+1} = \dots = 0$;
- $\mathcal{R}(\mathbf{J}_t^\dagger) = \mathcal{N}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_R\}$;
- $\mathcal{N}(\mathbf{J}_t^\dagger) = \mathcal{R}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{u}_{R+1}, \dots, \mathbf{u}_M\}$.

Notice that, if the Jacobian matrix is full-rank, the range space of \mathbf{J}_t^\dagger is an M -dimensional subspace of \mathbb{R}^N and the null space of \mathbf{J}_t^\dagger is trivial. In a singular configuration ($R < M$), instead, the range space of \mathbf{J}_t^\dagger is an R -dimensional subspace of \mathbb{R}^N , and an $M-R$ -dimensional null space of \mathbf{J}_t^\dagger exists.

The range space of \mathbf{J}_t^\dagger is the set of joint-space velocities $\dot{\mathbf{q}}$ that can be obtained via the inverse kinematic mapping (11.13) as a result of all possible task velocities $\dot{\mathbf{t}}$. Since these $\dot{\mathbf{q}}$ belong to the orthogonal complement of the null space of \mathbf{J}_t , the pseudoinverse solution (11.13) satisfies the least-squares condition, as expected.

The null space of \mathbf{J}_t^\dagger is the set of the task velocities $\dot{\mathbf{t}}$ which yield null joint-space velocity in the current configuration; these $\dot{\mathbf{t}}$, on the other hand, belong to the orthogonal complement of the space of feasible task velocities. Therefore, one effect of the pseudoinverse solution (11.13) is to filter out the unfeasible components of the commanded task velocity while allowing exact tracking of the feasible components; this is related to the minimum-norm property.

If the assigned task velocity is aligned with \mathbf{u}_i , the corresponding joint-space velocity – computed via (11.13) – is obtained along \mathbf{v}_i modulated by the factor $1/\sigma_i$. When a singularity is approached, the R -th singular value tends to zero and a fixed task velocity command along \mathbf{u}_R requires joint-space velocities along \mathbf{v}_R that grow unboundedly in proportion to the factor $1/\sigma_R$. At the singular configuration, the \mathbf{u}_R direction becomes unfeasible for the task variables and \mathbf{v}_R adds to the null-space velocities of the arm.

According to the above, two main problems are inherently related to the basic inverse differential kinematics solution (11.13), namely:

- at near-singular configurations, excessive joint-space velocities may result, due to the component of $\dot{\mathbf{t}}$ along the direction which becomes unfeasible at the singularity;
- at the singular configuration, discontinuity of the joint-space solution is experienced if $\dot{\mathbf{t}}$ has a non-null unfeasible component.

The same is obviously true for the complete inverse solution (11.12).

Both the above problems are of major concern for kinematic control of manipulators, where the computed joint-space velocities must actually be executed by the robot arm. This has motivated the development of modified inverse differential mappings, so as to en-

sure proper behavior of the manipulator throughout its workspace. A reasonable approach is to preserve the mapping (11.13) far from singularities and to set up local modifications of it only inside a region enclosing the singular configuration; the definition of the region depends on a suitable measure of distance from the singularity, while the modified mapping must ensure feasible and continuous joint velocities.

Modification of the Planned Trajectory

One way to tackle the problem of singularities is to act at the planning level by either designing trajectories that avoid unavoidable singularities or assigning task-space motion commands that are feasible to the robot arm. However, these solutions rely on perfect task planning and cannot be used in real-time sensory control applications, in which motion commands are generated online.

Avoidance of singular configurations at the motion planning level is relatively simple when dealing with those naturally characterized in the task space such as the shoulder singularity of an anthropomorphic arm. However, this approach may result difficult for those singularities, like the wrist one, that may occur everywhere in the workspace.

Another possibility is to perform a joint-space interpolation when the planned trajectory is close to a singularity [11.14]; nevertheless, this may cause large errors in tracking the originally assigned task-space motion.

Acting in the task space, a method based on time-scale transformation is presented in [11.15], which slows down the manipulator's motion when a singularity is approached; this technique, however, fails at the singularity.

Since a task-space robot control system must be able to guide the motion of the manipulator safely through singularities, considerable research effort has been instead devoted to the derivation of well-defined and continuous inverse kinematic mappings.

Removal of Dependent Rows or Columns of the Jacobian Matrix

The first requirement of solution (11.13) is the availability of a general algorithm to compute the pseudoinverse of \mathbf{J}_t also when the Jacobian is singular. Several techniques presented in the literature can be arranged in this framework; they consist either in removing the unfeasible end-effector reference components [11.16] or in using nonsingular blocks of the Jacobian matrix [11.10]. The main problem with this type of solution is the spec-

ification of the directions of unfeasible velocities in a systematic way and the need to have smooth transitions between the usual inverse kinematic algorithm and the algorithms used close to the singularities.

A systematic procedure to compute the pseudoinverse of the Jacobian matrix can be devised by taking advantage of kinematic analysis of the manipulator structure since for typical manipulators it is possible to identify and describe classes of singular configurations in suitably defined link-fixed frames. The approach has been demonstrated for a six-degree-of-freedom elbow geometry in [11.17, 18].

As for the continuity of the solution across a singularity, it must be observed that, while the singular vectors change very little in the neighborhood of the singularity, the term

$$\frac{1}{\sigma_M} \mathbf{v}_M \mathbf{u}_M^\top \dot{\mathbf{t}}$$

suddenly disappears from (11.16) when R becomes less than M at the singular configuration.

One possibility to avoid this problem is to make

$$\mathbf{u}_M^\top \dot{\mathbf{t}} \approx 0$$

in the neighborhood of the singularity, which means avoiding commanding task velocities along the direction that becomes unfeasible at the singular configuration. Nevertheless, as anticipated Sect. 11.3.2, it is reasonable to apply this approach only for preplanned trajectories in relation to unavoidable singularities that are naturally characterized in the task space.

Independently from the assigned $\dot{\mathbf{t}}$, continuity of the pseudoinverse solution can be ensured by treating the manipulator as singular in a suitably defined region around each singularity through a modified Jacobian $\tilde{\mathbf{J}}_t$, so that $M-R$ extra degrees of freedom are available [11.17–19]; these can be used without significantly affecting the end-effector velocity, because the modified Jacobian $\tilde{\mathbf{J}}_t$ approximates \mathbf{J}_t inside the region. The described approach is difficult to generalize for multiple singularities. For the typical anthropomorphic geometry of industrial manipulators, however, only the wrist singularity is of primary concern since it may occur everywhere in the workspace, while the elbow and shoulder singularities are naturally characterized in the task space and thus can be avoided during planning.

Regularization/Damped Least-Squares Technique

The use of the damped least-squares technique in the inverse differential kinematics problem has been

independently proposed in [11.9, 20]. The method corresponds to solving the equation

$$\mathbf{J}_t^\top \dot{\mathbf{t}} = (\mathbf{J}_t^\top \mathbf{J}_t + \lambda^2 I) \dot{\mathbf{q}} \quad (11.17)$$

in place of (11.2). Here, $\lambda \in \mathbb{R}$ is the damping factor. It can be recognized that, when λ is zero, (11.17) and (11.2) become identical.

The solution to (11.17) can be written in two equivalent forms:

$$\dot{\mathbf{q}} = \mathbf{J}_t^\top (\mathbf{J}_t \mathbf{J}_t^\top + \lambda^2 I)^{-1} \dot{\mathbf{t}}, \quad (11.18)$$

$$\dot{\mathbf{q}} = (\mathbf{J}_t^\top \mathbf{J}_t + \lambda^2 I)^{-1} \mathbf{J}_t^\top \dot{\mathbf{t}}. \quad (11.19)$$

The computational load of (11.18) is lower than that of (11.19), since usually $N \geq M$. In the remainder, we will refer to the damped least-squares solution as

$$\dot{\mathbf{q}} = \mathbf{J}_t^*(\mathbf{q}) \dot{\mathbf{t}}, \quad (11.20)$$

whenever explicit specification of the computation used is not essential.

Solution (11.20) satisfies the condition

$$\min_{\dot{\mathbf{q}}} \left(\|\dot{\mathbf{t}} - \mathbf{J}_t \dot{\mathbf{q}}\|^2 + \lambda^2 \|\dot{\mathbf{q}}\|^2 \right), \quad (11.21)$$

which realizes a trade-off between the least-squares and the minimum-norm properties. Condition (11.21) implies consideration of accuracy and feasibility at the same time as choosing the joint-space velocity required to match the given $\dot{\mathbf{t}}$. In this regard it is essential to suitably select the value to be assigned to the damping factor: small values of λ give accurate solution but low robustness to the occurrence of singular and near-singular configurations; high values of λ result in low tracking accuracy even when a feasible and accurate solution would be possible.

In the framework of singular value decomposition, the solution (11.20) can be written as

$$\dot{\mathbf{q}} = \sum_{i=1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^\top \dot{\mathbf{t}}. \quad (11.22)$$

Remarkably, we have

- $\mathcal{R}(\mathbf{J}_t^*) = \mathcal{R}(\mathbf{J}_t^\dagger) = \mathcal{N}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_R\}$,
- $\mathcal{N}(\mathbf{J}_t^*) = \mathcal{N}(\mathbf{J}_t^\dagger) = \mathcal{R}^\perp(\mathbf{J}_t) = \text{span}\{\mathbf{u}_{R+1}, \dots, \mathbf{u}_M\}$.

Analogously to \mathbf{J}_t^\dagger , if the Jacobian matrix is full-rank, the range space of \mathbf{J}_t^* is an M -dimensional subspace of \mathbb{R}^N and the null space of \mathbf{J}_t^* is trivial; in a singular configuration, instead, the range space of \mathbf{J}_t^* is an R -dimensional subspace of \mathbb{R}^N , and an $M-R$ -dimensional null space of \mathbf{J}_t^* exists.

It is clear that, with respect to the pure least-squares solution (11.13), in (11.22) the components for which $\sigma_i \gg \lambda$ are little influenced by the damping factor, since in this case

$$\frac{\sigma_i}{\sigma_i^2 + \lambda^2} \approx \frac{1}{\sigma_i}.$$

On the other hand, when a singularity is approached, the smallest singular value tends to zero while the associated component of the solution is driven to zero by the factor σ_i/λ^2 ; this progressively reduces the joint velocity required to achieve near-degenerate components of the commanded $\dot{\mathbf{t}}$. At the singularity, the solutions (11.20) and (11.13) behave identically as long as the remaining singular values are significantly larger than the damping factor. Remarkably, due to the damping factor, an upper bound of $1/(2\lambda)$ exists on the gain factor relating for each i the task velocity component along \mathbf{u}_i to the resulting joint velocity along \mathbf{v}_i ; this bound is reached when $\sigma_i = \lambda$.

Selection of the Damping Factor. According to above, the value selected for the damping factor establishes the closeness of the current configuration to a singularity; moreover, λ determines the degree of approximation introduced with respect to the pure least-squares solution given by the pseudoinverse. An optimal choice for λ requires consideration of the smallest non-null singular value experienced along the given trajectory and of the minimum damping needed to ensure feasible joint velocities.

To achieve good performance in the entire manipulator's workspace the use of a configuration-varying damping factor has been proposed [11.9]. The natural choice is to adjust λ as a function of some measure of distance from the singularity at the current configuration of the robot arm. Far from singular configurations feasible joint velocities are obtained; thus the accuracy requirement prevails and low damping must be used. Close to a singularity, task velocity commands along the unfeasible directions give large joint velocities and the accuracy requirement must be relaxed; in these cases, high damping is needed.

A first proposal was to adjust the damping factor as a function of the manipulability measure [11.9]. Since a more effective measure of distance from singular configurations is the smallest singular value of the Jacobian matrix [11.5], its use has been considered later for building a variable damping factor.

If an estimate $\hat{\sigma}_M$ of the smallest singular value is available, the following choice for the damping factor

can be adopted [11.21]

$$\lambda^2 = \begin{cases} 0 & \text{when } \hat{\sigma}_M \geq \varepsilon \\ \left[1 - (\hat{\sigma}_M/\varepsilon)^2\right] \lambda_{\max}^2 & \text{otherwise,} \end{cases} \quad (11.23)$$

which ensures continuity and good shaping of the solution. In (11.23), ε defines the size of the singular region, in which damping is used, and λ_{\max} sets the maximum value of the damping factor, which occurs just at the singularity.

Numerical Filtering. As can be recognized from (11.22), the damping factor affects the accuracy of the solution along each end-effector velocity component; however, the sole unfeasible direction is responsible for the loss of tracking ability. To overcome this problem, selective filtering of the end-effector velocity components was proposed in [11.6]. The method can be generalized as follows; if an estimate $\hat{\mathbf{u}}_i$ of the output singular vector associated to the $M-K$ smallest singular values – which give the components to become unfeasible – is available, the solution can be written in the form

$$\dot{\mathbf{q}} = \mathbf{J}_t^\top \left(\mathbf{J}_t \mathbf{J}_t^\top + \lambda^2 \mathbf{I} + \beta^2 \sum_{i=K+1}^M \hat{\mathbf{u}}_i \hat{\mathbf{u}}_i^\top \right)^{-1} \dot{\mathbf{i}}, \quad (11.24)$$

where β provides the largest contribution to damping only along the unfeasible components. This can also be recognized from the expression

$$\dot{\mathbf{q}} \approx \sum_{i=1}^K \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^\top \dot{\mathbf{i}} + \sum_{i=K+1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2 + \beta^2} \mathbf{v}_i \mathbf{u}_i^\top \dot{\mathbf{i}}, \quad (11.25)$$

in which the approximation is due to the estimates $\hat{\mathbf{u}}_i$ in (11.24). Notice that $K \leq R$; nevertheless, a nonzero value of λ is kept to guarantee satisfactory conditioning of the mapping (11.24) even for incorrect estimates of the output singular vectors.

Similarly, additional damping can be provided to the joint-space velocity components given by the input singular vectors associated to the smallest singular values, since they are close to become the null-space velocities [11.22]. The solution can be generalized in the form

$$\dot{\mathbf{q}} = \left(\mathbf{J}_t^\top \mathbf{J}_t + \lambda^2 \mathbf{I} + \beta^2 \sum_{i=K+1}^N \hat{\mathbf{v}}_i \hat{\mathbf{v}}_i^\top \right)^{-1} \mathbf{J}_t^\top \dot{\mathbf{i}}, \quad (11.26)$$

where β provides the largest contribution to damping only along the $N-K$ estimated null-space velocity components $\hat{\mathbf{v}}_i$. This can be also recognized from the expression

$$\dot{\mathbf{q}} \approx \sum_{i=1}^K \frac{\sigma_i}{\sigma_i^2 + \lambda^2} \mathbf{v}_i \mathbf{u}_i^\top \dot{\mathbf{i}} + \sum_{i=K+1}^R \frac{\sigma_i}{\sigma_i^2 + \lambda^2 + \beta^2} \mathbf{v}_i \mathbf{u}_i^\top \dot{\mathbf{i}}, \quad (11.27)$$

in which again the approximation is due to the estimates $\hat{\mathbf{v}}_i$ in (11.26). Also in this case a nonzero value of λ is kept to guarantee satisfactory conditioning of the mapping (11.26) even for incorrect estimates of the input singular vectors.

Comparison of (11.27) with (11.25) shows that, in the case of accurate estimate of the singular vectors, the solutions (11.24) and (11.26) behave identically.

11.3.3 Joint Trajectory Reconstruction

When solving the inverse kinematics problem at the first-order differential level, one obtains the joint velocity profile $\dot{\mathbf{q}}(t)$ that corresponds to an assigned end-effector task velocity profile $\dot{\mathbf{i}}(t)$; however, the robot motion controller needs reference position trajectories in addition to the velocity references for the joints. The reconstruction of the joint-position profile from the joint-velocity profile obtained from an end-effector task velocity profile $\dot{\mathbf{i}}(t)$ realizes a kinematic inversion that can be seen as an *inverse kinematics algorithm*.

If the joint-velocity profile were completely specified (e.g., by its analytical expression) the corresponding joint-position profile could be obtained from time integration

$$\mathbf{q}(t) = \mathbf{q}(t_0) + \int_{t_0}^t \dot{\mathbf{q}}(\tau) d\tau. \quad (11.28)$$

Nevertheless, digital implementation of the robot control system makes it more likely that a discrete-time sequence of samples $\dot{\mathbf{q}}_k$ of the computed joint velocities at the time instants t_k will be available, i.e.,

$$\dot{\mathbf{q}}_k = \dot{\mathbf{q}}(t_k).$$

For this reason, a discrete-time numerical approximation of the continuous-time integral (11.28) must be suitably devised.

Accurate discrete-time approximations of a continuous-time integral usually require a trade-off between the complexity of the interpolating algorithm and the

length of the time step. In real-time applications, such as robot motion control, high-order interpolation results in large finite-time delay that degrade the dynamic performance of the control loop. This time delay can be reduced by suitably shortening the time step; however, if the time step is sufficiently short even a low-order interpolation may give acceptable accuracy of the numerical integration. The typical case is that of a first-order interpolation, e.g., an Euler forward rectangular rule that transforms the integral (11.28) into

$$\mathbf{q}_k = \mathbf{q}_0 + \sum_{h=0}^{k-1} \dot{\mathbf{q}}_h \Delta t, \quad (11.29)$$

where Δt is the time step. Equation (11.29) is usually written in the more effective recursive form

$$\mathbf{q}_k = \mathbf{q}_{k-1} + \dot{\mathbf{q}}_{k-1} \Delta t.$$

Closed-Loop Inverse Kinematics (CLIK)

No matter what kind of interpolation is used, the small though unavoidable error suffered at each numerical integration step accumulates, leading to long-term drifting

of the reconstructed profile from the exact joint-position profile. Another source of error affecting any integral reconstruction method is the possible uncertainty in the initial value of the joint position.

Algorithmic solutions that overcome these problems are based on the use of a feedback correction term; these are termed *closed-loop inverse kinematics (CLIK)* algorithms [11.23]. Considering, e.g., the case of first-order kinematics, the joint velocity at the k -th time instant is computed as (compare with (11.12))

$$\begin{aligned} \dot{\mathbf{q}}_k &= \mathbf{J}_t^\dagger(\mathbf{q}_k) \{ \dot{\mathbf{t}}_k + \mathbf{K}[\mathbf{t}_k - \mathbf{k}_t(\mathbf{q}_k)] \} \\ &\quad + [\mathbf{I} - \mathbf{J}_t^\dagger(\mathbf{q}_k) \mathbf{J}_t(\mathbf{q}_k)] \dot{\mathbf{q}}_{0k}, \end{aligned} \quad (11.30)$$

where \mathbf{K} is a constant positive-definite gain matrix.

Second-order CLIK algorithms are also available that solve for joint positions, velocities, and accelerations [11.24, 25]. The CLIK approach was originally proposed in [11.26] and [11.27] based on the Jacobian transpose in lieu of the pseudoinverse, which provides remarkable computational savings and provides inherent singularity handling capabilities [11.28].

11.4 Redundancy Resolution via Optimization

For a kinematically redundant manipulator, the inverse kinematics problem admits an infinite number of solutions, so that a criterion to select one of them is needed. In this section we will consider the problem of redundancy resolution via optimization at the first-order differential kinematics level. Before discussing algorithmic schemes for computing joint velocities, we provide a short review of possible performance criteria.

11.4.1 Performance Criteria

The availability of degrees of freedom in excess with respect to those strictly needed to execute a given task can be used to improve the value of performance criteria during the motion. These criteria may depend on the robot joint configuration only, or also involve velocities and/or accelerations.

Among the additional objectives that can be pursued by defining a suitable criterion, the most important is probably singularity avoidance. In fact, one of the main reasons for introducing kinematic redundancy is to reduce the extension of the workspace region where the manipulator is necessarily a singular configuration (*unavoidable* singularities). A discussion of avoidable and unavoidable singularities in redundant manipula-

tors can be found in [11.29]. If the assigned end-effector task does not pass through unavoidable singularities, it is in principle always possible to compute a joint trajectory along which the task Jacobian \mathbf{J}_t is continuously full-rank. To this end, possible performance criteria are the configuration-dependent functions introduced in Sect. 11.2.2 that characterize the distance from singularities, i.e., the manipulability measure, the condition number, and the smallest singular value of \mathbf{J}_t . Maximizing (or keeping as large as possible) these functions during the motion is a reasonable plan in order to avoid singular configurations during the motion.

Since kinematic inversion produces diverging joint velocities in the vicinity of singular configurations, a conceptually different possibility is to minimize the norm of the joint velocity generated by the redundancy resolution scheme. However, this approach guarantees singularity avoidance only if such a norm is minimized in an integral sense along the motion of the manipulator. Local minimization of the norm [11.10] does not lead to singularity avoidance in any practical sense [11.29].

Redundancy can be also used to keep the manipulator linkage away from undesired regions of the joint space, for example, mechanical joint limits that are typically present in robot manipulators may be avoided by

minimizing the cost function [11.30]

$$\mathbf{H}(\mathbf{q}) = \frac{1}{2} \sum_{i=1}^N \left(\frac{q_i - q_{i,\text{mid}}}{q_{i,\text{max}} - q_{i,\text{min}}} \right)^2$$

where $[q_{i,\text{min}}, q_{i,\text{max}}]$ is the available range for joint i and $q_{i,\text{mid}}$ is its midpoint. Another interesting application is obstacle avoidance, which can be enforced by minimizing suitable *artificial potential* functions defined on the basis of the image of the obstacle region in the configuration space [11.31, 32].

Many other performance criteria have been proposed in the literature; some of them are mentioned in Sects. 11.6 and 11.9.

11.4.2 Local Optimization

The simplest form of local optimization is represented by the pseudoinverse solution (11.13), which provides the joint velocity with the minimum norm among those which realize the task constraint. Clearly, the joint movement generated by this locally optimal solution does not provide global velocity minimization along the whole manipulator motion. This means that, despite the local minimization of joint velocities, singularity avoidance is not guaranteed [11.29].

Another possibility is to use the general solution (11.12), choosing the arbitrary joint velocity $\dot{\mathbf{q}}_0$ in the direction of the antigradient of a scalar configuration-dependent performance criteria $\mathbf{H}(\mathbf{q})$ which must be minimized:

$$\dot{\mathbf{q}}_0 = -k_H \nabla \mathbf{H}(\mathbf{q}), \quad (11.31)$$

where k_H is a scalar step size and $\nabla \mathbf{H}(\mathbf{q})$ denotes the gradient of \mathbf{H} at the current joint configuration. This leads to the following redundancy resolution scheme [11.30]

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger \dot{\mathbf{t}} - k_H (\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t) \nabla \mathbf{H}(\mathbf{q}). \quad (11.32)$$

Since its second term is the projection of the antigradient of \mathbf{H} in the null space of the task Jacobian, the above expression is reminiscent of the projected gradient method for constrained minimization [11.33]. In particular, it can be shown [11.34] that the inverse kinematic solution (11.32) minimizes the complete quadratic function

$$L(\mathbf{q}, \dot{\mathbf{q}}) = \frac{1}{2} \dot{\mathbf{q}}^\top \dot{\mathbf{q}} + k_H \dot{\mathbf{q}}^\top \nabla \mathbf{H}(\mathbf{q})$$

at the current configuration \mathbf{q} . Thus, (11.32) represents a natural trade-off between the unconstrained local minimization of the performance criteria \mathbf{H} (which would lead to choose $\dot{\mathbf{q}} = -k_H \nabla \mathbf{H}(\mathbf{q})$) and the satisfaction of constraint (11.2) by a minimum-norm joint velocity.

The choice of the step size k_H is critical for the performance of the redundancy resolution scheme (11.32). In particular, a small value of the step size may slow down the minimization of the performance criteria, but on the other hand a large value may even lead to an increase of \mathbf{H} (recall that the antigradient is the *local* direction of maximum decrease). In practice, to identify at each configuration an appropriate value of k_H in a reasonable time, one may use a simplified *line search* technique such as Armijo's rule [11.33].

11.4.3 Global Optimization

The main advantage of the redundancy resolution scheme (11.32) is its simplicity: if the computation of $\nabla \mathbf{H}(\mathbf{q})$ and k_H is efficient, such a scheme is a realistic option for real-time kinematic inversion. Its disadvantage is to be found in the local nature of the optimization process, which can lead to unsatisfactory performance over long tasks, for example, use of (11.32) with $\mathbf{H} = -\mu$ (the manipulability measure) will perform better than the simple pseudoinverse solution, but still cannot guarantee singularity avoidance.

It is therefore natural to consider the possibility of selecting $\dot{\mathbf{q}}_0$ in (11.12) so as to minimize integral criteria of the form

$$\int_{t_i}^{t_f} \mathbf{H}(\mathbf{q}) dt$$

defined over the duration $[t_i, t_f]$ of the whole task (e.g., the integral manipulability along the motion). Unfortunately, the solution of this problem (naturally formulated within the framework of calculus of variations) may not exist, and in any case it admits no closed form in general. Remarkably, one way to make the problem certainly solvable is to include under the integral a quadratic form in the joint velocities or accelerations. However, this is more easily done at the second-order kinematic level (see Sect. 11.6).

11.5 Redundancy Resolution via Task Augmentation

Another approach to redundancy resolution consists in augmenting the task vector so as to tackle ad-

ditional objectives expressed as constraints. In this section, we review the basic task augmentation tech-

niques for solving the first-order differential kinematics (11.2).

11.5.1 Extended Jacobian

The extended Jacobian technique, proposed by *Bailieul* [11.35] and later revisited by *Chang* [11.36], enforces an appropriate number of functional constraints to be fulfilled along with the original end-effector task so as to identify a single solution among the infinite compatible with the end-effector task.

Let us consider an objective function $g(\mathbf{q})$ to be optimized and let also $\mathbf{N}_{\mathbf{J}_t}(\mathbf{q})$ be a matrix spanning the null space of \mathbf{J}_t at a nonsingular configuration \mathbf{q} , e.g.,

$$\mathbf{N}_{\mathbf{J}_t} = \mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t.$$

It can be recognized that, for a given t_0 , if \mathbf{q}_0 is a configuration at which the function $g(\mathbf{q})$ is at an extreme under the constraint $t_0 = \mathbf{k}_t(\mathbf{q}_0)$, one has

$$\frac{\partial g(\mathbf{q})}{\partial \mathbf{q}} \Big|_{\mathbf{q}=\mathbf{q}_0} \mathbf{N}_{\mathbf{J}_t}(\mathbf{q}_0) = \mathbf{0}^\top. \quad (11.33)$$

If the Jacobian \mathbf{J}_t has full rank M , then $\mathbf{N}_{\mathbf{J}_t}$ has rank $N-M$; therefore, equation (11.33) yields a set of $N-M$ independent constraints that can be written in vector form as

$$\mathbf{h}(\mathbf{q}) = \mathbf{0};$$

for example, these can be obtained by taking the scalar product of the gradient $\partial g(\mathbf{q})/\partial \mathbf{q}$ by each of the $N-M$ vectors constituting a base of the null space of \mathbf{J}_t , i.e.,

$$\mathbf{h}(\mathbf{q}) = \left(\frac{\partial g(\mathbf{q})}{\partial \mathbf{q}} (\mathbf{v}_{M+1}(\mathbf{q}) \dots \mathbf{v}_N(\mathbf{q})) \right)^\top.$$

At this point, the condition (11.33) implies that the equation

$$\begin{pmatrix} \mathbf{k}_t(\mathbf{q}_0) \\ \mathbf{h}(\mathbf{q}_0) \end{pmatrix} = \begin{pmatrix} t_0 \\ \mathbf{0} \end{pmatrix}$$

is satisfied.

For motion starting from t_0 with \mathbf{q}_0 that tracks a trajectory $\mathbf{t}(t)$ by keeping $g(\mathbf{q})$ extremized at each time one has

$$\begin{pmatrix} \mathbf{k}_t(\mathbf{q}(t)) \\ \mathbf{h}(\mathbf{q}(t)) \end{pmatrix} = \begin{pmatrix} \mathbf{t}(t) \\ \mathbf{0} \end{pmatrix}.$$

By differentiating both sides with respect to time one obtains

$$\begin{pmatrix} \mathbf{J}_t(\mathbf{q}) \\ \frac{\partial \mathbf{h}(\mathbf{q})}{\partial \mathbf{q}} \end{pmatrix} \dot{\mathbf{q}} = \begin{pmatrix} \mathbf{t}' \\ \mathbf{0} \end{pmatrix}, \quad (11.34)$$

where the matrix premultiplying the vector $\dot{\mathbf{q}}$ is square and is called the *extended Jacobian* \mathbf{J}_{ext} .

Therefore, if the initial configuration \mathbf{q}_0 extremizes $g(\mathbf{q})$ and provided that \mathbf{J}_{ext} does not become singular, the time integral of the inverse mapping

$$\dot{\mathbf{q}} = \mathbf{J}_{\text{ext}}^{-1}(\mathbf{q}) \begin{pmatrix} \mathbf{t}' \\ \mathbf{0} \end{pmatrix} \quad (11.35)$$

tracks the assigned end-effector trajectory $\mathbf{t}(t)$ propagating joint configurations that extremize $g(\mathbf{q})$.

The extended Jacobian method has a major advantage over pseudoinverse techniques of the form (11.13) in that it is *cyclic* (see Sect. 11.7). Moreover, solution (11.35) can be made equivalent to (11.12) via suitable choice of the vector $\dot{\mathbf{q}}_0$ [11.35, 37].

11.5.2 Augmented Jacobian

Another approach, the so-called task-space augmentation, introduces a constraint task to be fulfilled along with the end-effector task; then, an augmented Jacobian matrix is set-up whose inverse gives the sought joint velocity solution. The concept of task-space augmentation has been independently introduced by *Sciavicco* and *Siciliano* [11.28, 38, 39] and *Egeland* [11.40] and later revisited by *Seraji* in the framework of the configuration control method [11.41].

In detail, let us consider the vector $\mathbf{t}_c = (t_{c,1} \dots t_{c,P})^\top$ which describes the additional tasks to be fulfilled besides the M -dimensional end-effector task \mathbf{t} . In the general case $P \leq N-M$, although full redundancy exploitation suggests the consideration of exactly as many additional tasks as the number of redundant degrees of freedom, i.e., $P = N-M$.

The relation between the joint-space coordinate vector \mathbf{q} and the *constraint-task* vector \mathbf{t}_c can be considered as a direct kinematics equation

$$\mathbf{t}_c = \mathbf{k}_c(\mathbf{q}), \quad (11.36)$$

where \mathbf{k}_c is a continuous nonlinear vector function. Accordingly, it is useful to consider the mapping

$$\dot{\mathbf{t}}_c = \mathbf{J}_c(\mathbf{q}) \dot{\mathbf{q}}, \quad (11.37)$$

that can be obtained by differentiating Eq. (11.36). In (11.37), $\dot{\mathbf{t}}_c$ is the constraint-task velocity vector, and $\mathbf{J}_c(\mathbf{q}) = \partial \mathbf{k}_c / \partial \mathbf{q}$ is the $P \times N$ constraint-task Jacobian matrix.

At this point, an *augmented-task* vector can be defined by stacking the end-effector task vector with the constraint-task vector as

$$\dot{\mathbf{t}}_a = \begin{pmatrix} \dot{\mathbf{t}} \\ \dot{\mathbf{t}}_c \end{pmatrix} = \begin{pmatrix} \mathbf{k}_t(\mathbf{q}) \\ \mathbf{k}_c(\mathbf{q}) \end{pmatrix}.$$

According to this definition, finding a joint configuration \mathbf{q} that results in some desired value for $\dot{\mathbf{t}}_a$ means satisfying both the end-effector and the constraint task at the same time.

A solution to this problem can be found at the differential level by inverting the mapping

$$\dot{\mathbf{t}}_a = \mathbf{J}_a(\mathbf{q}) \dot{\mathbf{q}} \quad (11.38)$$

in which the matrix

$$\mathbf{J}_a = \begin{pmatrix} \mathbf{J}_t \\ \mathbf{J}_c \end{pmatrix}$$

is termed the *augmented Jacobian*.

A particular choice for the constraint-task vector is $\mathbf{t}_c = \mathbf{h}(\mathbf{q})$, with \mathbf{h} defined as explained in Sect. 11.5.1, which allows the augmented Jacobian method to embed the extended Jacobian one.

11.5.3 Algorithmic Singularities

The definition of additional goals besides tracking the end-effector velocity raises the possibility that configurations exist at which the augmented kinematics problem is singular while the sole end-effector task kinematics is not; these configurations are then termed *algorithmic singularities* [11.35]. With reference to the velocity mappings (11.34) and (11.38), an algorithmically singular configuration is one at which, respectively, the extended and the augmented Jacobians are singular while \mathbf{J}_t is full-rank.

Since the origin of task-augmentation redundancy resolution methods, Baillieul pointed out that algorithmic singularities are not a specific problem of the extended Jacobian technique but that they arise from the way in which the constraint task conflicts with the end-effector task [11.35, 37]. This is easily understandable in simple situations such as that of a trajectory tracking with obstacle avoidance problem: if the assigned trajectory passes through an obstacle either the trajectory is

tracked or the obstacle is avoided so that both tasks cannot be achieved. If the origin of the conflict between the two tasks has a clear meaning the algorithmic singularity may then be avoided by keenly specifying the constraint task case by case (e.g., [11.23]). In more general situations analytical tools may be useful in finding algorithmic singularities and guiding the choice of the constraint function [11.42] or in finding configurations that better harmonize the two tasks [11.43].

Looking at the tasks definitions in (11.2) and (11.37), by considering their inverse mappings it can be recognized that the two tasks are in conflict when

$$\mathcal{R}(\mathbf{J}_c^\top) \cap \mathcal{R}(\mathbf{J}_t^\top) \neq \{\mathbf{0}\} \quad (11.39)$$

and then this is the condition for the occurrence of an algorithmic singularity. On the other hand, when

$$\mathcal{R}(\mathbf{J}_c^\top) \cap \mathcal{R}(\mathbf{J}_t^\top) = \{\mathbf{0}\}$$

the two tasks are compatible since the two inverse mappings are linearly independent; a special case of task compatibility is when

$$\mathcal{R}(\mathbf{J}_c^\top) \equiv \mathcal{R}^\perp(\mathbf{J}_t^\top) \quad (11.40)$$

and the two mappings are orthogonal.

At the algorithmic singularities the augmented Jacobian cannot be inverted but singularity-robust techniques can be adopted. Since the exact solution does not exist there are reconstruction errors and these affect both the task vectors. To counteract this problem the use of weighted damped least-squares has been considered to invert the augmented Jacobian matrix [11.44, 45]. A different approach is the so-called task priority inverse kinematics.

11.5.4 Task Priority

Conflicts between the end-effector task and the constraint task are handled in the framework of the task-priority strategy by suitably assigning an order of priority to the given tasks and then satisfying the lower-priority task only in the null space of the higher-priority task [11.46, 47]. In the typical case, an end-effector task is considered as the primary task, although examples might be given in which it becomes the secondary task [11.23]. The idea is that, when an exact solution does not exist, the reconstruction error should only affect the lower-priority task.

With reference to solution (11.12), the task-priority method consists of computing $\dot{\mathbf{q}}_0$ so as to suitably achieve the P -dimensional constraint-task velocity $\dot{\mathbf{t}}_c$.

Remarkably, the projection of \dot{q}_0 onto the null space of J_t ensures lower priority of the constraint task with respect to the end-effector task since this results in a null-space velocity for it [11.48].

When the secondary task \dot{i}_c is orthogonal to the primary task \dot{i} (in the sense of Eq. (11.40)) the joint velocity

$$\dot{q}_0 = J_c^\dagger(\dot{q})\dot{i} \quad (11.41)$$

would easily solve the problem, being in addition already a null-space velocity for the primary-task velocity mapping (11.2) (i. e., projection through N_{J_t} would not be needed). However, in the general case the two tasks may be compatible but not orthogonal or may conflict and there not exist a joint velocity solution that ensures the achievement of both \dot{i} and \dot{i}_c . Coherently with the defined order of priority between the two tasks, a reasonable choice is then to guarantee exact tracking of the primary-task velocity while minimizing the constraint-task velocity reconstruction error $\dot{i}_c - J_c\dot{q}$; this gives [11.49]

$$\dot{q}_0 = [J_c(I - J_t^\dagger J_t)]^\dagger(\dot{i}_c - J_c J_t^\dagger \dot{i}). \quad (11.42)$$

Finally, by observing that the null-space projection operator is both hermitian and idempotent, the solution given by (11.12) and (11.42) can be simplified to [11.46]

$$\dot{q} = J_t^\dagger \dot{i} + [J_c(I - J_t^\dagger J_t)]^\dagger(\dot{i}_c - J_c J_t^\dagger \dot{i}). \quad (11.43)$$

It can be recognized that the problem of algorithmic singularities still remains; in fact, when condition (11.39) is satisfied the matrix $J_c(I - J_t^\dagger J_t)$ loses rank with full-rank J_t and J_c . However, differently from the task-space augmentation approach, correct primary-task solutions are expected as long as the sole primary-task Jacobian matrix is full-rank. On the other hand, out of the algorithmic singularities the task-priority strategy gives the same solution as the task-space augmentation approach; this implies that close

to an algorithmic singularity the solution becomes ill-conditioned and large joint velocities may result. This problem has partly been solved by looking at the efficient rank of the matrix involved and treating it as singular depending on a suitable threshold [11.46]; the obtained joint velocities are thus limited, but continuity of the null-space component must be ensured.

Another approach is to relax minimization of the secondary-task velocity reconstruction constraint and simply pursue tracking of the components of (11.41) that do not conflict with the primary task [11.50, 51], namely

$$\dot{q} = J_t^\dagger \dot{i} + (I - J_t^\dagger J_t)J_c^\dagger \dot{i}_c. \quad (11.44)$$

An intuitive justification of this solution can be given as follows: The pseudoinverses J_t^\dagger and J_c^\dagger are used to solve separately for the joint velocities associated with the respective task velocities; the joint velocity associated with the (secondary) constraint task is then projected onto the null space of J_t to remove the components that would interfere with the (primary) end-effector task and finally added to the joint velocity associated with the end-effector task. As a result, a nice property of solution (11.44) is that algorithmic singularities are decoupled from the singularities of J_c .

By construction, the solution (11.44) leads to larger constraint-task reconstruction errors than solution (11.43); this is the price paid to give smooth and feasible trajectories for the joint velocity in tracking conflicting tasks. Nevertheless, solution (11.44) is better used in a CLIK implementation which allows to recover the secondary-task tracking error out of the algorithmic singularities. In this case, it becomes

$$\dot{q} = J_t^\dagger w_t + (I - J_t^\dagger J_t)J_c^\dagger w_c$$

with

$$w_t = \dot{i} + K_t(t - k_t(q))$$

$$w_c = \dot{i}_c + K_c(t_c - k_c(q)).$$

11.6 Second-Order Redundancy Resolution

Redundancy resolution at the acceleration level allows the consideration of dynamic performance along the manipulator motion. Moreover, the obtained acceleration profiles can be directly used as reference signals (together with the corresponding positions and velocities) of a task-space dynamic controller. On the other hand, a second-order redundancy resolution scheme is

inevitably more demanding in terms of computational load.

The simplest scheme operating at the acceleration level is represented by (11.15), i. e., the solution with the minimum norm among those which realize the task constraint (11.8). Similarly to the velocity-level pseudoinverse solution, the joint movement generated by

this locally optimal solution does not provide global acceleration minimization along the whole manipulator motion. Remarkably, however, the use of (11.15) leads to the minimization over $[t_i, t_f]$ of the integral index

$$\int_{t_i}^{t_f} \dot{\mathbf{q}}^\top \ddot{\mathbf{q}} dt,$$

provided that the appropriate boundary conditions are satisfied [11.52], for example, in the case of free endpoints (neither joint positions nor velocities specified at t_i and t_f) the boundary conditions to be satisfied are split and expressed as

$$\dot{\mathbf{q}}(\bar{t}) = \mathbf{J}_t^\dagger \dot{\mathbf{t}}(\bar{t}) \quad \bar{t} = t_i, t_f.$$

In spite of the apparent simplicity and elegance of the solution (11.15), therefore, actual minimization of the above integral cost requires the solution of a two-point boundary value problem (TPBVP), which is a computationally intensive numerical procedure impractical for real-time kinematic control. However, this may be perfectly acceptable for offline redundancy resolution in an industrial setting.

More flexibility in the choice of (both local and global) performance criteria is obviously obtained by considering the full second-order solution (11.14). Let the manipulator dynamic model be expressed as

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\tau}_g(\mathbf{q}), \quad (11.45)$$

where $\boldsymbol{\tau}$ is the vector of actuator torques, \mathbf{H} is the manipulator inertia matrix, \mathbf{c} is the vector of centrifugal/Coriolis terms, and $\boldsymbol{\tau}_g$ is the gravitational torque vector. Choosing the null-space acceleration in (11.14) as

$$\ddot{\mathbf{q}}_0 = -[\mathbf{H}(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t)]^\dagger \tilde{\boldsymbol{\tau}}, \quad (11.46)$$

with

$$\tilde{\boldsymbol{\tau}} = \mathbf{H} \mathbf{J}_t^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) + \mathbf{c} + \boldsymbol{\tau}_g.$$

leads to the local minimization of the actuator torque norm $\boldsymbol{\tau}^\top \boldsymbol{\tau}$ [11.53]. This particular redundancy resolution scheme performs reasonably over short tasks, but may lead to instability (more precisely, very high joint torques) in the long run, essentially due to the build-up of null-space joint velocities. Note also that the matrix product $\mathbf{H}(\mathbf{I} - \mathbf{J}_t^\dagger \mathbf{J}_t)$ in (11.46) is not full-rank, so that its pseudoinverse must be computed through a SVD procedure. Minimization of the integral joint torque is also possible [11.54]; this solution obviously avoids the instability problem, but once again the solution of a TPBVP is required.

Another interesting inverse solution is the following

$$\ddot{\mathbf{q}} = \mathbf{J}_{t,H}^\dagger (\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t \dot{\mathbf{q}}) + (\mathbf{I} - \mathbf{J}_{t,H}^\dagger \mathbf{J}_t) \mathbf{H}^{-1} \mathbf{c}, \quad (11.47)$$

which is slightly modified with respect to the general formula (11.14) in view of the use of a weighted pseudoinverse. In particular, $\mathbf{J}_{t,H}^\dagger$ is the inertia-weighted task Jacobian pseudoinverse, given in the full-rank case by the following expression

$$\mathbf{J}_{t,H}^\dagger = \mathbf{H}^{-1} \mathbf{J}_t^\top (\mathbf{J}_t \mathbf{H}^{-1} \mathbf{J}_t^\top)^{-1}.$$

The solution (11.47) minimizes

$$\int_{t_i}^{t_f} \frac{1}{2} \dot{\mathbf{q}}^\top \mathbf{H}(\mathbf{q}) \dot{\mathbf{q}} dt,$$

i.e., the integral over $[t_i, t_f]$ of the manipulator kinetic energy [11.52]. Once again, the correct boundary conditions must be used; for example, the case of free endpoints leads to

$$\dot{\mathbf{q}}(\bar{t}) = \mathbf{J}_{t,H}^\dagger \dot{\mathbf{t}}(\bar{t}) \quad \bar{t} = t_i, t_f.$$

11.7 Cyclicity

A common drawback of redundancy resolution schemes based on differential kinematics is the lack of *cyclicity* (also called *repeatability*): in general, the joint-space trajectory corresponding to a cyclic task space trajectory is not cyclic itself (i.e., the final position of the joints does not coincide with the initial position). This phenomenon is clearly undesirable, because it basically means that the behavior of the manipulator along periodic tasks to be repeated over and over is unpredictable.

A mathematical condition for cyclicity exists for a particular class of redundancy resolution methods [11.55]. In particular, consider any scheme of the form

$$\dot{\mathbf{q}} = \mathbf{G}_t(\mathbf{q}) \dot{\mathbf{t}}, \quad (11.48)$$

where \mathbf{G}_t is any *generalized inverse* of the task Jacobian \mathbf{J}_t , i.e., an $N \times M$ matrix such that $\mathbf{J}_t \mathbf{G}_t \mathbf{J}_t = \mathbf{J}_t$ (the pseudoinverse matrix \mathbf{J}_t^\dagger in (11.13) is a particular

generalized inverse). Assume that the assigned task $t(t)$ describes a cyclic trajectory in a simply connected region of the task space, and denote by $\mathbf{g}_{ti}(\mathbf{q})$ the i -th column of \mathbf{G}_t . A necessary and sufficient condition for (11.48) to generate cyclic joint trajectories is that the *distribution*

$$\Delta_{\mathbf{G}_t}(\mathbf{q}) = \text{span}\{\mathbf{g}_{t1}(\mathbf{q}), \dots, \mathbf{g}_{tM}(\mathbf{q})\}$$

is involutive (i.e., it is closed under the Lie bracket operation).

It should be emphasized that the involutivity of $\Delta_{\mathbf{G}_t}$ is a strong condition, because it must be satisfied at any configuration. This suggests that most generalized inverses are not cyclic. Note also that the above condition

for cyclicity depends on the chosen generalized inverse (i.e., pseudoinverse, weighted pseudoinverse, and so on) as well as on the form of \mathbf{J}_t , which in turn is related to the mechanical structure of the manipulator. This means that cyclicity must be established on a case-by-case basis.

As for redundancy resolution schemes which do not fall in the class (11.48) – namely, those entailed by the general inverse solution (11.12) – they are in general not cyclic. In particular, this is true for when local optimization is used to solve redundancy, as in (11.32). A notable exception is the extended Jacobian method, which is always cyclic.

11.8 Hyperredundant Manipulators

A natural question arising from consideration of kinematic redundancy is: what happens as the number of joints (and hence degree of redundancy) becomes much larger than the task-space dimension, and ultimately increases towards infinity? Examples of serial rigid-link systems with many joints exist in nature (snakes, and mammalian and fish backbones, for example), and these biological *existence proofs* have provided motivation and insight for robot analysts and hardware designers for many years. This interest has resulted in the development of several special sub-classes of redundant manipulators, collectively known as *hyperredundant manipulators*. This section reviews the underlying issues and state of the art in this interesting area.

A manipulator is generally considered to be hyperredundant if its controllable configuration (joint) space degrees of freedom are comparable to, or exceed, its task space degrees of freedom. (Hence, seven- or eight-DOF spatial rigid-link manipulators are not usually considered to be hyperredundant.) Hyperredundant manipulators have enhanced potential to use their extra joints for whole arm grasping/manipulation and maneuvering within tight obstacle fields. Their anticipated applications therefore include operations in congested environments (disaster relief, medical applications, etc.).

Since as we have seen the addition of (any) redundant degrees of freedom adds fundamentally new capabilities (self-motion, subtask performance capability), intuitively it would seem that the addition of abundant degrees of freedom would enable (and demand from motion planners) increasingly novel and sophisticated behaviors. However, on closer observation, many of the motivating biological hyperredundant systems actu-

ally perform relatively restricted movements, controlled by very simple algorithms. For example, (biological) snake backbones have very many joints, yet snake movement is typically restricted to approximately sinusoidal motions, governed by simple parameters (amplitude, frequency). Therefore there are some key simplifications which designers and algorithm developers have sought and made use of in the development of hyperredundant manipulators, as discussed in Sect. 11.8.3.

In terms of hardware development, the field has evolved in two major directions: *vertebrate-like* rigid-link designs, and *invertebrate-like* continuum manipulators. Summaries of the history and state of the art of each of these areas are given in the following two subsections. This is followed by a discussion of the unique analysis techniques required of and developed for hyperredundant robot systems. In all cases, the key issue is that of handling complexity, in one form or another.

11.8.1 Rigid-Link Hyperredundant Designs

This category of hyperredundant manipulators is perhaps the most *natural*, in terms of being the logical evolution from traditional serial rigid link manipulators (redundant or not). Designs in this category feature a hyperabundance of joints in their (usually serial) rigid-link structure. A good early example of this class of manipulator hardware is the **JPL Serpentine Robot** [11.56], which featured 12 degrees of freedom in a modular design.

The general trend has to shrink the size of the links, so that the robot structure resembles that of a biolog-

Fig. 11.4 17-DOF robot (courtesy Robotics Research Corporation)

ical *backbone*. This approach conceptually allows the development of manipulators with a very high degree of redundancy; for example, the 30-DOF planar manipulator developed at Caltech [11.57] remains perhaps the best known hyperredundant manipulator.

Note that various types of *nontraditional* rigid-link based manipulator systems can be classified as hyperredundant systems within this category. A novel elephant's trunk was based on a design featuring a 32-DOF backbone [11.58]. Several *dual-arm/torso* designs [11.59] including **NASA's special-purpose dexterous manipulator (SPDM)** [11.60] can be grouped in this category of hyperredundant manipulators, and researchers in the area of humanoid robots have made contributions to the area, both in terms of theory and hardware.

Another important special group in this category is that of robotic snakes. This area owes much to the pioneering work of Hirose [11.61], who analyzed the movements of (biological) snakes and incorporated the understanding generated into the design and control of a series of innovative snake-like robots. Of particular in-

Fig. 11.5 The **NASA** special-purpose dexterous manipulator (SPDM) (courtesy MDA Federal)

Fig. 11.6 Active cord mechanism (courtesy S. Hirose)

terest here were the series of hyperredundant *active cord mechanism (ACM)* robots developed by Hirose's group.

Numerous other snake robot designs have been proposed over the years, and the area continues to be highly active.

The key conceptual advantage of rigid-link hyperredundant designs is that they inherit the kinematics of their conventional industrial manipulator counterparts. Therefore, all the traditional modeling techniques (for example Denavit–Hartenberg-based approaches for modeling the forward kinematics and finding the manipulator Jacobian) apply. Therefore, in theory all the techniques discussed earlier in this chapter apply directly to this category of hyperredundant manipu-

Fig. 11.7 The OctArm continuum manipulator (courtesy I. Walker)

lator (although complexity of the resulting models is a key obstacle to analysis and understanding). However, the second main category, overviewed in the following subsection, by taking hyperredundancy to its logical extreme, does not inherit these particular advantages.

11.8.2 Continuum Robot Designs

The term *continuum manipulator*, first coined in [11.62], indicates the hyperredundant robot concept taken to the extreme. In other words, conceptually this category of robots have backbone structures *taken to the limit*, with their number of *joints* tending to infinity, but with their *link lengths* tending to zero. While this concept initially appears idealistic, complicated, and impossible to implement, the limiting case (a smooth *continuum* curve, with the ability to bend at any point along the backbone) is quite easy to realize in hardware. Numerous continuum designs have been proposed since the early 1960s [11.62, 63]. The key design issues revolve around how to actuate (bend and possibly extend/contract) the backbone. Two basic design strategies have emerged: (1) extrinsic actuation, where the actuators are separate from the backbone structure [11.64]; and (2) intrinsic actuation, where the actuators represent a fundamental part of the backbone, e.g., [11.65]. Tendons have proved a popular and generally successful choice for intrinsically actuated continuum designs [11.58, 64]. Artificial muscle technologies, notably *McKibben* muscles, have proved effective in intrinsically actuated hardware realizations [11.65].

A commercially successful group of extrinsically actuated continuum manipulators are currently manu-

Fig. 11.8 The continuum manipulator (courtesy OC Robotics)

factured and retailed by OCR Robotics in the United Kingdom [11.64].

While continuum manipulators are thus seen to be the extreme case of hyperredundancy, it was quickly realized that they represent a fundamentally new class of manipulators [11.62]. A continuous flexible backbone features, at least in theory, an infinite number of degrees of freedom. As such, the traditional tools in robotics for modeling (a finite number of) serial rigid links no longer apply. Additionally, it is obviously not possible to actuate an infinite number of degrees of freedom in practice. Continuum manipulator hardware universally features a finite number of actuators, applying forces/torques to the backbone at a fixed and preselected set of locations. Continuum robots are therefore inherently both hyperredundant and underactuated. This causes significant complexity in their analysis. However, significant progress has been made, and understanding resulting from analysis of continuum kinematics has been applied to the benefit of both continuum and non-continuum hyperredundant manipulators, as discussed in the following subsection.

11.8.3 Hyperredundant Manipulator Modeling

Clearly, to correctly model continuum manipulators, models based on continuous backbones are required. Interestingly, such models have also proved to be key theoretical resources in the motion planning of rigid-link hyperredundant systems. As noted earlier, in theory discrete-link hyperredundant manipulators can be modeled using (and their planning based on) traditional manipulator modeling techniques. However, it was quickly found that the computational complexity of such approaches made them difficult to implement, and the corresponding models hard to visualize. An alternative strategy (and a more successful one in practice) has been to adopt an approach based on continuum manipulator kinematics. In the following, we overview the recent development of continuum manipulator kinematics. We then discuss how the existence of both discrete-link and continuum models have enhanced motion planning for each category of hyperredundant system.

The lack of distinct links in continuum systems makes the standard robot manipulator modeling strategy of a finite number of coordinate frames (each fixed in one link) inappropriate for their modeling. Instead, the natural approach is to model continuum kinematics via a frame that evolves along the backbone, parameterized by arc length s . Local motion of the backbone at point s is modeled in terms of the local frame. This strategy allows computation of *forward kinematics*, and the construction of *continuum Jacobians*, analogous to those for rigid-link systems [11.65, 66].

Numerous alternatives for selection of the backbone frame have been proposed [11.67, 68]. A popular choice is the well-known Serret–Frenet frame [11.66], which evolves along the backbone according to:

$$\begin{aligned}\frac{dt}{ds} &= \kappa n, \\ \frac{dn}{ds} &= -\kappa t + \tau b, \\ \frac{db}{ds} &= -\tau n.\end{aligned}$$

In the above, the frame origin is given by x , where the unit tangent to the curve $t = dx/ds$, and forms one of the frame axes. The other axes are defined as the normal ($t \cdot n = 0$) and the binormal $b = t \times n$. The curvature κ and torsion τ dictate the shape of the curve. The axes of the Serret–Frenet frame provide an intuitive visualization of local movement: two possible dimensions of bending, corresponding to rotations

about the normal and binormal axes, and one of extension/contraction (present and controllable in several continuum robots), corresponding to translation along the tangent axis. The Frenet–Serret model has the advantage of being a well-established means for modeling continuous spatial curves. Alternative frame representations in the continuum robot literature have selected the axes of the frame to align with the controlled motion axes of particular hardware realizations [11.68]. In either case, given a frame, the key problem is how to use the resulting model to plan motions for hyperredundant robots. The basic issue is that the continuum kinematics models in their basic form feature infinite degrees of freedom (as necessary to model arbitrary spatial curves). However, hyperredundant robots (discrete-joint or continuum) can be controlled in only a finite number of ways, thus admitting a reduced set of physical solutions. Therefore, research in hyperredundant manipulators has concentrated on how to constrain continuum kinematics models to best represent robot hardware.

The initial major breakthrough in motion planning for hyperredundant arms was made in a landmark series of papers [11.57, 67, 69] introducing continuum kinematics and using them to approximate rigid-link hyperredundant systems [11.67]. Basically the philosophy is to use a (theoretical) curve to model the physical backbone of a hyperredundant robot. Motion planning is performed for the curve, and the (discrete) robot backbone is then *fitted* to the resulting (continuous) solution curve. This approach has proved quite effective, and the associated research introduced several key theoretical concepts to the area. In particular, the use of a modal approach [11.69] (restricting the classes of allowable solutions to shapes generated via simple linear combinations of *modes*), arose from this approach to redundancy resolution for hyperredundant manipulators. This influential concept can be viewed as a *top-down* approach of building a general model, and adapting it (via mode selection and curve fitting) to hardware.

More recent research has concentrated on the *dual* notion to that of the previous section, using the physical constraints imposed on the backbones of specific continuum robot hardware types to construct continuum kinematics. This can be viewed as a *bottom-up* approach, focused on particular hardware classes, with the main aim of sufficiently modeling the hardware to avoid the use of approximations in the motion planning. Examples of this approach are given in [11.65, 68], where the key constraint imposed on a general continuum kinematics model arises from the observation that many continuum hardware implementations resolve into

a finite number of constant curvature sections. (This arises naturally from the imposition of a finite number of input force/torques on a stiff continuum backbone.) In [11.65] it is noted that the resulting constant-curvature models can be viewed as a particular case of the general modal approach of [11.69].

The above approach [11.65] involves several transformations, to transition the map between task and actuator space via a *section* space. As a key part of this transformation, a conventional (theoretical) rigid-link model is used to model the kinematics of each section. Thus rigid-link kinematics have proven key to resolving redundancy for continuum manipulators, as continuum kinematics play a key part in redundancy

resolution for rigid-link hyperredundant arms. Finally, a series of Jacobians are formed. The difference here is that the continuum Jacobian is a function of locally meaningful variables (bending angle, curvature, and extension) defining section shape or the direct values of the actuators that determine these variables. Given the existence of continuum Jacobians, the redundancy is usually resolved as

$$\dot{\boldsymbol{I}} = \boldsymbol{J}_E^\dagger \dot{\boldsymbol{i}}_E + (\boldsymbol{I} - \boldsymbol{J}_E^\dagger \boldsymbol{J}_E) \dot{\boldsymbol{I}}_0$$

in the same way as for conventional redundant manipulators (and with the same general corresponding advantages and issues), as discussed earlier in the chapter.

11.9 Conclusion and Further Reading

Research on kinematically redundant robots has been flourishing for over two decades now, and is still very active. The number of papers dealing with this subject is therefore enormous. The few works cited below are simply a small addition to the fundamental contributions already referenced so far, and constitute by no means an exhaustive list.

The mechanical design of kinematically redundant manipulators has been studied in many papers, see, e.g., [11.70–74]. In particular, the superiority of human-arm-like manipulators over conventional 6-DOF robots was first advocated in [11.75]. Reconfiguration of this arm so as to ensure full mobility in the whole workspace is studied in [11.76, 77].

A general analysis of the inverse kinematic problem for redundant manipulators is presented in [11.78]. In particular, the geometric structure of self-motions is analyzed in [11.79].

Weighting the damped least-squares solution for guaranteed singularity avoidance in anisotropic end-effector tasks was proposed in [11.9, 21, 80].

In addition to singularity avoidance, redundancy has also been exploited to achieve obstacle avoidance [11.37, 46, 81, 82], minimization of the effects of joint elasticity [11.83], fault tolerance [11.84], reduction of impact force [11.85, 86], and maximization of various dexterity measures [11.4, 5, 43, 87]. A completely different approach for obstacle avoidance with redundant robots is presented in [11.88].

A review of redundancy resolution via local optimization is given in [11.89]. A numerically efficient alternative for redundancy resolution via local optimization is proposed in [11.90]. A redundancy resolution approach with somehow intermediate characteristics between local and global optimization is presented in [11.91]. Other methods for second-order redundancy resolution are discussed, e.g., in [11.92]. Also worth citing is the dynamically consistent generalized inverse of [11.93].

The cyclicity issue was first pointed out in [11.94], and further investigated, e.g., in [11.95, 96]. General formalisms for redundancy resolution of vehicle-manipulator systems subject to nonholonomic constraints are described in [11.97, 98].

Parallel Mechanisms and Robots

Jean-Pierre Merlet, Clément Gosselin

This chapter presents an introduction to the kinematics and dynamics of parallel mechanisms, also referred to as parallel robots. As opposed to classical serial manipulators, the kinematic architecture of parallel robots includes *closed-loop kinematic chains*. As a consequence, their analysis differs considerably from that of their serial counterparts. This chapter aims to presenting the fundamental formulations and techniques used in their analysis.

12.1 Definitions

A *closed-loop kinematic chain* is one in which the links and joints are arranged such that at least one closed loop exists. Furthermore, a *complex closed-loop kinematic chain* is obtained when one of the links – other than the base – has a degree of connectivity greater than or equal to three, i. e., one link other than the base is connected through joints to at least three other links. A *parallel manipulator* can be defined as a closed-loop mechanism composed of an end-effector having n degrees of freedom and a fixed base, linked together by at least two independent kinematic chains.

An example of such a structure was patented in 1928 by *Gwinnett* [12.1] to be used as a platform for a movie theater. In 1947 *Gough* [12.2] established the basic principles of a mechanism with a closed-loop kinematic structure (Fig. 12.1) that allows the positioning and orientation of a moving platform so as to test tire wear and tear. He built a prototype of this machine in 1955. For this mechanism, the moving effector is a hexagonal

platform whose vertices are all connected to a link by a ball-and-socket (spherical) joint. The other end of the link is attached to the base by a universal joint. A linear actuator allows the modification of the total length of the link; this mechanism is therefore a closed-loop kinematic structure, actuated by six linear actuators.

In 1965, *Stewart* [12.3] suggested the use of such a structure for flight simulators and the Gough mechanism is sometimes referred to as a *Stewart platform*. The same architecture was also concurrently proposed by *Kappel* as a motion simulation mechanism [12.4]. Nowadays the Gough platform is the platform of choice for flight simulators. The latter application provides a convincing illustration of the main advantage of parallel robots namely, their load-carrying capacity. Indeed, while the ratio of the mass of the payload over the mass of the robot is typically smaller than 0.15 for serial 6R industrial robots, this ratio can be larger than 10 for parallel structures. Another advantage of the Gough platform is

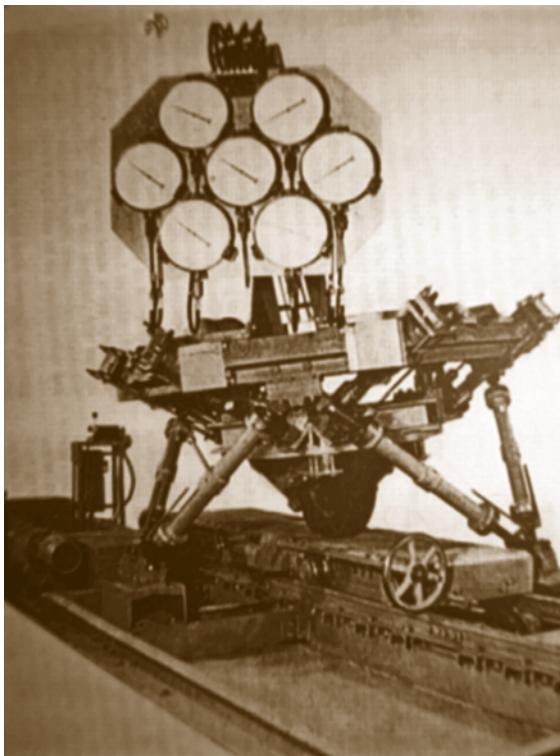

Fig. 12.1 Gough platform (1947)

its very good positioning accuracy. This high accuracy arises from the fact that the legs are working essentially in tension/compression and are subjected to virtually no bending – thereby leading to very small deformations – and from the fact that the errors in the internal sensors of the robot (the measurement of the lengths of the legs for the Gough platform) are mapped into very small errors of the platform position. Parallel robots are also almost insensitive to scaling (the same structure can be used for large or micro robots) and they can be built using almost any type of actuator or transmission, for example, wire transmissions can be used (see the *Robocrane* [12.5]). The main drawbacks of parallel robots are their small workspace and the singularities that can appear within the latter.

Apart from the Gough platform, the most successful designs of parallel robots are the Delta robot proposed by Clavel [12.6] (Fig. 12.2) and some planar parallel robots. The most common planar parallel robots have three identical legs each having an RPR or RRR architecture, where the underlined joint is the actuated one;

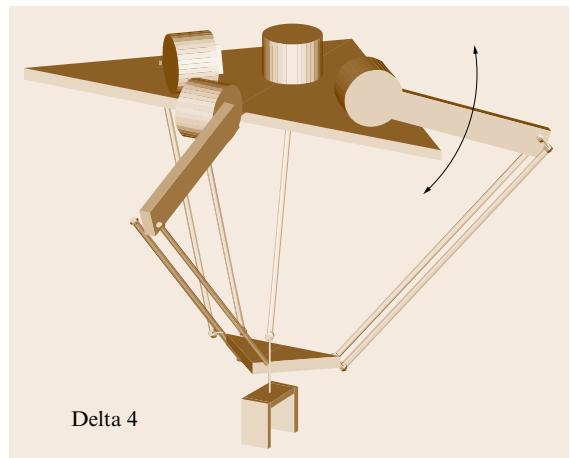

Fig. 12.2 The Delta robot

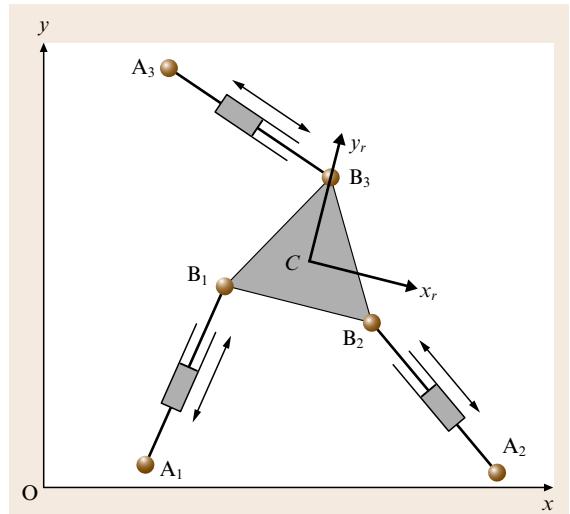

Fig. 12.3 The 3 – RPR planar parallel robot

such robots are often denoted as 3 – RPR (see Fig. 12.3) and 3 – RRR.

The geometric arrangement of the joints and links of the Delta structure provides three translational degrees of freedom at the platform. Numerous other types of parallel robots have been proposed in recent years. Although most existing architectures are based on the intuition of their designer, the synthesis of parallel mechanisms can be dealt with systematically. An overview of the main approaches to the type synthesis of parallel mechanisms is given in the next section.

12.2 Type Synthesis of Parallel Mechanisms

Determining all potential mechanical architectures of parallel robots that can produce a given motion pattern at the moving platform is a challenging problem. Several authors have addressed this problem, referred to as type synthesis. The approaches proposed in the literature can be divided into three groups:

- *Approaches based on graph theory*: the enumeration of all possible structures having a given number of degrees of freedom (DOFs) can be performed by considering that there is only a finite set of possible kinematic pairs, and hence a very large, but finite, set of possible structure combinations (see, for instance, [12.7]). Classical mobility formulae – e.g., the Chebychev–Grübler–Kutzbach formula – are then used to determine the number of DOFs in the structure. Unfortunately these formulae do not take into account geometric properties of the mechanism that can change the number of DOFs of the platform. Therefore, synthesis approaches based strictly on graph theory can produce only limited results and have been largely superseded by the other two groups.
- *Approaches based on group theory*: the motion of a rigid body has the special structure of a group, the *displacement group*. Subgroups of the group of displacements, such as the spatial translations or all the translational and rotational motions about all axes that are parallel to the axis defined by a given vector (Schönlies motion) play an important role as they can be combined through the *intersection* operation [12.8] when elements of subgroups act on the same rigid body. Type synthesis consists in determining all the possible subgroups to which the different kinematic chains that will constitute the legs of the robot may belong so that their intersection leads to the desired motion pattern for the platform. Synthesis approaches based on group theory led to the discovery of numerous possible architectures. Nevertheless, the displacement group has special properties that are not reflected by its group struc-

ture alone. Also, the approach is limited to motion patterns that can be described by a subgroup of the displacement group.

- *Approaches based on screw theory*: in this approach, the first step is to determine the wrench system S that is reciprocal to the desired velocity twist of the moving platform. Then, the wrenches of the kinematic chains of the robot whose union spans the system S (and that determine all the possible structures of the kinematic chains that will generate the corresponding wrenches) are enumerated. Then, since all considered twists and wrenches are instantaneous, it is necessary to verify that the mobility of the platform is full-cycle and not only instantaneous. A systematic implementation of this approach is provided in [12.9].

These synthesis methods have been used to generate a large number of architectures that cannot be presented in this book, but the Web site of Merlet [12.10] presents a comprehensive description of a large number of mechanical architectures. Among others, several remarkable architectures were proposed in the recent years to fully or partially decouple translational motions or Schönlies motions (see [12.9] and the references therein).

It should also be pointed out that for robots with fewer than six DOFs, synthesis methods generally lead to architectures that must satisfy stringent geometric constraints (such as for the Delta robot, where the axes of the parallelograms should be parallel and their sides of equal length). Such constraints cannot be exactly verified in practice and consequently the manipulator will exhibit *parasitic*, i.e., unwanted, motion. Open issues therefore include:

- the determination of the maximal amplitude of the parasitic motion over a given workspace and for a given robot
- the determination of the geometry of a given structure such that the maximal amplitude of the parasitic motion will be smaller than a given threshold

12.3 Kinematics

12.3.1 Inverse Kinematics

The solution of the inverse kinematic problem is usually straightforward for parallel robots. This can be illus-

trated with the Gough platform. The solution of the inverse kinematic problem consists in determining the vector of leg lengths \mathbf{q} for a given pose of the platform defined by the position vector \mathbf{p} of a given point on the

platform in a fixed reference frame and a rotation matrix \mathbf{R} representing the orientation of the platform with respect to the fixed frame. Let \mathbf{a}_i denote the position vector of the anchor point of the i th leg on the base given in the fixed reference frame and \mathbf{b}_i denote the position vector of the anchor point of the i th leg on the platform, given in a moving frame attached to the platform. The length of the i th leg is the norm of the vector connecting the two anchor points. The latter vector, denoted by \mathbf{s}_i , can be written as

$$\mathbf{s}_i = \mathbf{p} + \mathbf{R}\mathbf{b}_i - \mathbf{a}_i, \quad i = 1, \dots, 6. \quad (12.1)$$

Given the pose of the platform (vector \mathbf{p} and matrix \mathbf{R}), the vector \mathbf{s}_i is readily calculated using (12.1), and hence the leg lengths can be obtained.

12.3.2 Forward Kinematics

The solution of the forward kinematic problem consists in determining the pose of the platform for a given set of actuated joint coordinates (a given vector \mathbf{q}). This solution is needed for control purposes, calibration, and motion planning.

The forward kinematic problem of a parallel robot is usually much more complex than the inverse kinematic problem. Indeed, the loop closure equations (12.1) are typically highly nonlinear expressions of the pose variables. They form a nonlinear set of equations that generally admits multiple solutions (for example the Gough platform can have up to 40 solutions [12.11–13], while a table with the number of solutions for Gough platforms with special geometries is provided in [12.14]). The forward kinematic problem arises in two different contexts. In the first case, no estimate of the current pose of the platform is available (for example, when starting the robot) while in the second case, a relatively precise estimate of the pose is known (for example in real-time control when the forward kinematics has been solved at the previous sampling time of the controller). In the first case, the only known approach is to determine all the solutions of the inverse kinematic equations, although there is no known algorithm to sort the set of solutions. It is often possible to determine an upper bound on the number of real solutions. Consider for example the case of the planar 3 – $R_P R$ robot (Fig. 12.3), where the fixed reference frame has its origin at point A_1 and its x -axis passes through the point A_2 . Similarly, point B_1 is chosen as the origin of the moving frame while the x -axis of this frame passes through point B_2 . The pose of the platform is then defined by the coordinates (x, y) of point B_1 in the fixed reference frame and by the angle θ between the x -axes of the reference and moving frames. The known length q_1 of link 1 is also known that point B_3 of the lever moves on a cir-

cle, i. e., a second-order algebraic curve. For a given set of actuated joint coordinates, solutions to the forward kinematic problem arise when the two curves intersect, i. e., when the mechanism can be assembled. Bezout's theorem states that algebraic curves of order m, n intersect at nm points, counting their order of multiplicity. In the above case, this means that the curves intersect in 12 points. However, these 12 points include the two circular imaginary points that belong to the coupler curve of the four-bar linkage and to any circle, thereby to their intersection. These points are counted three times in Bezout's theorem and hence the forward kinematic problem will have at most six real solutions, corresponding to the intersection points.

Various methods have been proposed for the solution of the forward kinematic problem: elimination [12.15], continuation [12.13], Gröbner bases [12.16], and interval analysis [12.17]. Elimination is usually not very stable numerically (i. e., it can produce spurious roots and miss solutions) unless special care is taken in the implementation of the resulting univariate equation and the elimination steps. For instance, the transformation of polynomial solutions into eigenvalue problems can be used [12.18]. Polynomial continuation, on the other hand, is much more stable numerically since mature algorithms can be found in the literature [12.19]. The fastest methods – although not appropriate for real-time use – are Gröbner bases and interval analysis. They also have the advantage of being numerically certified (no roots can be missed and the solution can be computed with an arbitrarily prescribed accuracy).

However, in the simplest cases, elimination can usually be used to produce stable implementations. Consider, for example, the case of the planar 3 – $R_P R$ robot (Fig. 12.3), where the fixed reference frame has its origin at point A_1 and its x -axis passes through the point A_2 . Similarly, point B_1 is chosen as the origin of the moving frame while the x -axis of this frame passes through point B_2 . The pose of the platform is then defined by the coordinates (x, y) of point B_1 in the fixed reference frame and by the angle θ between the x -axes of the reference and moving frames. The known length q_1 of link 1 can thus be written simply as

$$q_1^2 = x^2 + y^2. \quad (12.2)$$

Then, the length q_i of the other links can be written as:

$$q_i^2 = x^2 + y^2 + g_i(x, y, \theta), \quad i = 2, 3, \quad (12.3)$$

where g_i is linear in x, y . Subtracting the length of link 1 from the latter two equations leads to a linear system of

two equations in the unknowns x and y . This system is solved and x and y are obtained as functions of θ . The expressions for x and y are then substituted into (12.2), thereby leading to a single equation in the unknown θ . This unknown appears in the equation through its sine and cosine, and by using the Weierstrass substitution, the equation can be transformed into a sixth-order polynomial equation in the unknown $T = \tan(\theta/2)$. Solving this equation in T allows one to compute all possible solutions in θ , from which the values of x and y are readily obtained. It is noted that this polynomial is of minimal degree since it was established that the number of real solutions cannot exceed six. It can also be shown that there exist configurations of the robot for which there are exactly six real solutions to the forward kinematics. Finally, it should be pointed out that the forward kinematic problem of the 3–RRR robot is mathematically exactly the same as the one developed above for the 3–RPR robot. This is typical for parallel robots.

When a priori information (an initial guess of the solution) is available, the forward kinematics is usually solved using the Newton–Raphson or the Newton–Gauss iterative scheme. Consider the solution to the inverse kinematic problem, written as:

$$\mathbf{q} = \mathbf{f}(\mathbf{x}). \quad (12.4)$$

Iteration k of the Newton–Raphson procedure is written as

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{A}(\mathbf{q} - \mathbf{f}(\mathbf{x}_k)), \quad (12.5)$$

where \mathbf{q} is the vector of prescribed joint variables. The matrix \mathbf{A} is usually chosen as $(\frac{\partial \mathbf{f}}{\partial \mathbf{q}})^{-1}(\mathbf{x}_k)$ (the inverse matrix may not be computed at each iteration or even be chosen as constant). The iterative scheme stops when the magnitude of the difference vector $(\mathbf{q} - \mathbf{f}(\mathbf{x}_k))$ is smaller than a chosen threshold.

The choice of the inverse kinematics equations plays an important role in the convergence of this method [12.20]. For example, for a Gough platform, a minimal set of equations (six equations involving six

unknowns: three for the translation and three orientation angles) can be used, but other representations are possible. For instance, the position coordinates of three of the platform anchor points – in the fixed reference frame – can be used as unknowns (the coordinates of the remaining three points are then readily computed upon convergence). Using this representation, nine equations are needed. Six equations are obtained based on the known distances between the anchor points on the base and platform and three additional equations are obtained based on the known distances between all combinations of the three selected platform anchor points.

Provided that a good initial estimate of the solution is available, the Newton–Raphson algorithm is usually very fast. However, the procedure may not converge or, even worse, it may converge to a solution that is not the correct pose of the platform, i.e., it may converge to another assembly mode. Such a situation may occur even if the initial guess is arbitrarily close to the correct pose. If the result is used in a control loop, the consequences can be catastrophic. Fortunately mathematical tools such as the Kantorovitch theorem combined with interval analysis can be used to determine if the solution found by the Newton–Raphson scheme is the correct pose of the robot, i.e., to certify the result at the cost of a larger computation time, yet still compatible with real time [12.17].

Another possible approach for the solution of the forward kinematic problem is either to add sensors on the passive joints (e.g., on the U joints of a Gough platform) or to add passive legs with sensed joints. The main issue is then to determine the number and location of the additional sensors that will lead to a unique solution [12.21, 22] and to determine the effect of the sensor errors on the positioning error of the platform. For example, Stoughton mentions that, for a Gough platform with sensors in the U joints, it was still necessary to use the Newton–Raphson scheme to improve the accuracy of the solution because the solutions obtained with the additional sensors were very sensitive to measurement noise [12.23].

12.4 Velocity and Accuracy Analysis

Similarly to serial robots, the actuated joint velocity vector of parallel robots $\dot{\mathbf{q}}$ is related linearly to the vector of translational and angular velocities of the platform (for simplicity, the latter vector is denoted here by $\dot{\mathbf{p}}$, although the angular velocity is not the time derivative

of any set of angular parameters). The linear mapping between the two vectors is provided by the Jacobian matrix \mathbf{J} :

$$\dot{\mathbf{p}} = \mathbf{J}(\mathbf{p})\dot{\mathbf{q}}. \quad (12.6)$$

However, for parallel robots, a closed-form expression is usually available for the inverse Jacobian \mathbf{J}^{-1} , but this is much more difficult for \mathbf{J} (more precisely, the closed form for most six-DOF robots will be so complex that it cannot be used in practice). For example, a simple static analysis can be used to show that the i th row \mathbf{J}_i^{-1} of matrix \mathbf{J}^{-1} for a Gough platform can be written as

$$\mathbf{J}_i^{-1} = \mathbf{n}_i^\top (\mathbf{c}_i \times \mathbf{n}_i)^\top, \quad (12.7)$$

where \mathbf{n}_i represents the unit vector defined along leg i and \mathbf{c}_i is the vector connecting the origin of the mobile frame attached to the platform to the i th anchor point on the platform.

The effect of the joint sensor errors $\Delta\mathbf{q}$ on the positioning error $\Delta\mathbf{p}$ follows the same relationship, namely

$$\Delta\mathbf{p} = \mathbf{J}(\mathbf{p})\Delta\mathbf{q}. \quad (12.8)$$

Since the matrix \mathbf{J} is difficult to obtain in closed form, accuracy analysis (i.e., finding the maximal positioning errors over a given workspace for bounded joint sensor errors) is much more difficult than for serial robots [12.20, 24]. Apart from the measurement errors, there are other sources of inaccuracy in parallel robots, namely: clearance in the passive joints, manufacturing tolerances, thermal errors, and gravity-induced and dynamic errors [12.25, 26]. The effect of joint clearances on trajectories followed by serial and parallel robots was studied in [12.27–29]. According to these works, it

is impossible to determine trends for the effect of the geometric errors: a case-by-case study must be performed since the effect is highly dependent on the mechanical architecture, dimensioning, and workspace of the robot. Thermal effects are sometimes mentioned as possible sources of inaccuracy, although few works substantiate this claim [12.30] and cooling may slightly reduce their effects [12.31].

Calibration is another means of improving the accuracy of parallel robots. This issue was addressed in Chap. 3. The methods and procedures used for parallel robots differ slightly from the ones used for serial robots since only the inverse kinematic equations are available and since the positioning of the platform is much less sensitive to the geometric errors than in serial robots [12.32, 33]. Hence the measurement noise occurring during calibration has a significant impact and may lead to surprising results. For example, the classical least-squares method may lead to parameters that are such that some constraint equations are not satisfied even when the measurement noise is taken into account [12.34]. It has also been shown with experimental data that classical parallel robot modeling leads to constraint equations that do not have any solution irrespective of the measurement noise [12.35]. Moreover, calibration is very sensitive to the choice of the calibration poses [12.36]: it seems that the optimal choice is to select poses on the workspace boundary [12.37, 38].

12.5 Singularity Analysis

12.5.1 General Formulation

The analysis of singularities of parallel mechanisms was first addressed by Gosselin and Angeles [12.39]. In this formulation, the kinematic equations were reduced to the input–output relationship between the actuated joint coordinate vector \mathbf{q} and the platform Cartesian coordinate vector \mathbf{p} , namely

$$f(\mathbf{q}, \mathbf{p}) = 0. \quad (12.9)$$

Differentiating (12.9) with respect to time leads to

$$\mathbf{B}\dot{\mathbf{q}} + \mathbf{A}\dot{\mathbf{p}} = \mathbf{0}. \quad (12.10)$$

Three types of singularities can then be defined:

- when matrix \mathbf{B} is singular (termed serial singularity)
- when matrix \mathbf{A} is singular (termed parallel singularity)

- when the input–output equations degenerate (termed an architecture singularity) in which case matrices \mathbf{A} and \mathbf{B} can both be singular.

In a serial singular configuration, the joints can have a nonzero velocity while the platform is at rest. In a parallel singularity, there exist nonzero platform velocities for which the joint velocities are zero. In the neighborhood of such a configuration, the robot can undergo an infinitesimal motion while the actuators are locked. Since the mobility of the end-effector should be zero when the actuators are locked, it is also said that in such a configuration the robot *gains* some DOFs. As a consequence, certain degrees of freedom of the platform cannot be controlled, and this is a major problem.

A more general study of singularities was proposed by Zlatanov [12.40]. The latter analysis uses the velocity equations involving the full twist of the end-effector and

all joint velocities (passive or actuated). This approach led to a more detailed classification of singularities and was also used later to reveal special singularities (referred to as *constraint singularities*) [12.41] that could not be found with the analysis presented in [12.39].

The singularity analyses discussed above are of the first order. Second- (and higher-)order singularity analyses can also be performed, although the latter are much more complex [12.29, 42].

12.5.2 Parallel Singularity Analysis

This type of singularity is especially important for parallel robots because it corresponds to configurations in which the control of the robot is lost. Furthermore, very large joint forces can occur in the vicinity of singular poses, that may lead to a breakdown of the robot. The main issues to be addressed in this context are:

- the characterization of the singularities
- the definition of performance indices representing the closeness to a singularity
- the development of algorithms that are capable of detecting the presence of singularities over a given workspace or trajectory

Parallel singularities arise when the 6×6 *full inverse Jacobian* \mathbf{J}_f (i.e., the matrix that maps the full twist of the platform into active – and eventually passive – joint velocities) is singular, i.e., when its determinant $\det(\mathbf{J}_f)$ is equal to 0. It is pointed out that passive joint velocities sometimes have to be included because restricting the analysis to the active joint velocities may not allow the determination of all singular configurations of the mechanism (see the example of the 3 – UPU robot [12.43]). Usually, a proper velocity analysis allows one to establish this matrix in closed form, but computing the determinant of this matrix may be difficult even with symbolic computation tools (see the example of the Gough platform [12.44, 45]). The advantage of this approach is that once the expression of the determinant is obtained, the locus of singular configurations can be plotted in the workspace, thereby leading to graphical representations that can be useful in a context of design. However, the determinant itself is usually a large expression that does not provide insight into the geometric conditions associated with the singularities.

An alternative approach is to use line geometry: indeed, for several parallel robots (although not all), a row of \mathbf{J}_f corresponds to the Plücker vector of some line defined on the links of the robot. For example, for a Gough platform, the rows of \mathbf{J}_f are the normalized Plücker

vectors of the lines associated with the legs of the robot. A singularity of matrix \mathbf{J}_f therefore implies a linear dependency between these vectors (they then constitute a *linear complex*), a situation that may occur only if the lines associated with the vectors verify particular geometric constraints [12.46] (for example, three Plücker vectors will be linearly dependent if and only if their associated lines are coplanar and intersect at a common point). These geometric constraints have been identified by Grassmann for every set of three, four, five or six vectors. Singularity analysis is thus reduced to determining conditions on the pose parameters for which these constraints are satisfied, giving geometric information on the singularity variety. The closed-form singularity condition can then be substituted into the Jacobian matrix and the kernel of the matrix calculated in order to determine the singular motion [12.47].

Measuring closeness between a pose and a singular configuration is a difficult problem: there exists no mathematical metric defining the distance between a prescribed pose and a given singular pose. Hence, a certain level of arbitrariness must be accepted in the definition of the *distance* to a singularity and none of the proposed indices is perfect. For example, a possible index is the determinant of \mathbf{J}_f : unfortunately when the platform is subjected to both translational and rotational motion, the latter matrix is not dimensionally homogeneous and hence the value of the determinant will change according to the physical units used to describe the geometry of the robot. Dexterity indices, as defined in Chap. 11 (although they are less relevant for parallel robots than for serial robots [12.24]), can also be used and special indices for parallel robots have also been proposed [12.48, 49].

Most of the analyses based on the above indices are local, i.e., valid only for a given pose, while in practice the problem is to determine if a singular configuration can occur over a given workspace or trajectory. Fortunately, an algorithm exists that allows this verification, even if the geometric model of the robot is uncertain [12.50]. However, it should be pointed out that a singularity-free workspace may not always be optimal for parallel robots. Indeed, other performance requirements may impose the presence of singularities in the workspace or, the robot may have part of its workspace singularity-free (for example its working region) while exhibiting singularities outside this region. Therefore, a motion planner producing a trajectory that avoids singularities while remaining close to a desired path is advisable and various approaches have been proposed to address this problem [12.51, 52].

Finally, it is noted that being close to a singular configuration may be useful in some cases. For example, large amplification factors between the end-effector motion and the actuated joint motion may be interesting for fine-positioning devices with a very small workspace or for improving the sensitivity along some

measurement directions for a parallel robot used as a force sensor [12.53]. It should also be mentioned that parallel robots that remain *permanently* in a singular configuration may be interesting since they are capable of producing complex motions with only one actuator [12.54–56].

12.6 Workspace Analysis

As mentioned in the introduction, one of the main drawbacks of parallel robots is their small workspace. Moreover, their workspace analysis is usually more complex than for serial robots, especially if the platform has more than 3 DOFs. Indeed, the platform motion capabilities are usually coupled, thereby prohibiting simple graphical representations of the workspace. *Decoupled robots* have also been proposed [12.57–59] but they do not provide the load-carrying capacity of conventional parallel robots. In general, the workspace of parallel robots is restricted by

- the limitations on the actuated joint variables: for example, the length of the legs of a Gough platform have a minimum and maximum value,
- the limitations on the range of motion of the passive joints: for example the U and S joints of a Gough platform have restricted ranges of angular motion,
- the mechanical interferences between the bodies of the mechanism (legs, base, and platform).

Different types of workspaces can be defined such as the *dexterous* workspace (the set of platform locations in which all rotations are possible), the *maximal* workspace (the set of platform locations that may be reached with at least one orientation) or the *orientation* workspace (the set of orientations that can be reached for a given location of the platform).

A possible approach for representing the workspace of parallel robots with $n > 3$ DOFs is to fix the value of $n - 3$ pose parameters in order to be able to plot the workspace over the remaining three DOFs. Such plots can be obtained very efficiently using geometric methods if the plotted variables involve only translational motions because a geometric approach usually allows one to establish the nature of the boundary of the workspace (see, for example, [12.60, 61] for the calculation of the workspace of a Gough platform when its orientation is fixed). Another advantage of this approach is that it allows the computation of the surface and volume of the workspace while being very efficient

in terms of storage space. However, when rotational motion is included, the geometric approach becomes rather complex. Possible alternatives include:

- discretization methods in which all poses of a n -dimensional grid are checked with respect to the kinematic constraints. Such methods are computationally intensive because the computation time increases exponentially with the resolution of the mesh. Also they require a large storage space. On the other hand, the advantage of discretization is that it is usually simple to implement and it allows one to take into account all kinematic constraints as they can usually be simply verified for a given pose,
- numerical methods that allow the determination of the workspace boundary [12.62, 63],
- numerical methods based on interval analysis that allow the determination of an approximation of the workspace volume up to an arbitrary accuracy [12.64]. This representation is also appropriate for motion planning problems.

Singularities can also split the workspace calculated from the above kinematic constraints into elementary components, called *aspects* by Wenger [12.65] and which are separated by a singularity variety. However, determining the aspects for spatial robots is still an open problem. A parallel robot may not always be able to move from one aspect to another (at least without considering the dynamics of the robot [12.66]) and hence the useful workspace can be reduced.

A problem related to workspace analysis is the *motion planning problem*, which is slightly different from that encountered with serial robots. For parallel robots, the problem is not to avoid obstacles within the workspace but to determine if a given trajectory lies entirely inside the workspace of the robot or to determine a trajectory between two poses that lies in the workspace and is singularity-free. Algorithms for checking if a trajectory is valid are available [12.67] but finding such a trajectory is more difficult. Indeed, classical serial

robot motion planners work in the joint space and assume that there is a one-to-one relationship between the joint space and the operational space. With this assumption, it is possible to determine a set of points in the joint space that is collision-free and to use this knowledge to build a collision-free path between two poses. However, this assumption is not valid for parallel robots because the mapping between the joint space and the operational space is not one-to-one: a point in the joint space may either correspond to multiple points in the operational space or have no correspondence because the closure equations of the mechanism are not satisfied. For parallel robots, the most efficient motion planner seems to be an adaptation of a probabilistic motion planner that takes into account – to a certain extent – the closure equations [12.68, 69].

Another motion planning problem is related to tasks where a limited number of DOFs of the robot are used. For example, when a six-DOF parallel robot is used for machining, the rotation of the platform around the axis of the tool is not used since the spindle rotation ensures the needed motion. Thus, an additional DOF is available that can be used to increase the machine's workspace, to avoid singularities or to optimize some performance index of the robot [12.70, 71]. Along the same lines, it is possible to define the *part positioning* problem [12.72] as determining the pose of a rigid body with respect to the workspace of the robot so that this pose satisfies some constraints (e.g., the rigid body should lie fully inside the workspace and at all points of its surface the robot should have some rotational ability).

12.7 Static Analysis and Static Balancing

Similarly to serial robots, the static analysis of parallel robots can be readily performed using the Jacobian matrix. Indeed, the mapping between the vector of actuated joint forces/torques τ and the external wrench f exerted by the platform can be written as

$$\tau = J^\top f, \quad (12.11)$$

where J^\top is the transpose of the Jacobian matrix of the robot. Equation (12.11) can be used for various purposes, namely

- during the *design* process in order to determine the actuator forces/torques (for actuator selection). In this case, the designer is interested in finding the maximal actuator forces/torques over the robot workspace. This is a complex issue since J^\top is not known in closed form,
- in applications where the robot is used as a *force sensor*: if τ is measured and the pose of the platform is known, then (12.11) can be used to calculate f so that the robot can be used both as a motion and sensing platform [12.73–75].

The stiffness matrix K of a parallel robot is defined similarly to that of serial robots as

$$K = J^{-\top} K_j J^{-1}, \quad (12.12)$$

where K_j is the diagonal matrix of actuated joint stiffness. Duffy [12.76] notes that this derivation is, in general, incomplete. For example, for a Gough platform

this derivation assumes that there is no initial load on the elastic element of the link. Assuming that the length of the unloaded link is q_i^0 leads to

$$\begin{aligned} \Delta f &= \sum_{i=1}^{i=6} k \Delta q_i \mathbf{n}_i + k_i (q_i - q_i^0) \Delta \mathbf{n}_i, \\ \Delta m &= \sum_{i=1}^{i=6} k \Delta q_i \mathbf{c}_i \times \mathbf{n}_i + k_i (q_i - q_i^0) \Delta (\mathbf{c}_i \times \mathbf{n}_i), \end{aligned}$$

where k_i denotes the axial stiffness of the leg, \mathbf{n}_i represents the unit vector defined along the i th leg, \mathbf{c}_i is the vector connecting the origin of the moving reference frame to the i th anchor point of the platform, and f and m are the external force and moment vectors that are applied by the platform. Consequently, the stiffness matrix as defined in (12.12) is valid only if $q_i = q_i^0$, and is coined the *passive stiffness*.

Moreover, it was pointed out in the literature [12.77] that the formulation of (12.12) is valid only when the external wrench is zero. Indeed, the above formulation does not account for the fact that the Jacobian matrix is configuration dependent and therefore changes with the applied loads. The formulation proposed in [12.77] and termed the *conservative congruence transformation* (CCT) takes these changes into account and leads to a stiffness matrix defined as

$$K_c = J^{-\top} K_j J^{-1} + \left(\frac{\partial J^{-\top} \tau}{\partial p} \right), \quad (12.13)$$

where \mathbf{p} is the vector of Cartesian coordinates and $\boldsymbol{\tau}$ is the vector of actuated joint forces/torques. Whenever possible, the formulation of (12.13) should be used instead of that of (12.12) because it is mechanically consistent.

Another interesting static problem is the static balancing of parallel robots. The static balancing of mechanisms in general has been an important research topic for several decades (see, for instance, [12.78] for an account of the state of the art and many recent new results). Parallel mechanisms are said to be *statically balanced* when the weight of the links does not produce any torque (or force) at the actuators under static conditions, for any configuration of the manipulator or mechanism. This condition is also referred to as *gravity compensation*. The gravity compensation of parallel mechanisms was addressed by *Dunlop* [12.79] who suggested the use of counterweights to balance a two-DOF parallel robot used for antenna aiming, and by *Jean* [12.80] for planar robots. The latter case leads to simple and elegant balancing conditions.

In general, static balancing can be achieved using counterweights and/or springs. When springs are used, static balancing can be defined as the set of conditions for which the total potential energy in the mechanism – including gravitational energy and the elastic energy stored in the springs – is constant for any configuration of the mechanism. When no springs – or other means of storing elastic energy – are used, then static balancing conditions imply that the center of mass of the mechanism does not move in the direction of the gravity vector, for any motion of the mechanism.

Consider a general spatial n -degree-of-freedom parallel mechanism composed of n_b moving bodies and one fixed link. Moreover, let the position vector of the center of mass of each moving body with respect to a fixed reference frame be noted \mathbf{c}_i and let the mass of the i th moving body be noted m_i . The position vector of the center of mass of the mechanism with respect to the fixed frame, noted \mathbf{c} , can be written as

$$\mathbf{c} = \frac{1}{M} \sum_{i=1}^{n_b} m_i \mathbf{c}_i , \quad (12.14)$$

where M is the total mass of the moving links, i. e.,

$$M = \sum_{i=1}^{n_b} m_i . \quad (12.15)$$

In general, the vector \mathbf{c} is a function of the configuration of the mechanism, i. e.,

$$\mathbf{c} = \mathbf{c}(\boldsymbol{\theta}) , \quad (12.16)$$

where $\boldsymbol{\theta}$ is the vector comprising all the joint coordinates of the mechanism.

Following this notation, and if no elastic components are used, the condition for static balancing can be written as

$$\mathbf{e}_z^\top \mathbf{c} = C_t , \quad (12.17)$$

where C_t is an arbitrary constant and \mathbf{e}_z is a unit vector oriented in the direction of gravity.

When elastic components are used, the total potential energy in the mechanism, denoted by V , is defined as the sum of the gravitational and elastic potential energy and can be written as

$$V = g \mathbf{e}_z^\top \sum_{i=1}^{n_b} m_i \mathbf{c}_i + \frac{1}{2} \sum_{j=1}^{n_s} k_j (s_j - s_j^0)^2 , \quad (12.18)$$

where g is the magnitude of the gravitational acceleration, n_s is the number of linear elastic components in the system, k_j is the stiffness of the j th elastic component, s_j is the length of the j -th elastic component, and s_j^0 is its undeformed length. As mentioned above, when elastic elements are used, the condition for static balancing is that the total potential energy is constant, which can be written as

$$V = V_c , \quad (12.19)$$

where V_c is an arbitrary constant.

The general equations given above can be used to obtain the conditions under which a given mechanism is statically balanced. In general, the equations provide sufficient conditions for balancing. The problem of statically balancing spatial parallel robots is usually complex. Several papers were published recently on this subject [12.81, 82]. Among other results, it was pointed out that it is not possible to balance a 6-UPS robot in all poses by using only counterweights [12.83]. Alternative mechanisms (using parallelograms) that can be balanced using only springs were suggested [12.81, 84, 85].

A natural extension of static balancing is dynamic balancing. The dynamic balancing problem consists in finding parallel mechanisms that do not produce any reaction force or torque on their base for arbitrary trajectories. This problem was addressed for planar and spatial parallel mechanisms. In [12.86], it was shown that dynamically balanced parallel mechanisms with up to six DOFs can be synthesized, although the resulting mechanical architectures may be complex.

12.8 Dynamic Analysis

The dynamic model of parallel robots has a form similar to that of serial robots (see Chap. 2), namely

$$\mathbf{M}(\mathbf{x})\ddot{\mathbf{p}} + \mathbf{C}(\dot{\mathbf{p}}, \mathbf{p}, \mathbf{q}) + \mathbf{G}(\mathbf{p}, \mathbf{q}) = \boldsymbol{\tau}, \quad (12.20)$$

where \mathbf{M} is the positive-definite generalized inertia matrix, \mathbf{G} is the gravitational term, and \mathbf{C} is the centrifugal and Coriolis term. However, this equation is more difficult to obtain for parallel robots because the closure equations have to be satisfied. A classical method for calculating the dynamic models of closed-chain mechanisms is to consider first an equivalent tree-structure, and then to enforce the kinematic constraints using Lagrange multipliers or d'Alembert's principle [12.87, 88], a principle that has proved to be valid in [12.89]. Other approaches include the use of the principle of virtual work [12.90–93], the Lagrange formalism [12.94–96], Hamilton's principle [12.97], and Newton–Euler equations [12.98–103].

The main drawbacks of dynamic models obtained for parallel robots is that they are usually rather complex, they require the determination of dynamic parameters that are often not well known, and they involve solving the forward kinematics. Therefore, their calculation

is computer intensive while they must be used in real time.

Using dynamic models for control purposes was proposed [12.104, 105], usually in the context of an adaptive control scheme, in which the tracking errors are used online to correct the parameters used in the dynamic equations [12.106, 107]. Control laws were proposed mainly for planar robots and for the Delta robot [12.108–110] although some implementations have been proposed for general six-DOF robots [12.111, 112] or vibration platforms [12.113]. However for six-DOF robots, the benefits of using dynamic models for high-speed motions are difficult to establish because the computational burden of the dynamic model somewhat reduces the potential gains.

This is clearly an important and open issue since parallel robots can operate at velocities and accelerations much larger than those of serial robots. For example, some Delta robots have reached accelerations of the order of 500 m/s^2 while wire-driven robots can probably exceed this value.

Finally, the optimization of the dynamic properties of parallel mechanisms can be addressed by minimizing the variation of the inertia over the workspace [12.114].

12.9 Design

The design of a robot can be decomposed into two main phases:

- *structural synthesis*: finding the general mechanical structure of the robot
- *geometric synthesis*: determining the value of the geometric parameters involved in a given structure (here geometric parameters must be understood in a loose sense, for example, mass and inertia may also be involved)

The problem of structural synthesis (type synthesis) was addressed in Sect. 12.2. However, performance requirements other than the motion pattern of the robot have to be taken into account in the design of a robot. Serial robots have the advantage that the number of possible mechanical architectures is relatively small and that some of these architectures have clear advantages in terms of performance compared to others (for example, the workspace of a 3R structure is much larger than the workspace of a Cartesian robot of similar size).

Unfortunately no such rules exist for parallel robots, for which there are furthermore a large number of possible mechanical designs. Additionally, the performances of parallel robots are very sensitive to their geometric parameters. For example, the extremal stiffness of a Gough platform over a given workspace can change by 700% for a change of only 10% of the platform radius. Consequently, structural synthesis cannot be dissociated from the geometric synthesis. In fact, it is conjectured that a well-dimensioned robot of any structural type will in general perform better than a poorly designed robot with a structure that may seem more appropriate for the task at hand.

Usually the design process is treated as an optimization problem. To each specified performance requirement is associated a performance index whose value increases with the level of violation of the performance requirement. These performance indices are summed in a weighted real-valued function called the *cost function*, which is a function of the geometric design parameters

and then a numerical optimization procedure is used to find the parameters that minimize the cost function (hence this approach leads to what is called an *optimal design*) [12.115–117]. There are however numerous drawbacks to this approach: the determination and effect of the weights in the cost function are difficult to ascertain, imperative requirements are difficult to incorporate and make the optimization process more complex, and the definition of the performance indices is not trivial, to name but a few. The main issues can be stated as:

- the robustness of the design solution obtained with the cost function approach with respect to the uncertainties in the final design. Indeed the real instantiation of a theoretical solution will always differ from the latter because of the manufacturing tolerances and other uncertainties that are inherent to a mechanical system,
- performance requirements may be antagonistic (e.g., workspace and accuracy) and the optimal design approach only provides a compromise between these requirements that is difficult to master through the weights.

An alternative to optimal design is referred to as *appropriate design*, in which no optimization is considered but the objective is to ensure that desired requirements are satisfied. This approach is based on the definition of the *parameter space* in which each dimension is associated with a design parameter. Performance requirements are considered in turn and the regions of the parameter space that correspond to robots satisfying the requirements are calculated. The design solution is then obtained as the intersection of the regions obtained for each individual requirement.

In practice, only an approximation of the regions is necessary since values close to the boundary cannot be physically realized due to manufacturing tolerances. For that calculation, interval analysis was successfully used in various applications [12.20, 118].

The appropriate design approach is clearly more complex to implement than the cost function approach but has the advantage of providing all design solutions, with the consequence that manufacturing tolerances may be taken into account to ensure that the real robot will also satisfy the desired requirements.

12.10 Application Examples

Parallel robots have been successfully used in many applications, a few of which will now be briefly mentioned. Almost all recent land-based telescopes use parallel robots, either as a secondary mirror alignment system (for example the University of Arizona MMT or the European Organisation for Astronomical Research in the Southern Hemisphere (ESO) Visible and Infrared Survey Telescope for Astronomy (VISTA)) or as a primary mirror pointing device. A wire-driven parallel robot flew in the space shuttle mission STS-63 in February 1999 while an octopod (a parallel robot with eight legs) was used to isolate the space shuttle payload from vibration. A parallel platform is used in the medical rehabilitation platform Caren of Motek. All flight simulators use a parallel structure as a motion platform. They are nowadays used for driving simulators as well [12.119].

In industry, numerous machine tools based on parallel structures have been designed: some of them have found a niche market (e.g., the Tricept) and it can be expected that more will be used in the future (especially for high-speed manufacturing) as soon as a controller specifically designed for parallel structures is developed (current controllers are basically identical to the ones used for the classical linear machine tools and hence do not allow the potential of parallel structures to be fully exploited). Ultra-accurate positioning devices based on parallel robots are proposed by companies such as Physik Instrumente, Micos, and Alio. In the food industry the Delta robot proposed by Demaurex and SIG Robotics is widely used for fast packaging. Other companies such as Adept are also developing fast parallel robots with three and four degrees of freedom.

12.11 Conclusion and Further Reading

The analysis of a parallel mechanism may be partly based on methods that are presented in other chapters of this handbook:

- *kinematics*: kinematics background is covered in Chap. 1,
- *dynamics*: general approaches are presented in Chap. 2 while identification of the dynamic parameters is addressed in Chap. 14,
- *design*: design methodologies are covered in Chap. 10,
- *control*: control issues are presented in Chaps. 5, 6, and 7 although the closed-loop structure of parallel robots may require some adaptation of the control schemes.

It must also be emphasized that efficient numerical analysis is a key point for many algorithms related to parallel robots. System solving with Gröbner basis, continuation method, and interval analysis is essential for kinematics, workspace, and singularity analysis.

Further information and up-to-date extensive references and papers related to parallel robots can be found on the following two web sites [12.120, 121]

Useful complementary readings on parallel robots are [12.9, 122, 123].

Parallel robots are slowly finding their way into various applications, not only in industry but also in field and service robotics, as discussed in Part F of this handbook. Still, compared to their serial counterpart, their analysis is far from being complete.

13. Robots with Flexible Elements

Alessandro De Luca, Wayne Book

Design issues, dynamic modeling, trajectory planning, and feedback control problems are presented for robot manipulators having components with mechanical flexibility, either concentrated at the joints or distributed along the links. The chapter is divided accordingly in two main parts. Similarities or differences between the two types of flexibility are pointed out wherever appropriate.

For robots with flexible joints, the dynamic model is derived in detail by following a Lagrangian approach and possible simplified versions are discussed. The problem of computing the nominal torques that produce a desired robot motion is then solved. Regulation and trajectory tracking tasks are addressed by means of linear and nonlinear feedback control designs.

For robots with flexible links, relevant factors that lead to the consideration of distributed flexibility are analyzed. Dynamic models are presented, based on the treatment of flexibility through lumped elements, transfer matrices, or assumed modes. Several specific issues are then highlighted, including the selection of sensors,

the model order used for control design, and the generation of effective commands that reduce or eliminate residual vibrations in rest-to-rest maneuvers. Feedback control alternatives are finally discussed.

In each of the two parts of this chapter, a section is devoted to the illustration of the original references and to further readings on the subject.

The standard assumption underlying robot kinematics, dynamics, and control design is that manipulators consist only of rigid bodies (links and motion transmission components). This is, however, an ideal situation that may be considered valid only for slow motion and small interacting forces. In practice, mechanical flexibility in robot manipulators is present for two main reasons: the use of compliant transmission elements and the reduction of the mass of the moving links through the use of lightweight material and slender design. These two kinds of flexibility introduce static and dynamic deflections between the position of the driving actuators and the position of the manipulator end-effector. If flexibility is not taken into account when considering robot

design and control, a degradation of the overall expected performance of the robot typically occurs.

From a modeling point of view, flexibility can be assumed as concentrated at the robot joints or distributed (in different ways) along the robot links. The dynamic modeling steps are similar, with the need to introduce additional generalized coordinates besides those used to describe the rigid motion of the robot arm. However, the properties of the resulting models are quite different from a control point of view. Therefore, the case of *robots with flexible joints* and of *robots with flexible links* are presented in this chapter mostly as separate items, pointing out similarities or structural differences wherever appropriate. For both classes of

flexible robots, the relevant design issues, dynamic modeling, inverse dynamics algorithms, and control laws for set-point regulation and trajectory tracking will be discussed. Indeed, joint and link flexibilities may be present (and dynamically interact) at the same time. Many of

the presented results can be extended to this case as well.

In the following, it is assumed that the reader is already familiar with basic issues on kinematics, dynamics, and control of rigid robots (Chaps. 1, 2, 6).

13.1 Robots with Flexible Joints

The presence of joint flexibility is common in current industrial robots, when motion transmission/reduction elements such as belts – [as in the selective compliant assembly robot arm (**SCARA**) family], long shafts (as in the forearm of the Unimation Puma arm), cables, harmonic drives, or cycloidal gears are used. The purpose of these components is to allow relocation of the actuators next to the robot base, thus improving dynamic efficiency, or to guarantee high reduction ratios with power-efficient compact inline devices.

However, when subject to the forces/torques arising in normal robot operation, these components are intrinsically flexible (e.g., the flexspline in harmonic drives, see Fig. 13.1) and introduce a time-varying displacement between the position of the actuators and that of the driven links. Without a specific control action, an oscillatory behavior, typically of small magnitude but at a relatively high frequency, is observed at the robot end-effector level during free motion. In addition, some form of instability (e.g., chattering) may occur in tasks involving contact with the environment.

Recently, flexible actuation/transmission elements have been deliberately selected in robots intended for physical human–robot interaction. In fact, this form of mechanical compliance guarantees an inertial decoupling between the actuator and the (possibly, lightweight) link, thus reducing the kinetic energy

involved in undesired collisions with humans. Such a safety-oriented mechanical design should be traded-off with a more complex control design aimed at preserving the same performance of rigid robots in terms of speed and accuracy of the end-effector motion (Chap. 57).

Figures 13.2 and 13.3 show two examples of robot manipulators with flexible joints, the 8R robot *Dexter* and the 7R lightweight manipulator *DLR LWR-III*. The first robot has motors 3–8 located inside the second link,

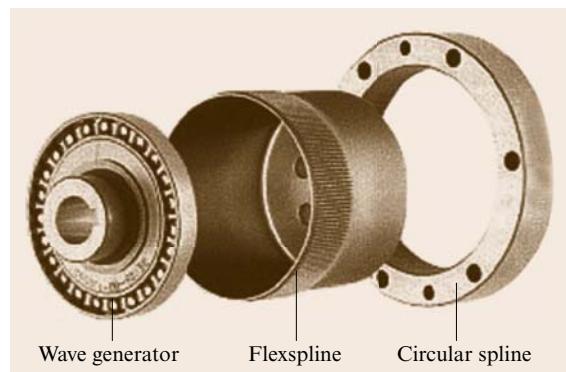

Fig. 13.1 The components of a harmonic drive

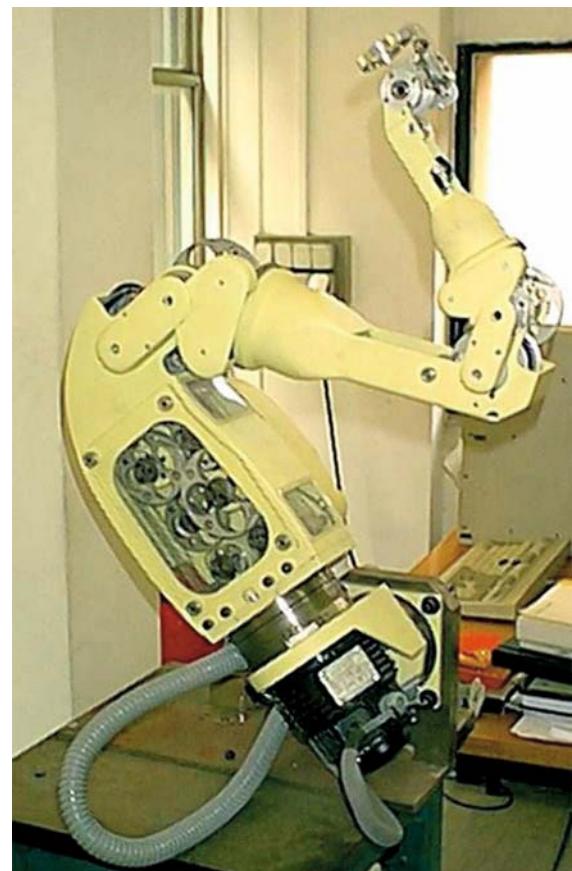

Fig. 13.2 The cable-driven robot *Dexter* by Scienzia Machinale

Fig. 13.3 The lightweight manipulator *DLR LWR-III* by the German Aerospace Center

with motion transmitted to the distal links through steel cables and pulleys; the second has a modular structure, with each motor integrated in the associated joint and using an harmonic drive as reduction element. The joint stiffnesses of the *Dexter* robot vary between 120 and 6300 Nm/rad depending on the joint, while for the *DLR LWR-III* manipulator the range is 6000–15 000 Nm/rad. These numerical values refer to deflections and associated torques evaluated after the reduction gears.

Deflection of the flexible transmission elements can be modeled as being *concentrated at the joints* of the robot, thus limiting the complexity of the associated equations of motion. When compared to the rigid case, the dynamic model of robots with flexible joints (and rigid links) requires *twice* the number of generalized coordinates to completely characterize the configuration of all rigid bodies (motors and links) constituting the arm.

As a result, the case of flexible joint robots is one example in which the number of control inputs is strictly less than the number of mechanical degrees of freedom. This suggests that the design of control schemes

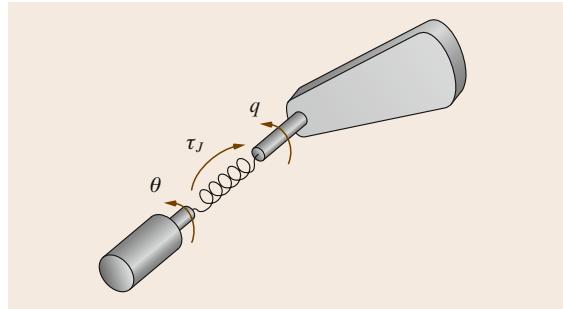

Fig. 13.4 Schematic representation of an elastic joint

realizing standard motion tasks is expected to be more difficult than for rigid robots. Moreover, the implementation of a full state feedback law will require twice the number of sensors, measuring quantities that are *before* and *after* (or across) the joint deformation. On the other hand, the motor torques used to command the robot as well as the disturbance torques due to joint flexibility perform work on the same joint axes (they are *physically collocated*). It should be noted that this is one relevant difference with respect to the case of flexibility distributed along the links. This characteristic is very helpful for rejecting vibrations and controlling the overall robot motion. Roughly speaking, we will be able to use input commands acting before the source of flexibility to ensure that output variables defined beyond the flexibility behave in a desired way.

13.1.1 Dynamic Modeling

Dynamic models that explicitly include joint flexibility are used to evaluate quantitatively vibratory effects superposed on the rigid motion, verify whether the control laws obtained under the assumption of joint rigidity can still work in practice (or to what extent they should be modified), and enable the design of new model-based feedforward and feedback controllers.

We consider a robot with flexible joints as an open kinematic chain having $N + 1$ rigid bodies, the base and the N links, interconnected by N (rotary or prismatic) joints undergoing deflection, and actuated by N electrical drives. From a mechanical point of view, each motor (with its stator and rotor) is an additional rigid body with its inertial properties. All joints are considered to be flexible, though mixed situations may be encountered due to the use of different transmission devices. When reduction gearings are present, they are modeled as being placed *before* the joint deflection occurs.

The following standard assumptions are made.

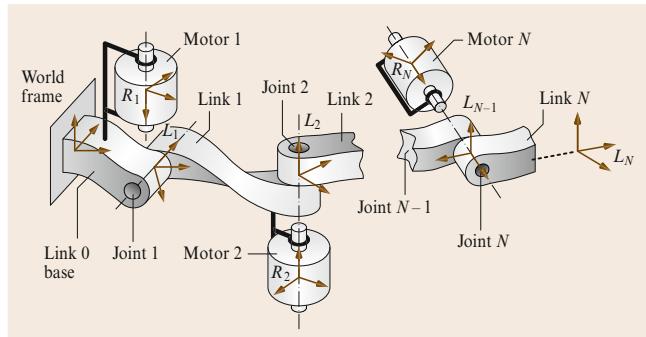

Fig. 13.5 Arrangement of motors and links in an open kinematic chain

- A1** Joint deflections are small, so that flexibility effects are limited to the domain of linear elasticity.
- A2** The actuators' rotors are modeled as uniform bodies having their center of mass on the rotation axis.
- A3** Each motor is located on the robot arm in a position preceding the driven link. (This can be generalized to the case of multiple motors simultaneously driving multiple distal links.)

The first assumption supports the terminology of robots with *elastic* joints often used in the literature. The elasticity at joint i is modeled by a spring of stiffness $K_i > 0$, which is torsional for rotational joints and linear for translational ones. Figure 13.4 shows a single link driven by a motor through a rotational elastic joint. Nonlinear stiffness characteristics for the flexible joint can also be considered, provided that the map from deflection to force is smooth and invertible. Assumption A2 is a basic requirement for long life of an electrical drive and thus very reasonable. As we shall see, it implies that the inertia matrix and the gravity term in the robot dynamic model will be independent of the angular position of the motors. A typical arrangement of motors satisfying assumption A3 is shown in Fig. 13.5. The simplest situation is when the i -th motor moves link i and is mounted on link $i - 1$ with its rotation axis aligned with the i -th joint. This is, for instance, the case for the *LWR-III* manipulator. The dislocation of the actuating motors along the structure has a great influence on the structure of the dynamic equations of motion.

For kinematic and dynamic analysis, $2N$ frames are attached to the $2N$ moving rigid bodies (links and motors) in the robot chain: the link frames L_i and the motor frames R_i , for $i = 1, \dots, N$ (Fig. 13.5). For the

definition of the link frames L_i , the standard Denavit–Hartenberg convention can be used. The frames R_i are attached to the motor stators, aligned with the axes of symmetry of the motors and with the z -axis along the spinning direction of the rotor.

Accordingly, $2N$ generalized coordinates will be needed. A possible set of coordinates is given by

$$\boldsymbol{\Theta} = \begin{pmatrix} \mathbf{q} \\ \boldsymbol{\theta} \end{pmatrix} \in \mathbb{R}^{2N},$$

where \mathbf{q} is the N -vector of link positions and $\boldsymbol{\theta}$ is the N -vector of motor (i.e., rotor) positions, as reflected through the transmission/reduction gears. This choice of variables is quite convenient because:

1. the model will be formally independent of the reduction ratios;
2. these position variables will have a similar dynamic range;
3. the kinematics of the robot will be a function of the link variables \mathbf{q} only (these variables are already *beyond* the joint flexibility) so that all issues related to direct/inverse kinematics will be identical to the case of fully rigid robots.

For some considerations, it is useful to define also the variable $\boldsymbol{\theta}_m$, namely the N -vector of motor positions before reduction, which are the quantities directly measured by encoders mounted on the motors. In the case of a motor directly placed on the i -th joint axis, one has $\dot{\boldsymbol{\theta}}_{m,i} = n_i \dot{\boldsymbol{\theta}}_i$, where $n_i \geq 1$ is the reduction ratio at the i -th joint. In addition, for $i = 1, \dots, N$, the difference $\delta_i = q_i - \theta_i$ is the deflection at the i -th joint, while $\tau_{J,i} = K_i(\theta_i - q_i)$ is the torque transmitted to the i -th link through the associated elastic spring (Fig. 13.4) – the quantity measured by a joint torque sensor, whenever present. Note that for robots with flexible links, the set $(\boldsymbol{\theta}, \boldsymbol{\delta})$ is typically used in the dynamic modeling, where $\boldsymbol{\delta}$ is the vector of link deflection coordinates.

Following a Lagrangian approach, the single energy contributions to the Lagrangian $\mathcal{L} = \mathcal{T}(\boldsymbol{\Theta}, \dot{\boldsymbol{\Theta}}) - \mathcal{U}(\boldsymbol{\Theta})$ will be derived next.

The *potential energy* of the robot is due to gravity and joint elasticity. The gravity part is related to the position of the barycenter of the links (each of mass m_i) and of the motors (of mass m_{r_i}). Because of assumption A2, the latter will be independent of $\boldsymbol{\theta}$. Thus,

$$\mathcal{U}_{\text{grav}} = \mathcal{U}_{\text{grav,link}}(\mathbf{q}) + \mathcal{U}_{\text{grav,motor}}(\mathbf{q}).$$

For the elastic part of the potential, because of assumption **A1**, we have

$$\begin{aligned}\mathcal{U}_{\text{elas}} &= \frac{1}{2} (\boldsymbol{q} - \boldsymbol{\theta})^\top \mathbf{K}(\boldsymbol{q} - \boldsymbol{\theta}), \\ \mathbf{K} &= \text{diag}(K_1, \dots, K_N).\end{aligned}$$

As a result, $\mathcal{U}(\boldsymbol{\Theta}) = \mathcal{U}_{\text{grav}}(\boldsymbol{q}) + \mathcal{U}_{\text{elas}}(\boldsymbol{q} - \boldsymbol{\theta})$.

The *kinetic energy* of the robot is the sum of the link and rotor contributions. For the links, there is no difference with respect to the standard rigid robot case and it will be sufficient to write in general

$$\mathcal{T}_{\text{link}} = \frac{1}{2} \dot{\boldsymbol{q}}^\top \mathbf{M}_L(\boldsymbol{q}) \dot{\boldsymbol{q}}, \quad (13.1)$$

with the positive-definite symmetric link inertia matrix $\mathbf{M}_L(\boldsymbol{q})$. For the rotors, some more detail is needed:

$$\begin{aligned}\mathcal{T}_{\text{rotor}} &= \sum_{i=1}^N \mathcal{T}_{\text{rotor}_i} \\ &= \sum_{i=1}^N \left(\frac{1}{2} m_{r_i} \mathbf{v}_{r_i}^\top \mathbf{v}_{r_i} + \frac{1}{2} {}^{R_i} \boldsymbol{\omega}_{r_i}^\top {}^{R_i} \mathbf{I}_{r_i} {}^{R_i} \boldsymbol{\omega}_{r_i} \right),\end{aligned} \quad (13.2)$$

where \mathbf{v}_{r_i} is the linear velocity of the center of mass of the i -th rotor and $\boldsymbol{\omega}_{r_i}$ is the angular velocity of the i -th rotor body. All quantities in the angular contributions in (13.2) are conveniently expressed in the local frame R_i . According to assumption **A2**, the rotor inertia matrix is then diagonal

$${}^{R_i} \mathbf{I}_{r_i} = \text{diag}(I_{r_{i,xx}}, I_{r_{i,yy}}, I_{r_{i,zz}}),$$

with $I_{r_{i,xx}} = I_{r_{i,yy}}$, while \mathbf{v}_{r_i} can be expressed as a function of \boldsymbol{q} and $\dot{\boldsymbol{q}}$ only. Moreover, due to assumption **A3**, the angular velocity of the i -th rotor has the general expression

$${}^{R_i} \boldsymbol{\omega}_{r_i} = \sum_{j=1}^{i-1} \mathbf{J}_{r_i,j}(\boldsymbol{q}) \dot{q}_j + \begin{pmatrix} 0 \\ 0 \\ \dot{\theta}_{m,i} \end{pmatrix}, \quad (13.3)$$

where $\mathbf{J}_{r_i,j}(\boldsymbol{q})$ is the j -th column of the Jacobian relating the link velocities $\dot{\boldsymbol{q}}$ to the angular velocity of the i -th rotor in the robot chain. By substituting (13.3) into (13.2) and expressing $\dot{\theta}_m$ in terms of $\dot{\boldsymbol{\theta}}$, it can be shown that

$$\begin{aligned}\mathcal{T}_{\text{rotor}} &= \frac{1}{2} \dot{\boldsymbol{q}}^\top \left[\mathbf{M}_R(\boldsymbol{q}) + \mathbf{S}(\boldsymbol{q}) \mathbf{B}^{-1} \mathbf{S}^\top(\boldsymbol{q}) \right] \dot{\boldsymbol{q}} \\ &\quad + \dot{\boldsymbol{q}}^\top \mathbf{S}(\boldsymbol{q}) \dot{\boldsymbol{\theta}} + \frac{1}{2} \dot{\boldsymbol{\theta}}^\top \mathbf{B} \dot{\boldsymbol{\theta}},\end{aligned} \quad (13.4)$$

where \mathbf{B} is the constant diagonal inertia matrix collecting the rotors inertial components $I_{r_{i,zz}}$ around their spinning axes, $\mathbf{M}_R(\boldsymbol{q})$ contains the rotor masses (and, possibly,

the rotor inertial components along the other principal axes), and the square matrix $\mathbf{S}(\boldsymbol{q})$ expresses the inertial couplings between the rotors and the previous links in the robot chain.

A simple example illustrates the derivation and the actual expressions of the terms in (13.4). We also include the reduction elements to show how the rotor inertial component around the spinning axis will appear in the kinetic energy, weighted by different powers of the reduction ratios. Consider a planar robot with two rotational elastic joints, a first link of length ℓ_1 , and motors mounted directly on the joint axes. The kinetic energies of the two rotors are

$$\begin{aligned}\mathcal{T}_{\text{rotor}_1} &= \frac{1}{2} I_{r_{1,zz}} \dot{\theta}_{m,1}^2 = \frac{1}{2} I_{r_{1,zz}} n_1^2 \dot{\theta}_1^2 \\ \mathcal{T}_{\text{rotor}_2} &= \frac{1}{2} m_{r_2} \ell_1^2 \dot{q}_1^2 + \frac{1}{2} I_{r_{2,zz}} (\dot{q}_1 + \dot{\theta}_{m,2})^2 \\ &= \frac{1}{2} m_{r_2} \ell_1^2 \dot{q}_1^2 + \frac{1}{2} I_{r_{2,zz}} (\dot{q}_1^2 + 2n_2 \dot{q}_1 \dot{\theta}_2 + n_2^2 \dot{\theta}_2^2),\end{aligned}$$

leading to

$$\begin{aligned}\mathbf{B} &= \begin{pmatrix} I_{r_{1,zz}} n_1^2 & 0 \\ 0 & I_{r_{2,zz}} n_2^2 \end{pmatrix}, & \mathbf{S} &= \begin{pmatrix} 0 & I_{r_{2,zz}} n_2 \\ 0 & 0 \end{pmatrix}, \\ \mathbf{M}_R &= \begin{pmatrix} m_{r_2} \ell_1^2 & 0 \\ 0 & 0 \end{pmatrix}, & \mathbf{S} \mathbf{B}^{-1} \mathbf{S}^\top &= \begin{pmatrix} I_{r_{2,zz}} & 0 \\ 0 & 0 \end{pmatrix}.\end{aligned}$$

In this case, the matrix \mathbf{S} (as well as \mathbf{M}_R) is constant. Note that for large reduction ratios n_i , the dominant inertial effect due to the rotors is given by the matrix \mathbf{B} . Also, if the second motor were mounted remotely on the first joint (as it is often the case in the class of SCARA arms), or still close to the second joint but with the spinning axis orthogonal to the axis of this joint, then the matrix \mathbf{S} would be zero.

In general, as a consequence of assumption **A3**, the matrix $\mathbf{S}(\boldsymbol{q})$ always has a strictly upper-triangular structure with a cascaded dependence of its nonzero elements:

$$\mathbf{S}(\boldsymbol{q}) =$$

$$\begin{pmatrix} 0 & S_{12} & S_{13}(\boldsymbol{q}_2) & S_{14}(\boldsymbol{q}_2, \boldsymbol{q}_3) & \dots & \dots & S_{1N}(\boldsymbol{q}_2, \dots, \boldsymbol{q}_{N-1}) \\ 0 & 0 & S_{23}(\boldsymbol{q}_3) & \dots & \dots & S_{2N}(\boldsymbol{q}_3, \dots, \boldsymbol{q}_{N-1}) \\ 0 & 0 & 0 & S_{34} & \dots & \dots & S_{3N}(\boldsymbol{q}_4, \dots, \boldsymbol{q}_{N-1}) \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 0 & S_{N-2,N-1} & S_{N-2,N}(\boldsymbol{q}_{N-1}) \\ 0 & 0 & 0 & \dots & 0 & 0 & S_{N-1,N} \\ 0 & 0 & 0 & \dots & 0 & 0 & 0 \end{pmatrix}. \quad (13.5)$$

Summing up, the total kinetic energy of the robot is

$$\begin{aligned}\mathcal{T} &= \frac{1}{2} \dot{\Theta}^\top \mathcal{M}(\Theta) \dot{\Theta} \\ &= \frac{1}{2} (\dot{q}^\top \dot{\theta}^\top) \begin{pmatrix} M(q) & S(q) \\ S^\top(q) & B \end{pmatrix} \begin{pmatrix} \dot{q} \\ \dot{\theta} \end{pmatrix},\end{aligned}$$

with

$$M(q) = M_L(q) + M_R(q) + S(q)B^{-1}S^\top(q). \quad (13.6)$$

As anticipated, the total inertia matrix \mathcal{M} of the robot depends only on q .

Using the Lagrange equations finally yields the complete dynamic model

$$\begin{pmatrix} M(q)S(q) \\ S^\top(q) & B \end{pmatrix} \begin{pmatrix} \ddot{q} \\ \ddot{\theta} \end{pmatrix} + \begin{pmatrix} c(q, \dot{q}) + c_1(q, \dot{q}, \dot{\theta}) \\ c_2(q, \dot{q}) \end{pmatrix} + \begin{pmatrix} g(q) + K(q - \theta) \\ K(\theta - q) \end{pmatrix} = \begin{pmatrix} 0 \\ \tau \end{pmatrix}, \quad (13.7)$$

where the inertial terms (related to the total inertia matrix $M(q)$), the Coriolis and centrifugal terms (collectively denoted by $c_{\text{tot}}(\Theta, \dot{\Theta})$), and the potential terms $(\partial U(\Theta)/\partial \Theta)^\top$ have been written separately. In particular, $g(q) = (\partial U_{\text{grav}}(q)/\partial q)^\top$ while $\tau_j = K(\theta - q)$ is the elastic torque transmitted through the joints.

The first N and the last N equations of the dynamic model (13.7) are referred to as the *link* and the *motor equations*, respectively.

On the right-hand side of (13.7), all nonconservative generalized forces should appear. When dissipative effects are not considered, only the motor torque τ producing work on the θ variable is present (i.e., the torques on the motor output shafts, amplified by the square of the reduction ratios) in the motor equations. If the robot end-effector is in contact with the environment, the zero in the right-hand side of the link equations should be replaced by $\tau_{\text{ext}} = J^\top(q)F$, where $J(q)$ is the robot Jacobian and F the forces/torques acting from the environment on the robot.

In the presence of energy-dissipating effects, additional terms appear in the right-hand side of (13.7). For instance, viscous friction at both sides of the transmissions and spring damping of the (visco)elastic joints give rise to the vector term

$$\begin{pmatrix} -F_q \dot{q} - D(\dot{q} - \dot{\theta}) \\ -F_\theta \dot{\theta} - D(\dot{\theta} - \dot{q}) \end{pmatrix}, \quad (13.8)$$

where the diagonal, positive-definite matrices F_q , F_θ , and D contain, respectively, the viscous coefficients on

the link side and on the motor side, and the damping of the elastic springs at the joints. More general forms of nonlinear friction τ_F can be considered. Note that, in principle, friction acting on the motor side can be fully compensated by a suitable choice of the control torque τ , while this is not true for friction acting on the link side, due to the noncollocation.

Model Properties

All elements in the $2N$ -vector $c_{\text{tot}}(\Theta, \dot{\Theta})$ of velocity-dependent terms in (13.7) are independent of the motor position θ . The specific dependence of the N -vectors c , c_1 , and c_2 follows from the general expression of the components of c_{tot} based on Christoffel symbols:

$$c_{\text{tot},i}(\Theta, \dot{\Theta}) = \frac{1}{2} \dot{\Theta}^\top \left[\frac{\partial \mathcal{M}_i}{\partial \Theta} + \left(\frac{\partial \mathcal{M}_i}{\partial \Theta} \right)^\top - \frac{\partial \mathcal{M}}{\partial \Theta_i} \right] \dot{\Theta},$$

for $i = 1, \dots, 2N$, where \mathcal{M}_i is the i -th column of the total inertia matrix $\mathcal{M}(\Theta)$. In particular, the velocity vectors c_1 and c_2 contain terms arising from the presence of the $S(q)$ matrix. Performing calculations, it can be shown that:

1. the vector c_1 does not contain quadratic velocity terms in \dot{q} or $\dot{\theta}$, but only in $\dot{\theta}_j \dot{q}_j$;
2. when the matrix S is constant, both c_1 and c_2 vanish.

The dynamic model (13.7) also shares some properties of the rigid case, such as:

- the model equations admit a linear parametrization in terms of a suitable set of dynamic coefficients, including joint stiffnesses and motor inertias, which is useful for model identification and adaptive control;
- the Coriolis and centrifugal terms can always be factorized as $c_{\text{tot}}(\Theta, \dot{\Theta}) = \mathcal{C}(\Theta, \dot{\Theta})\dot{\Theta}$, in such a way that matrix $\mathcal{M} - 2\mathcal{C}$ is skew-symmetric – a property used in control analysis;
- for robots having only rotational joints, the gradient of the gravity vector $g(q)$ is globally bounded in norm by a constant.

Finally, when the joint stiffness is extremely large ($K \rightarrow \infty$), then $\theta \rightarrow q$ while $\tau_j \rightarrow \tau$. It is easy to check that the dynamic model (13.7) collapses in this limit to the standard model of fully rigid robots (including links and motors).

Reduced Model

In general, the link and motor equations in (13.7) are not only dynamically coupled through the elastic torque τ_j

at the joints, but also (at the acceleration level) via the inertial components of matrix $\mathbf{S}(\mathbf{q})$ – usually a path of low energy transfer. The presence and actual relevance of these inertial couplings depend on the kinematic arrangement of the manipulator arm and, in particular, on the specific location of the motors and transmission devices. There are cases in which the matrix \mathbf{S} is constant (e.g., the planar case, as in the previous example, with any number of links) or zero (e.g., for a single link with elastic joint or for a robot with $N = 2$ links having the two joint axes orthogonal and the motors mounted at the joints). As a result, the dynamic equations will simplify considerably.

For a generic robot with elastic joints, one can take advantage of the presence of large reduction ratios (with the n_i of the order 100–150) and simply neglect energy contributions due to the inertial couplings between the motors and the links (see again the $2R$ planar example). This is equivalent to considering the following simplifying assumption:

A4 The angular velocity of the rotors is due only to their own spinning, i.e.,

$$R_i \boldsymbol{\omega}_{r_i} = \begin{pmatrix} 0 & 0 & \dot{\theta}_{m,i} \end{pmatrix}^\top, \quad i = 1, \dots, N,$$

instead of the complete (13.3).

As a result, the total angular kinetic energy of the rotors is just $\frac{1}{2} \dot{\boldsymbol{\theta}}^\top \mathbf{B} \dot{\boldsymbol{\theta}}$ (or $\mathbf{S} \equiv \mathbf{0}$), and the dynamic model (13.7) reduces to

$$\begin{aligned} \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) + \mathbf{K}(\boldsymbol{\theta} - \boldsymbol{\theta}) &= \mathbf{0} \\ \mathbf{B}\ddot{\boldsymbol{\theta}} + \mathbf{K}(\boldsymbol{\theta} - \boldsymbol{\theta}) &= \boldsymbol{\tau}, \end{aligned} \quad (13.9)$$

with $\mathbf{M}(\mathbf{q}) = \mathbf{M}_L(\mathbf{q}) + \mathbf{M}_R(\mathbf{q})$. The main feature of this model is that the link and motor equations are dynamically coupled only through the elastic torque $\boldsymbol{\tau}_J$. In addition, the motor equations are now fully linear.

We note that the complete model (13.7) and the reduced model (13.9) display different characteristics with respect to certain control problems. In fact, the reduced model is always feedback linearizable by *static* state feedback, whereas this is never the case for the complete model as soon as a coupling $\mathbf{S} \neq \mathbf{0}$ is present.

Singular Perturbation Model

It is interesting to show the *two-time-scale* dynamic behavior that it is induced in robots with elastic joints when the joint stiffness \mathbf{K} is relatively large, but still finite. This behavior can be made explicit by a simple linear change of coordinates, namely replacing $\boldsymbol{\theta}$ with the joint

torque $\boldsymbol{\tau}_J$. For the sake of simplicity, this is illustrated on the reduced model only (without dissipation).

Since the diagonal joint stiffness matrix is assumed to have large but similar elements, a common scalar factor $1/\epsilon^2 \gg 1$ can be extracted as

$$\mathbf{K} = \frac{1}{\epsilon^2} \hat{\mathbf{K}} = \frac{1}{\epsilon^2} \text{diag}(\hat{K}_1, \dots, \hat{K}_N).$$

The *slow* subsystem is then given by the link equations, once they are rewritten as

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau}_J. \quad (13.10)$$

To obtain the dynamics of the *fast* subsystem, the joint torque is differentiated twice, the motor and link accelerations are replaced from (13.9), and the above definition of $\hat{\mathbf{K}}$ is used. This leads to

$$\begin{aligned} \epsilon^2 \ddot{\boldsymbol{\tau}}_J &= \hat{\mathbf{K}} \left\{ \mathbf{B}^{-1} \boldsymbol{\tau} - [\mathbf{B}^{-1} + \mathbf{M}^{-1}(\mathbf{q})] \boldsymbol{\tau}_J \right. \\ &\quad \left. + \mathbf{M}^{-1}(\mathbf{q})[\mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q})] \right\}. \end{aligned} \quad (13.11)$$

For small ϵ , (13.10, 13.11) represent a singularly perturbed system. The two separate time scales governing the slow and fast dynamics are t and $\sigma = t/\epsilon$, since

$$\epsilon^2 \ddot{\boldsymbol{\tau}}_J = \epsilon^2 \frac{d^2 \boldsymbol{\tau}_J}{dt^2} = \frac{d^2 \boldsymbol{\tau}_J}{d\sigma^2}.$$

This model serves as a basis for composite control schemes, where the control torque has the general form

$$\boldsymbol{\tau} = \boldsymbol{\tau}_s(\mathbf{q}, \dot{\mathbf{q}}, t) + \epsilon \boldsymbol{\tau}_f(\mathbf{q}, \dot{\mathbf{q}}, \boldsymbol{\tau}_J, \dot{\boldsymbol{\tau}}_J). \quad (13.12)$$

This includes a slow action $\boldsymbol{\tau}_s$, designed when neglecting joint elasticity, and an additional action $\boldsymbol{\tau}_f$ for locally stabilizing the fast flexible dynamics around a suitable manifold in the state space. It can be verified that, when setting $\epsilon = 0$ in (13.10, 11, 12), the equivalent rigid robot model is recovered as

$$[\mathbf{M}(\mathbf{q}) + \mathbf{B}] \ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau}_s.$$

A similar singular perturbation model (and control design) can also be derived for robot manipulators with flexible links.

13.1.2 Inverse Dynamics

Given a desired motion of a robot, we wish to compute the nominal torque needed to reproduce this motion exactly in ideal conditions (the inverse dynamics problem). Such nominal torque can be used as the feedforward term in a trajectory-tracking control law.

For rigid robots, the inverse dynamics is a straightforward algebraic computation obtained by replacing

the desired motion of the generalized coordinates in the dynamic model. The minimum requirement for exact reproduction is that the planned motion has a continuously differentiable desired velocity. For robots with elastic joints, a motion task can be conveniently expressed in terms of a desired link trajectory $\mathbf{q} = \mathbf{q}_d(t)$ (possibly obtained from the kinematic inversion of a desired motion in Cartesian space). The additional complexity lies in the fact that not all robot coordinates are directly assigned in this way, so that additional derivations should be performed. This will require some higher degree of smoothness of the desired trajectory $\mathbf{q}_d(t) \in [0, T]$, where the final time T may or may not be finite.

Reduced Model

Consider first the case of the reduced model (13.7) and set $\mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q})$ for compactness. By evaluating the link equations on the desired link motion

$$\mathbf{M}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\mathbf{q}_d = \mathbf{K}\theta_d, \quad (13.13)$$

the nominal position θ_d of the motors associated with the desired link motion is readily obtained. The nominal elastic torque at the joints is $\tau_{J,d} = \mathbf{K}(\theta_d - \mathbf{q}_d)$; note that, from (13.13), this quantity can be expressed as a function of \mathbf{q}_d , $\dot{\mathbf{q}}_d$, and $\ddot{\mathbf{q}}_d$, which is independent of \mathbf{K} . Differentiating (13.13) leads to the expression for the nominal motor velocity $\dot{\theta}_d$,

$$\mathbf{M}(\mathbf{q}_d)\mathbf{q}_d^{[3]} + \dot{\mathbf{M}}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \ddot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\dot{\mathbf{q}}_d = \mathbf{K}\dot{\theta}_d, \quad (13.14)$$

where the notation $\mathbf{y}^{[i]} = d^i \mathbf{y} / dt^i$ is used. Differentiating once more, we obtain

$$\begin{aligned} \mathbf{M}(\mathbf{q}_d)\mathbf{q}_d^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q}_d)\mathbf{q}_d^{[3]} + \ddot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ + [\ddot{\mathbf{M}}(\mathbf{q}_d) + \mathbf{K}]\ddot{\mathbf{q}}_d = \mathbf{K}\ddot{\theta}_d, \end{aligned} \quad (13.15)$$

to be used in the motor equations evaluated along the desired motion. After simplifications, the nominal torque is obtained as

$$\begin{aligned} \tau_d = & [\mathbf{M}(\mathbf{q}_d) + \mathbf{B}]\ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ & + \mathbf{B}\mathbf{K}^{-1} \left\{ \mathbf{M}(\mathbf{q}_d)\mathbf{q}_d^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q}_d)\mathbf{q}_d^{[3]} \right. \\ & \left. + \ddot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \ddot{\mathbf{M}}(\mathbf{q}_d) + \mathbf{K}\ddot{\mathbf{q}}_d \right\}, \end{aligned} \quad (13.16)$$

where the extra contributions to the nominal torque of the rigid case due to joint elasticity can be clearly recognized. The evaluation of τ_d involves the computation of

first- and second-order partial derivatives of the dynamic model terms. For instance, one needs to compute

$$\dot{\mathbf{M}}[\mathbf{q}_d(t)] = \sum_{i=1}^N \frac{\partial \mathbf{M}_i(\mathbf{q})}{\partial \mathbf{q}} \Big|_{\mathbf{q}=\mathbf{q}_d(t)} \dot{\mathbf{q}}_d(t) \mathbf{e}_i^\top,$$

where \mathbf{e}_i is the i -th unit vector. This and other similar expressions can be obtained by symbolic manipulation software. From (13.16) it follows that the minimum requirement for the exact reproducibility of the desired motion is that $\mathbf{q}_d(t)$ admits a continuously differentiable jerk (i.e., that $\mathbf{q}_d^{[4]}(t)$ exists in the time interval $[0, T]$). Such a smoother requirement should not come unexpected, in view of the flexible nature of the system.

Complete Model

Some more analysis is needed for the model (13.9). For ease of exposition, and without loss of generality, the case of a constant matrix \mathbf{S} is considered. When evaluating the link equations on the desired link motion

$$\mathbf{M}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{S}\ddot{\theta}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K}\mathbf{q}_d = \mathbf{K}\theta_d, \quad (13.17)$$

the additional presence of the motor acceleration in the left-hand side does not allow the motor position θ_d to be expressed directly as a function of $(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)$ only. However, the strictly upper-triangular structure (13.5) of \mathbf{S} allows one to define θ_d componentwise, using the scalar equations in (13.17) recursively. The N -th equation is in fact independent of $\ddot{\theta}_d$,

$$\mathbf{M}_N^\top(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{0}^\top \ddot{\theta}_d + n_N(\mathbf{q}_d, \dot{\mathbf{q}}_d) + K_N q_{d,N} = K_N \theta_{d,N},$$

so that this equation can be used to define

$$\theta_{d,N} = f_N(\mathbf{q}_d, \dot{\mathbf{q}}_d, \ddot{\mathbf{q}}_d)$$

and, after double differentiation, its second time derivative

$$\ddot{\theta}_{d,N} = f_N''(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[4]}).$$

In the $(N-1)$ -th equation,

$$\begin{aligned} \mathbf{M}_{N-1}^\top(\mathbf{q}_d)\ddot{\mathbf{q}}_d + S_{N-1,N}\ddot{\theta}_{d,N} \\ + n_{N-1}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + K_{N-1}q_{d,N-1} = K_{N-1}\theta_{d,N-1}, \end{aligned}$$

the acceleration $\ddot{\theta}_{d,N}$ has already been determined in the previous step. Therefore, this equation can be used similarly to define

$$\theta_{d,N-1} = f_{N-1}(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[4]})$$

and, after two time differentiations, also

$$\ddot{\theta}_{d,N-1} = f_{N-1}''(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[6]}).$$

Note that whenever $S_{N-1,N} = 0$, there will be no increase in the degree of the highest-order derivatives of \mathbf{q}_d within the functional dependence of $\theta_{d,N-1}$. This argument also applies recursively to the following steps. Proceeding backward through the link equations, the scalar computations end up with the definition of

$$\theta_{d,1} = f_1(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2N]})$$

and

$$\ddot{\theta}_{d,1} = f_1''(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2(N+1)]}),$$

where the dependence on the highest possible differential degree of \mathbf{q}_d is shown. With $\ddot{\theta}_d = f''(\cdot)$ made available in this way, the nominal torque is finally computed from the motor equations, again evaluated along the desired motion. Using (13.17) to substitute for $K(\theta_d - q_0)$ yields:

$$\begin{aligned} \tau_d = & [\mathbf{M}(\mathbf{q}_d) + \mathbf{S}^\top] \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) \\ & + (\mathbf{B} + \mathbf{S}) \ddot{\theta}_d(\mathbf{q}_d, \dot{\mathbf{q}}_d, \dots, \mathbf{q}_d^{[2(N+1)]}). \end{aligned} \quad (13.18)$$

As a result, the presence of inertial motor-link couplings considerably increases the complexity of the solution to the inverse dynamics problem. The exact reproduction of a desired link trajectory by the nominal torque in (13.18) requires that $\mathbf{q}_d(t)$ has a continuously differentiable $(2N+1)$ -th time derivative (i.e., that $\mathbf{q}_d^{[2(N+1)]}(t)$ exists in the time interval $[0, T]$). For rest-to-rest motions, this implies a trajectory plan that imposes a very slow start and ending phases.

We finally remark that the possibility of expressing the evolution of the state and input of a system algebraically in terms of the evolution of an output variable (in our case \mathbf{q}) and a finite number of its derivatives is sometimes referred to as the *flatness* property. The above inverse dynamics analysis shows that \mathbf{q} is a flat output for robots with elastic joints modeled either by (13.7) or by (13.9).

Note also that, when a *constant* \mathbf{q}_d is considered, these computations all provide the same condition for the associated motor position

$$\theta_d = \mathbf{q}_d + \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) \quad (13.19)$$

and nominal static torque

$$\tau_d = \mathbf{g}(\mathbf{q}_d). \quad (13.20)$$

Presence of Dissipative Terms

Inclusion of dissipative terms in the inverse dynamics deserves some additional comments. Any model of frictional effects acting on the motor side of the transmissions can be included in the computation without extra

requirements. Friction at the link side should instead be described by a smooth model, because of the need to differentiate the link equations. Thus, some functional approximations may be needed (e.g., replacing discontinuous *sign* functions with hyperbolic tangents) before including this term in (13.13) or (13.17).

On the other hand, the presence of a nonnegligible spring damping \mathbf{D} (13.8) changes the structure of the computations. While this reduces the order of the derivatives of \mathbf{q}_d involved, the problem itself will become nonalgebraic; in fact, the inverse system will require the use of the solution of a dynamical system, albeit a simple one.

Consider for instance the model (13.9), including now all the dissipative terms given in (13.8). When evaluating the link equations,

$$\begin{aligned} \mathbf{M}(\mathbf{q}_d) \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + (\mathbf{D} + \mathbf{F}_q) \dot{\mathbf{q}}_d + \mathbf{K} \mathbf{q}_d \\ = \mathbf{D} \ddot{\theta}_d + \mathbf{K} \theta_d, \end{aligned} \quad (13.21)$$

the motor velocity $\dot{\theta}_d$ additionally appears on the right-hand side. Differentiating (13.21) leads to

$$\mathbf{D} \ddot{\theta}_d + \mathbf{K} \dot{\theta}_d = \mathbf{w}_d, \quad (13.22)$$

with

$$\begin{aligned} \mathbf{w}_d = & \mathbf{M}(\mathbf{q}_d) \mathbf{q}_d^{[3]} + [\dot{\mathbf{M}}(\mathbf{q}_d) + \mathbf{D} + \mathbf{F}_q] \ddot{\mathbf{q}}_d \\ & + \dot{\mathbf{n}}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{K} \dot{\mathbf{q}}_d. \end{aligned}$$

Equation (13.22) represents a first-order linear *asymptotically stable* dynamical system (internal dynamics), with state $\dot{\theta}_d$ and forcing signal $\mathbf{w}_d(t)$. For a given $\dot{\theta}_d(0)$, its solution $\dot{\theta}_d(t)$ and the associated solution derivative $\ddot{\theta}_d(t)$ are needed to evaluate the nominal torque in the motor equations. This yields

$$\tau_d = \mathbf{M}(\mathbf{q}_d) \ddot{\mathbf{q}}_d + \mathbf{n}(\mathbf{q}_d, \dot{\mathbf{q}}_d) + \mathbf{F}_q \dot{\mathbf{q}}_d + \mathbf{B} \ddot{\theta}_d + \mathbf{F}_\theta \dot{\theta}_d,$$

where (13.21) has been used to replace the term $\mathbf{D}(\dot{\theta}_d - \dot{\mathbf{q}}_d) + \mathbf{K}(\theta_d - \mathbf{q}_d)$. In this case, the desired link trajectory $\mathbf{q}_d(t)$ should have a continuously differentiable acceleration ($\mathbf{q}_d^{[3]}$) should exist, since it is used in the definition of \mathbf{w}_d . Note that any initialization $\dot{\theta}_d(0)$ of the internal dynamics (13.22) is feasible (i.e., it produces a specific torque profile $\tau_d(t)$ yielding the same link motion $\mathbf{q}_d(t)$), with the associated motor position $\theta_d(0)$ initialized from (13.21). However, we should match the actual initial state of the robot arm. For instance, starting from an equilibrium state implies the unique choice $\dot{\theta}_d(0) = \mathbf{0}$.

A similar procedure can also be applied to the complete model (13.7) in the presence of spring damping. Again a dynamical inverse system will be needed, while

the smoothness requirement on $\dot{q}_d(t)$ would be even more dramatically reduced in that case.

We finally remark that, for robots with flexible links, the inverse dynamics problem gives also rise to an internal dynamics, independently of the presence of modal damping. When specifying a desired motion for the tip of the flexible arm, the associated internal dynamics will be *unstable* and this critical issue has to be tackled to determine a feasible solution.

13.1.3 Regulation Control

We consider next the problem of controlling the motion of a robot with joint elasticity to a *constant* configuration. In this problem, no trajectory planning is involved and a feedback law should be found that achieves asymptotic stabilization of a desired closed-loop equilibrium. Global solutions (i.e., those valid when starting from any initial state) are indeed preferred.

From the analysis in the previous section, it should be clear that one needs to define only a constant reference \dot{q}_d (with $\ddot{q}_d(t) \equiv 0$) for the link coordinates. From (13.19), a unique reference θ_d for the motor variables is in fact associated with the desired \dot{q}_d (which, in turn, may result from a desired pose of the robot end-effector). Furthermore, (13.20) provides the needed static torque to be applied at steady state by any feasible controller.

A major aspect of the presence of joint elasticity is that the feedback part of the control law can depend in general on *four* variables for each joint: the motor and link position, and the motor and link velocity. However, in most robots where joint elasticity is not explicitly considered in the system design, at most two sensors are available for measurement at the joints: a position sensor (e.g., an encoder) and, in some cases, a tachometer as a velocity sensor. When no velocity sensors are present, velocity is typically reconstructed by suitable numerical differentiation of high-resolution position measurements. Due to the presence of joint elasticity, the position/velocity quantities that are actually measured depend on where these sensors are mounted in the motor/transmission assembly.

A single link driven through an elastic joint is introduced as a paradigmatic case study to show what can be achieved using different sets of partial state measurements. This simple provides indications on how to handle the general multilink case.

In the absence of gravity, it will be shown that a proportional-derivative (PD) controller based only on motor measurements is sufficient to achieve the desired regulation task. In the presence of gravity, various gravity compensation schemes can be added to the PD feedback controller. These control results mimic the situation of robots with rigid joints, once the convenient quantities for use in the feedback have been identified.

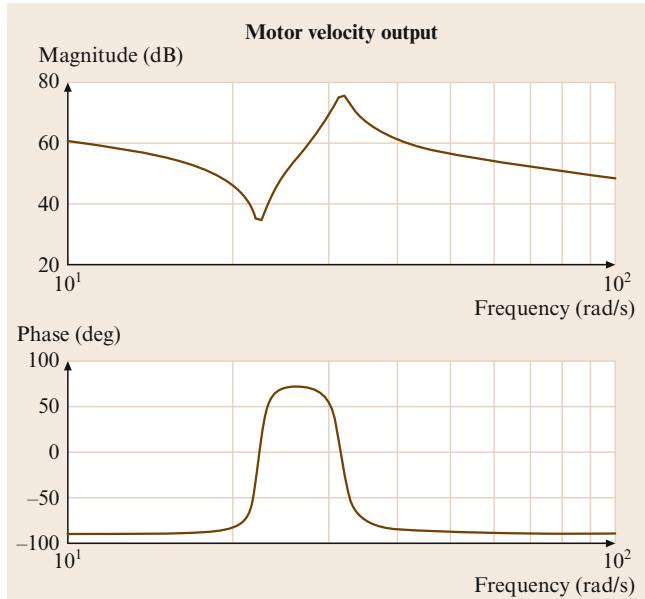

Fig. 13.6 Bode diagrams of the torque to motor velocity transfer function

Single Elastic Joint Example

Consider a single link rotating on a horizontal plane (thus, without gravity) and actuated with a motor through an elastic joint coupling (Fig. 13.4). When viscous friction on motor and link side as well as damping across the spring are included, the dynamic model is

$$\begin{aligned} M\ddot{\theta} + D(\dot{\theta} - \dot{\theta}) + K(\theta - \theta) + F_q\dot{\theta} &= 0, \\ B\ddot{\theta} + D(\dot{\theta} - \dot{\theta}) + K(\theta - \theta) + F_\theta\dot{\theta} &= \tau, \end{aligned}$$

where the same, now scalar, notation of Sect. 13.1.1 has been used. Since this system is described by linear equations, Laplace transforms are used to derive the transfer functions of interest, namely from input torque to motor position

$$\frac{\theta(s)}{\tau(s)} = \frac{Ms^2 + (D + F_q)s + K}{\text{den}(s)},$$

and from input torque to link position

$$\frac{q(s)}{\tau(s)} = \frac{Ds + K}{\text{den}(s)},$$

with the common denominator $\text{den}(s)$ given by

$$\text{den}(s) = \left\{ MB s^3 + [M(D + F_\theta) + B(D + F_q)] s^2 + [(M + B)K + (F_q + F_\theta)D + F_q F_\theta] s + (F_q + F_\theta)K \right\} s.$$

In the case of link position output, the transfer function has a larger relative degree (or pole-zero excess). Figures 13.6 and 13.7 show typical frequency responses in the two cases. For clarity, the outputs have been chosen at the velocity level. In the Bode diagram of the magnitude for the motor velocity output, note the presence of an antiresonance/resonance behavior. Similarly, there is a pure resonance (more pronounced for weak or zero spring damping D) for the link velocity output. The phase profile in Fig. 13.7, with a high-frequency lag of 270° , also indicates the greater control difficulty encountered when closing the feedback loop for link quantities. In experimental tests on a robot joint, such plots are quite characteristic of the presence of concentrated joint elasticity and can be used to assess the relevance of this phenomenon and for identifying model parameters.

For the analysis of the stabilizing properties of different feedback arrangements, all dissipative effects will be neglected ($D = F_q = F_\theta = 0$ is anyway the worst case). Consider first the transfer function relative to the motor position output:

$$\left. \frac{\theta(s)}{\tau(s)} \right|_{\text{no diss}} = \frac{Ms^2 + K}{[MB s^2 + (M + B)K] s^2}. \quad (13.23)$$

As well as a double pole at the origin, this transfer function has a pair of imaginary zeros and poles, with the zero pair occurring at the so-called locked frequency

$$\omega_1 = \sqrt{K/M},$$

which characterizes the oscillations occurring when the motor is locked ($\theta \equiv 0$), e.g., by a high-gain positional feedback. This frequency is used to assess the performance limit of a simple PD control for the motor variables. In order to achieve enough damping in the closed-loop system, the bandwidth should be limited, as a rule of thumb, to one third of ω_1 . Faster transients can be achieved only by taking into account the fourth-order dynamics of the elastic joint assembly. Note also that the frequency of these zeros is always *lower* than that of the poles in (13.23). This is related to the *passivity* of the mapping from torque to motor velocity, a property useful for stability and robust or adaptive control design.

Since the control objective is to regulate the link position output, we are also interested in the open-loop

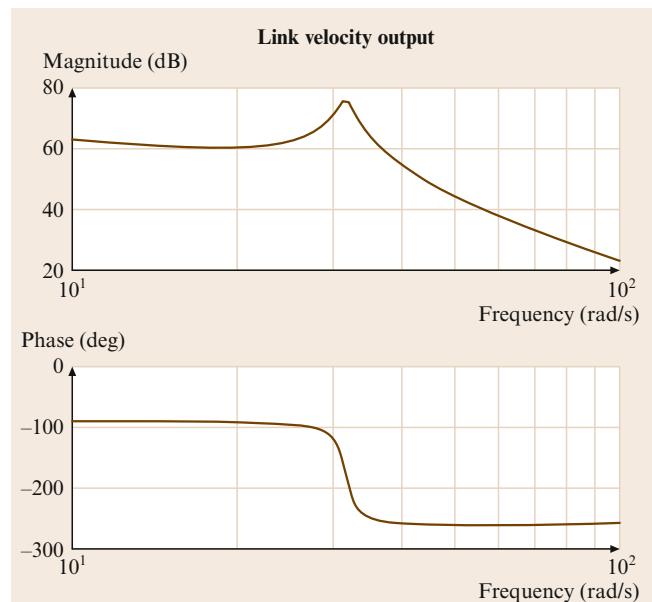

Fig. 13.7 Bode diagrams of the torque to link velocity transfer function

transfer function

$$\left. \frac{q(s)}{\tau(s)} \right|_{\text{no diss}} = \frac{K}{[MB s^2 + (M + B)K] s^2}. \quad (13.24)$$

This transfer function has *no zeros* (in fact, for this it is sufficient to have $D = 0$) so that the relative degree is now four, the maximum possible. We shall see that the nonlinear counterpart of the absence of zeros in (13.24) will play a relevant role also for trajectory control in the multilink case of robots with elastic joints.

It is also worth mentioning that this situation is completely different from the case in which the elastic spring would be moved out of the joint and placed anywhere along the link – a simple one-mode approximate model of link flexibility. In that case the analogous transfer function will possess two symmetric real zeros (a *non-minimum-phase* system), indicating the criticality of a direct inversion of the system input–output map for the execution of a desired link trajectory.

With the desired position given in terms of the link variable q_d , the most natural choice for the design of linear stabilizing feedback using one position and one velocity variable, is to close a PD loop from the link variables,

$$\tau = u_q - (K_{P,q}q + K_{D,q}\dot{q}), \quad (13.25)$$

with position and velocity gains $K_{P,q}$ and $K_{D,q}$, and with $u_q = K_{P,q}q_d$ being the external input used for defining

the set point. It is easy to verify that the closed-loop poles will be unstable no matter how the gains are chosen, so that error feedback from link variables alone should be avoided. In a similar way, also the combination of motor position and link velocity feedback is always unstable.

Another mixed feedback strategy is to use link position and motor velocity:

$$\tau = u_q - (K_{P,q}q + K_{D,m}\dot{\theta}). \quad (13.26)$$

This combination corresponds, e.g., to the case of a tachometer integrated in a direct-current (DC) motor and of an optical encoder placed on the load shaft for sensing its position (without any knowledge about the relevance of joint elasticity). Use of (13.26) leads to the closed-loop characteristic equation

$$\begin{aligned} BMs^4 + MK_{D,ms}^3 + (B + M)Ks^2 \\ + KK_{D,ms} + KK_{P,q} = 0. \end{aligned}$$

Using Routh's criterion, asymptotic stability occurs if and only if the motor velocity gain $K_{D,m} > 0$ and the link position gain satisfies $0 < K_{P,q} < K$, i.e., the proportional feedback should not *override* the spring stiffness. The existence of such an upper bound limits the usefulness of this scheme.

Finally, performing feedback from the motor variables

$$\tau = u_\theta - (K_{P,m}\theta + K_{D,m}\dot{\theta}), \quad (13.27)$$

the closed-loop system will be asymptotically stable provided that both $K_{P,m}$ and $K_{D,m}$ are strictly positive (and otherwise arbitrarily large). This favorable situation lends itself to a convenient generalization in the multilink case.

Note that other partial state feedback combinations would be possible, depending on the available sensing devices. For instance, mounting a strain gauge on the transmission shaft provides a direct measure of the elastic torque $\tau_I = K(\theta - q)$ for control use. Strain gauges are also useful sensors for flexible links. Indeed, full-state feedback may be designed so as to guarantee asymptotic stability and improve the transient behavior considerably; however, this would be obtained at the cost of additional sensors and requires proper tuning of the four gains.

PD Control Using only Motor Variables

For the general multilink case in the absence of gravity, consider the PD control law based on motor position and velocity feedback

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta}, \quad (13.28)$$

with symmetric (typically, diagonal) positive-definite gain matrices K_P and K_D . Since $\mathbf{g}(q) \equiv \mathbf{0}$, it follows from (13.19) that the reference value for the motor position is $\theta_d = q_d$ (no joint deflection is present nor an input torque is needed at steady state).

The control law (13.28) globally asymptotically stabilizes the desired equilibrium state $q = \theta = q_d$, $\dot{\theta} = \dot{\theta} = \mathbf{0}$. This can be shown through a Lyapunov argument, completed by the application of La Salle's theorem. In fact, a candidate Lyapunov function is given by the sum of the total energy of the system (kinetic plus elastic potential) and of the control energy due to the proportional term (a virtual elastic potential energy):

$$\begin{aligned} V = \frac{1}{2} \dot{\Theta}^\top \mathcal{M}(\Theta) \dot{\Theta} + \frac{1}{2} (q - \theta)^\top K(q - \theta) \\ + \frac{1}{2} (\theta_d - \theta)^\top K_P(\theta_d - \theta) \geq 0. \end{aligned} \quad (13.29)$$

Computing the time derivative of V along the trajectories of the closed-loop system given by (13.7) (or (13.9)) and (13.28), and taking into account the skew-symmetry of $\dot{\mathcal{M}} - 2\mathbf{C}$, leads to

$$\dot{V} = -\dot{\theta}^\top K_D \dot{\theta} \leq 0.$$

The inclusion of dissipative terms (viscous friction and spring damping) would render \dot{V} even more negative-semidefinite. The analysis is completed by verifying that the maximum invariant set contained in the set of states such that $\dot{V} = 0$ (i.e., those with $\dot{\theta} = \mathbf{0}$) collapses into the desired unique equilibrium state.

We point out that an identical control law is able to globally regulate, in the absence of gravity, robots with flexible links to a desired joint configuration. In that case, θ in (13.28) would be the rigid coordinates at the base of the flexible links of the robot.

PD with Constant Gravity Compensation

The presence of gravity requires the addition of some form of gravity compensation to the PD action (13.28). Moreover, this will need an additional structural assumption and may demand some caution in the selection of the control gains.

Before proceeding, we recall a basic property of the gravity vector $\mathbf{g}(q)$ (under assumption A2, the gravity vector in (13.7) is the same as that appearing in the dynamics of the equivalent rigid robot): for robots with rotational joints, elastic or not, a positive constant α exists such that

$$\left\| \frac{\partial \mathbf{g}(q)}{\partial q} \right\| \leq \alpha, \quad \forall q \in \mathbb{R}^N. \quad (13.30)$$

The norm of a matrix $A(\mathbf{q})$ is that induced by the Euclidean norm for vectors, i.e., $\|A\| = \sqrt{\lambda_{\max}(A^\top A)}$. Inequality (13.30) implies that

$$\|\mathbf{g}(\mathbf{q}_1) - \mathbf{g}(\mathbf{q}_2)\| \leq \alpha \|\mathbf{q}_1 - \mathbf{q}_2\|, \quad \forall \mathbf{q}_1, \mathbf{q}_2 \in \mathbb{R}^N. \quad (13.31)$$

In common practice, robot joints are never unrealistically *soft*. More precisely, they are stiff enough to have, under the load of the robot's own weight, a unique equilibrium link position \mathbf{q}_e associated with any assigned fixed motor position θ_e – the reverse of the relationship expressed by (13.19). This situation is by no means restrictive, but will be stated for clarity as a further modeling assumption:

A5 The lowest joint stiffness is larger than the upper bound on gravity forces acting on the robot, or

$$\min_{i=1,\dots,N} K_i > \alpha.$$

The simplest modification for handling the presence of gravity is to consider the addition of a constant term that compensates exactly the gravity load at the desired steady state. According to (13.19) and (13.20), the control law (13.28) is then modified to

$$\tau = \mathbf{K}_P(\theta_d - \theta) - \mathbf{K}_D\dot{\theta} + \mathbf{g}(\mathbf{q}_d), \quad (13.32)$$

with symmetric, typically diagonal, $\mathbf{K}_P > \mathbf{0}$ (as a minimum) and $\mathbf{K}_D > \mathbf{0}$, and with the motor reference given by $\theta_d = \mathbf{q}_d + \mathbf{K}^{-1}\mathbf{g}(\mathbf{q}_d)$.

A sufficient condition guaranteeing that $\mathbf{q} = \mathbf{q}_d$, $\theta = \theta_d$, $\dot{\mathbf{q}} = \dot{\theta} = \mathbf{0}$ will be a globally asymptotically stable equilibrium for the system (13.7) under the control law (13.32) is that

$$\lambda_{\min} \left[\begin{pmatrix} \mathbf{K} & -\mathbf{K} \\ -\mathbf{K} & \mathbf{K} + \mathbf{K}_P \end{pmatrix} \right] > \alpha, \quad (13.33)$$

with α defined in (13.30). Taking into account the diagonal structure of \mathbf{K} and \mathbf{K}_P , and thanks to assumption **A5**, it is always possible to fulfill this condition by increasing the smallest proportional gain in the controller (or, the smallest eigenvalue of \mathbf{K}_P if this matrix has not been chosen diagonal).

In the following, we sketch the motivation for this condition and the associated proof of asymptotic stability. The equilibrium positions of the closed-loop system are the solutions of

$$\mathbf{K}(\mathbf{q} - \theta) + \mathbf{g}(\mathbf{q}) = \mathbf{0},$$

$$\mathbf{K}(\theta - \mathbf{q}) - \mathbf{K}_P(\theta_d - \theta) - \mathbf{g}(\mathbf{q}_d) = \mathbf{0}.$$

Indeed, the pair (\mathbf{q}_d, θ_d) satisfies these equations. However, in order to obtain a global result one should

guarantee that this pair is the unique solution. Therefore, recalling (13.19), the null term $\mathbf{K}(\theta_d - \mathbf{q}_d) - \mathbf{g}(\mathbf{q}_d)$ can be added/subtracted to both equations to obtain

$$\begin{aligned} \mathbf{K}(\mathbf{q} - \mathbf{q}_d) - \mathbf{K}(\theta - \theta_d) &= \mathbf{g}(\mathbf{q}_d) - \mathbf{g}(\mathbf{q}) \\ -\mathbf{K}(\mathbf{q} - \mathbf{q}_d) + (\mathbf{K} + \mathbf{K}_P)(\theta - \theta_d) &= \mathbf{0}, \end{aligned}$$

where the matrix in condition (13.33) can be clearly recognized. Taking the norms of terms on both sides and bounding gravity terms using (13.31), the introduced condition (13.33) implies that the pair (\mathbf{q}_d, θ_d) is in fact the unique equilibrium. To show asymptotic stability, a candidate Lyapunov function is built based on that used in the absence of gravity (13.29):

$$\begin{aligned} V_{g1} &= V + \mathcal{U}_{\text{grav}}(\mathbf{q}) - \mathcal{U}_{\text{grav}}(\mathbf{q}_d) - (\mathbf{q} - \mathbf{q}_d)^\top \mathbf{g}(\mathbf{q}_d) \\ &\quad - \frac{1}{2} \mathbf{g}^\top(\mathbf{q}_d) \mathbf{K}^{-1} \mathbf{g}(\mathbf{q}_d) \geq 0. \end{aligned} \quad (13.34)$$

The last constant term is used to set the minimum value of V_{g1} to zero at the desired equilibrium. The positive-definiteness of V_{g1} and the fact that its unique minimum is at the desired state are again implied by condition (13.33). By the usual computations, it follows that $\dot{V}_{g1} = -\dot{\theta}^\top \mathbf{K}_D \dot{\theta} \leq 0$ and the result is obtained applying La Salle's theorem.

The control law (13.32) is based only on the knowledge of the gravity term $\mathbf{g}(\mathbf{q}_d)$ and of the joint stiffness \mathbf{K} . The latter appears in fact in the definition of the motor position reference θ_d . Uncertainties in the gravitational term $\mathbf{g}(\mathbf{q}_d)$ and on the joint stiffness \mathbf{K} affect the performance of the controller. Still, the existence of a unique closed-loop equilibrium and its asymptotic stability are preserved when the gravity bound by α is still correct and condition (13.33) holds for the true stiffness values. Indeed, the robot will converge to an equilibrium that is different from the desired one – the better the estimates $\hat{\mathbf{K}}$ and $\hat{\mathbf{g}}(\mathbf{q}_d)$ used, the closer the actual equilibrium will be to the desired one.

PD with Online Gravity Compensation

Similarly to the rigid robot case, a better transient behavior is to be expected if gravity compensation (or, more precisely, its perfect cancellation) is performed at all configurations during motion. However, the gravity vector in (13.7) depends on the link variables \mathbf{q} , which are assumed not to be measurable at this stage. It is easy to see that using $\mathbf{g}(\theta)$, with the measured motor positions in place of the link positions, leads in general to an incorrect closed-loop equilibrium. Moreover, even if \mathbf{q} were available, adding $\mathbf{g}(\mathbf{q})$ to a motor PD error feedback has no guarantee of success because this compensation, which appears in the motor equation, does

not instantaneously cancel the gravity load acting on the links.

With this in mind, a PD control with *online* gravity compensation can be introduced as follows. Define the variable

$$\tilde{\theta} = \theta - K^{-1}g(q_d), \quad (13.35)$$

which is a *gravity-biased* modification of the measured motor position θ , and let

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + g(\tilde{\theta}), \quad (13.36)$$

where $K_P > \mathbf{0}$ and $K_D > \mathbf{0}$ are both symmetric (and typically diagonal) matrices. The control law (13.36) can still be implemented using only motor variables. The term $g(\tilde{\theta})$ only provides an approximate cancellation (though of a large part) of gravity during motion, but leads to the correct gravity compensation in the steady state. In fact, by using (13.19) and (13.35), it follows that

$$\tilde{\theta}_d := \theta_d - K^{-1}g(q_d) = q_d,$$

so that $g(\tilde{\theta}_d) = g(q_d)$.

Global asymptotic stability of the desired equilibrium can be guaranteed under the same condition (13.33) used for the constant gravity compensation case. A slightly different Lyapunov candidate is defined, starting again from the one in (13.29), as

$$V_{g2} = V + \mathcal{U}_{\text{grav}}(q) - \mathcal{U}_{\text{grav}}(\tilde{\theta}) - \frac{1}{2}g^\top(q_d)K^{-1}g(q_d) \geq 0,$$

to be compared with (13.34).

The use of an online gravity compensation scheme typically provides a smoother time course and a noticeable reduction of the positional transient errors, with no additional control effort in terms of peak and average torques. We note that choices of low position gains, even when largely violating the sufficient condition (13.33) for stability, may still work, contrary to the case of constant gravity compensation. However also for increasing values of joint stiffness, in the limit for $K \rightarrow \infty$, the range of feasible values of K_P that guarantee exact regulation does not extend down to zero.

A possibility to refine the online gravity compensation scheme, again based only on motor position measurement, is offered by the use of a fast iterative algorithm that elaborates the measure θ in order to generate a quasistatic estimate $\bar{q}(\theta)$ of the current (unmeasured) q . In fact, in any steady-state configuration (q_s, θ_s) , a direct mapping is defined from q_s to θ_s :

$$\theta_s = h_g(q_s) := q_s + K^{-1}g(q_s).$$

Assumption A5 is sufficient to guarantee the existence and uniqueness also of the inverse mapping $q_s = h_g^{-1}(\theta_s)$. For a measured θ , the function

$$q = T(\theta) := \theta - K^{-1}g(\theta)$$

is then a *contraction mapping* and the iteration

$$q_{i+1} = T(q_i), \quad i = 0, 1, 2, \dots$$

will converge to the unique fixed point of this mapping, which is exactly the value $\bar{q}(\theta) = h_g^{-1}(\theta)$. A suitable initialization for q_0 is either the measured θ or the value \bar{q} computed at the previous sampling instant. In this way, just two or three iterations are needed to obtain sufficient accuracy and this is fast enough to be implemented within a sensing/control sampling interval of a digital robot controller.

With this iterative scheme running in the background, the regulation control law becomes

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + g[\bar{q}(\theta)], \quad (13.37)$$

with symmetric (diagonal) $K_P > \mathbf{0}$ and $K_D > \mathbf{0}$. A proof of the global asymptotic stability of this control scheme can be given by further modifying the previous Lyapunov candidates. The advantage of (13.37) is that any positive value of the feedback gain K_P is allowed, thus recovering in full the operative working conditions of the rigid case with exact gravity cancellation.

Both online gravity compensation schemes (13.36) and (13.37) realize a *compliance control* in the joint space with only motor measurements. The same idea can also be extended to the case of Cartesian compliance control by evaluating the direct kinematics and the Jacobian (transpose) of the robot arm with $\tilde{\theta}$ or, respectively, $\bar{q}(\theta)$ in place of q .

Full-State Feedback

When the feedback law is based on a full set of measurements of the robot state, the transient performance of regulation control laws can be improved. Taking advantage of the availability of a joint torque sensor, we present a convenient design for the reduced model (13.9) of robots with elastic joints, including spring damping as a dissipation effect. Full-state feedback can be obtained in two phases, by combining a preliminary torque feedback with the motor feedback law in (13.28).

Using $\tau_J = K(\theta - q)$, the motor equation can be rewritten as

$$B\ddot{\theta} + \tau_J + DK^{-1}\dot{\tau}_J = \tau.$$

The joint torque feedback

$$\tau = \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{u} + (\mathbf{I} - \mathbf{B}\mathbf{B}_\theta^{-1})(\tau_j + \mathbf{D}\mathbf{K}^{-1}\dot{\tau}_j), \quad (13.38)$$

where \mathbf{u} is an auxiliary input to be designed, transforms the motor equations into

$$\mathbf{B}_\theta\ddot{\tau}_j + \tau_j + \mathbf{D}\mathbf{K}^{-1}\dot{\tau}_j = \mathbf{u}.$$

In this way, the apparent motor inertia can be reduced to a desired, arbitrary small value \mathbf{B}_θ , with clear benefits in terms of vibration damping. For instance in the linear and scalar case, a very small B shifts the pair of complex poles in (13.23) to a very high frequency, with the joint behaving almost as a rigid one.

Setting

$$\mathbf{u} = \mathbf{K}_{P,\theta}(\theta_d - \theta) - \mathbf{K}_{D,\theta}\dot{\theta} + \mathbf{g}(q_d)$$

in (13.38) leads to the state feedback controller

$$\begin{aligned} \tau = & \mathbf{K}_P(\theta_d - \theta) - \mathbf{K}_D\dot{\theta} + \mathbf{K}_T[\mathbf{g}(q_d) - \tau_j] \\ & - \mathbf{K}_S\dot{\tau}_j + \mathbf{g}(q_d), \end{aligned} \quad (13.39)$$

with gains

$$\mathbf{K}_P = \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{K}_{P,\theta},$$

$$\mathbf{K}_D = \mathbf{B}\mathbf{B}_\theta^{-1}\mathbf{K}_{D,\theta},$$

$$\mathbf{K}_T = \mathbf{B}\mathbf{B}_\theta^{-1} - \mathbf{I}$$

and

$$\mathbf{K}_S = (\mathbf{B}\mathbf{B}_\theta^{-1} - \mathbf{I})\mathbf{D}\mathbf{K}^{-1}.$$

Indeed, the law (13.39) can also be rewritten in terms of $(\theta, q, \dot{\theta}, \dot{q})$, if the torque sensor is not available. However, keeping this structure of the gains preserves the interesting physical interpretation of what the full-state feedback controller is achieving.

13.1.4 Trajectory Tracking

As for rigid robot arms, the problem of tracking desired time-varying trajectories is harder for robots with elastic joints than achieving constant regulation. In general, solving this problem requires the use of full-state feedback and knowledge of all the terms in the dynamic model.

Under these conditions, we shall focus on the *feedback linearization* approach, namely a nonlinear state feedback law that leads to a closed-loop system with decoupled and exactly linear behavior for all the N degrees of freedom of the robot (in fact, the link variables \mathbf{q}). The tracking errors along the reference trajectory are forced to be *globally exponentially stable*, with a decaying rate that can be directly specified through the choice of the

scalar feedback gains in the controller. This fundamental result is the direct extension of the well-known *computed torque* method for rigid robots. Because of its relevant properties, the feedback linearization approach can be used as a reference to assess the performance of any other trajectory tracking control law, which may possibly be designed using less/approximate model information and/or only partial-state feedback.

However, in the presence of joint elasticity, the design of a feedback linearization law is not straightforward. Furthermore, as soon as $S \neq \mathbf{0}$, the dynamic model (13.7) will not satisfy the existing necessary conditions for exact linearization (nor those for input–output decoupling) when only a *static* (or, instantaneous) feedback law from the full state is allowed. Therefore, we will restrict our attention to the more tractable case of the reduced dynamic model (13.9) and sketch only briefly the more general picture.

As a second much simpler approach to trajectory tracking problems, we also present a *linear control design* that makes use of a model-based feedforward command and a precomputed state reference trajectory, as obtained from the inverse dynamics computations of Sect. 13.1.2, with the addition of a linear feedback from the full state. In this case, convergence to the desired trajectory is only locally guaranteed, i.e., the tracking errors should be small enough, but the control implementation is straightforward and the real-time computational burden is considerably reduced.

Feedback Linearization

Consider the reduced model (13.9) and let the reference trajectory be specified by a desired smooth link motion $q_d(t)$. The control design will proceed by system inversion, in a similar way to the inverse dynamics computations of Sect. 13.1.2 but using now the current measures of the state variables $(q, \theta, \dot{q}, \dot{\theta})$ instead of the reference state evolution $(q_d, \theta_d, \dot{q}_d, \dot{\theta}_d)$. Notably, there is no need to transform the robot equations into their state-space description, which is the standard form used in control design for general nonlinear systems; we will use the robot model directly in its second-order differential form (typical of mechanical systems).

The outcome of the inversion procedure will be the definition of a torque τ , in the form of a static state feedback control law, which cancels the original robot dynamics and replaces it with a desired linear and decoupled one of suitable differential order. In this sense, the control law *stiffens* the dynamics of the robot with elastic joints. The feasibility of inverting the system from the chosen output \mathbf{q} without causing instability prob-

lems (related to the presence of unobservable dynamics in the closed-loop system, after cancellation) is a relevant property of robots with elastic joints. In fact, this is the direct generalization to the nonlinear multiple-input multiple-output (MIMO) case of the possibility of inverting a scalar transfer function in the absence of zeros (see also the considerations made on (13.24)).

Rewrite the link equation in the compact form

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\mathbf{q} - \boldsymbol{\theta}) = \mathbf{0}, \quad (13.40)$$

where again we set $\mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q})$. None of the above quantities depends instantaneously on the input torque $\boldsymbol{\tau}$. Therefore, we can differentiate once and obtain

$$\mathbf{M}(\mathbf{q})\mathbf{q}^{[3]} + \dot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\dot{\mathbf{q}} - \dot{\boldsymbol{\theta}}) = \mathbf{0}. \quad (13.41)$$

Proceeding one step further leads to

$$\begin{aligned} \mathbf{M}(\mathbf{q})\mathbf{q}^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q})\mathbf{q}^{[3]} + \ddot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} \\ + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}(\ddot{\mathbf{q}} - \ddot{\boldsymbol{\theta}}) = \mathbf{0}, \end{aligned} \quad (13.42)$$

where $\ddot{\boldsymbol{\theta}}$ now appears. The motor acceleration is at the same differential level of $\boldsymbol{\tau}$ in the motor equation

$$\mathbf{B}\ddot{\boldsymbol{\theta}} + \mathbf{K}(\boldsymbol{\theta} - \mathbf{q}) = \boldsymbol{\tau}, \quad (13.43)$$

and thus, replacing $\ddot{\boldsymbol{\theta}}$ from (13.43), we get

$$\begin{aligned} \mathbf{M}(\mathbf{q})\mathbf{q}^{[4]} + 2\dot{\mathbf{M}}(\mathbf{q})\mathbf{q}^{[3]} + \ddot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{K}\ddot{\mathbf{q}} \\ = \mathbf{KB}^{-1} [\boldsymbol{\tau} - \mathbf{K}(\boldsymbol{\theta} - \mathbf{q})]. \end{aligned} \quad (13.44)$$

We note that, using (13.40), the last term $\mathbf{K}(\boldsymbol{\theta} - \mathbf{q})$ in (13.44) may also be replaced by $\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})$.

Since the matrix $\mathbf{A}(\mathbf{q}) = \mathbf{M}^{-1}(\mathbf{q})\mathbf{KB}^{-1}$ is always nonsingular, an arbitrary value \mathbf{v} can be assigned to the fourth derivative of \mathbf{q} by a suitable choice of the input torque $\boldsymbol{\tau}$. The matrix $\mathbf{A}(\mathbf{q})$ is the so-called decoupling matrix of the system and its nonsingularity is a necessary and sufficient condition for imposing a decoupled input-output behavior by nonlinear static state feedback. Moreover, (13.44) indicates that each component q_i of \mathbf{q} needs to be differentiated $r_i = 4$ times in order to be algebraically related to the input torque $\boldsymbol{\tau}$ (r_i is the relative degree of q_i , when this is chosen as a system output). Since there are N link variables, the total sum of the relative degrees is $4N$, equal to the dimension of the state of a robot with elastic joints. All these facts taken together lead to the conclusion that, when inverting (13.44) to determine the input $\boldsymbol{\tau}$ that imposes $\mathbf{q}^{[4]} = \mathbf{v}$, there will be no other dynamics left other than the one appearing in the closed-loop input-output map.

Therefore, choose

$$\begin{aligned} \boldsymbol{\tau} = \mathbf{BK}^{-1} & \left[\mathbf{M}(\mathbf{q})\mathbf{v} + \boldsymbol{\alpha}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \mathbf{q}^{[3]}) \right] \\ & + [\mathbf{M}(\mathbf{q}) + \mathbf{B}]\ddot{\mathbf{q}} + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}), \end{aligned} \quad (13.45)$$

with

$$\boldsymbol{\alpha}(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \mathbf{q}^{[3]}) = \ddot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + 2\dot{\mathbf{M}}(\mathbf{q})\mathbf{q}^{[3]} + \ddot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}}),$$

where the terms in $\boldsymbol{\alpha}$ have been ordered according to the dependence on increasing orders of derivatives of \mathbf{q} . The control law (13.45) leads to a closed-loop system fully described by

$$\mathbf{q}^{[4]} = \mathbf{v}, \quad (13.46)$$

i.e., chains of four input-output integrators from each auxiliary input v_i to each link position output q_i , for $i = 1, \dots, N$. The robot system thus has been exactly linearized and decoupled by the nonlinear feedback law (13.45).

The complete control law (13.45) is expressed as a function of the so-called *linearizing* coordinates $(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \mathbf{q}^{[3]})$ only. This has led to some misunderstandings in the past, as it seemed that the feedback linearization approach for robots with elastic joints would need direct measures of the link acceleration $\ddot{\mathbf{q}}$ and jerk $\mathbf{q}^{[3]}$, which are impossible to obtain with currently available sensors (or would require multiple numerical differentiations of position measures in real time, with critical noise problems).

When considering the latest technology in the field, it is now feasible to have a set of sensors for elastic joints measuring in a reliable and accurate way the motor position $\boldsymbol{\theta}$ (and, possibly, also its velocity $\dot{\boldsymbol{\theta}}$), the joint torque $\boldsymbol{\tau}_J = \mathbf{K}(\boldsymbol{\theta} - \mathbf{q})$, as well as the link position \mathbf{q} . For instance, this is the arrangement of sensors available at each joint of the *LWR-III* lightweight manipulator, where Hall sensors are used for the motor position, joint torque sensing is based on strain gauges, and a high-end capacitive sensor is used for the link position (Fig. 13.8). Therefore, only one numerical differentiation is needed in order to obtain a good estimate of $\dot{\mathbf{q}}$ and/or $\ddot{\mathbf{q}}$ as well. Note that, depending on the specific sensor resolution, it may also be convenient to evaluate \mathbf{q} using the measures of $\boldsymbol{\theta}$ and $\boldsymbol{\tau}_J$ as $\mathbf{q} = \boldsymbol{\theta} - \mathbf{K}^{-1}\boldsymbol{\tau}_J$.

With this in mind, it is easy to see that the following three sets of $4N$ variables

$$(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \mathbf{q}^{[3]}), \quad (\mathbf{q}, \boldsymbol{\theta}, \dot{\mathbf{q}}, \dot{\boldsymbol{\theta}}), \quad (\mathbf{q}, \boldsymbol{\tau}_J, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$$

are all equivalent state variables for a robot with elastic joints, related by globally invertible transformations.

Therefore, under the assumption that the dynamic model is available, we can completely rewrite the feedback linearizing control law (13.45) in terms of the more *conventional* state $(\mathbf{q}, \theta, \dot{\mathbf{q}}, \dot{\theta})$ or, taking advantage of a joint torque sensor, in terms of $(\mathbf{q}, \tau_j, \dot{\mathbf{q}}, \dot{\tau}_j)$. In particular, as a byproduct of (13.40) and (13.41), we have

$$\begin{aligned}\ddot{\mathbf{q}} &= \mathbf{M}^{-1}(\mathbf{q}) [\mathbf{K}(\theta - \mathbf{q}) - \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})] \\ &= \mathbf{M}^{-1}(\mathbf{q}) [\tau_j - \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}})],\end{aligned}\quad (13.47)$$

and

$$\begin{aligned}\mathbf{q}^{[3]} &= \mathbf{M}^{-1}(\mathbf{q}) [\mathbf{K}(\dot{\theta} - \dot{\mathbf{q}}) - \dot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} - \dot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}})] \\ &= \mathbf{M}^{-1}(\mathbf{q}) [\tau_j - \dot{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} - \dot{\mathbf{n}}(\mathbf{q}, \dot{\mathbf{q}})],\end{aligned}\quad (13.48)$$

where the acceleration $\ddot{\mathbf{q}}$ appearing in (13.48) has already been computed through (13.47). Therefore, the exact linearizing and decoupling control law can be rewritten in terms of a static state feedback law of the form $\boldsymbol{\tau} = \boldsymbol{\tau}(\mathbf{q}, \theta, \dot{\mathbf{q}}, \dot{\theta}, \mathbf{v})$ or $\boldsymbol{\tau} = \boldsymbol{\tau}(\mathbf{q}, \tau_j, \dot{\mathbf{q}}, \dot{\tau}_j, \mathbf{v})$. Indeed, the evaluation of the various derivatives of the dynamic model terms that are present in these expressions should be properly organized in order to save computational time.

Based on the resulting (13.46), the trajectory tracking problem is solved by setting

$$\begin{aligned}\mathbf{v} &= \mathbf{q}_d^{[4]} + \mathbf{K}_3(\mathbf{q}_d^{[3]} - \mathbf{q}^{[3]}) + \mathbf{K}_2(\ddot{\mathbf{q}}_d - \ddot{\mathbf{q}}) \\ &\quad + \mathbf{K}_1(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \mathbf{K}_0(\mathbf{q}_d - \mathbf{q}),\end{aligned}\quad (13.49)$$

where it is assumed that the reference trajectory $\mathbf{q}_d(t)$ is (at least) three times continuously differentiable (i. e., the fourth derivative $\mathbf{q}_d^{[4]}$ exists), and the *diagonal* matrices $\mathbf{K}_0, \dots, \mathbf{K}_3$ have elements such that

$$s^4 + K_{3,i}s^3 + K_{2,i}s^2 + K_{1,i}s + K_{0,i}, \quad i=1, \dots, N,$$

are Hurwitz polynomials. In view of the obtained decoupling, the trajectory position error $e_i(t) = q_{d,i}(t) - q_i(t)$ for the i -th link then satisfies

$$e_i^{[4]} + K_{3,i}e_i^{[3]} + K_{2,i}\ddot{e}_i + K_{1,i}\dot{e}_i + K_{0,i}e_i = 0;$$

yielding $e_i(t) \rightarrow 0$ in a global exponential way, for any initial state. A series of remarks are in order.

- When the initial state $(\mathbf{q}(0), \theta(0), \dot{\mathbf{q}}(0), \dot{\theta}(0))$ is matched with the reference trajectory and its first three derivatives at time $t = 0$ (for this check, (13.47, 48) are to be used), exact reproduction of the reference trajectory is achieved at all times.
- In the case of a discontinuity of the reference position trajectory, or of any of its first three derivatives, at a time $t^* \in [0, T]$, a trajectory error occurs at $t = t^*$

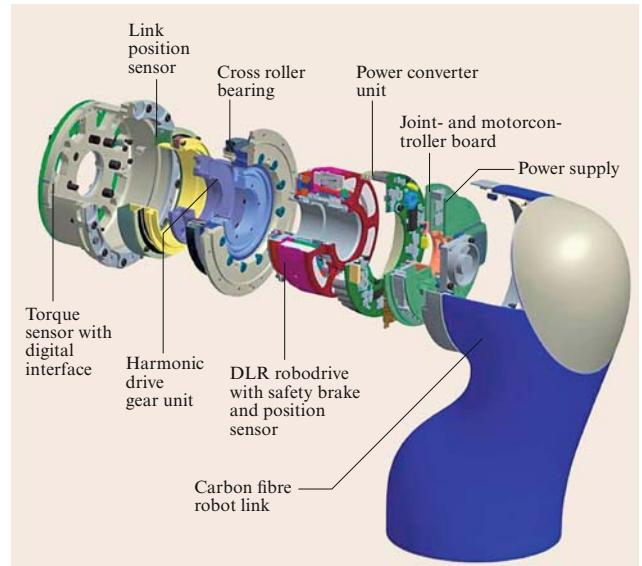

Fig. 13.8 Exploded view of a joint of the *DLR LWR-III* lightweight manipulator and its sensor suite

that will again decay to zero, independently for each link and with the prescribed exponential rate.

- The choice of the gains $K_{3,i}, \dots, K_{0,i}$ can be made by a pole placement procedure (equivalent in this case to an eigenvalue assignment). Let $\lambda_1, \dots, \lambda_4$ be four poles with negative real parts, possibly given in complex pairs and/or coincident, specifying the desired transient of the trajectory error. These closed-loop poles will be assigned by the unique choice of real and positive gains

$$K_{3,i} = -(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4),$$

$$K_{2,i} = \lambda_1(\lambda_2 + \lambda_3 + \lambda_4) + \lambda_2(\lambda_3 + \lambda_4) + \lambda_3\lambda_4,$$

$$K_{1,i} = -[\lambda_1\lambda_2(\lambda_3 + \lambda_4) + \lambda_3\lambda_4(\lambda_1 + \lambda_2)],$$

$$K_{0,i} = \lambda_1\lambda_2\lambda_3\lambda_4.$$

When the values of link and motor inertias are very different from each other, or when the joint stiffness is very large, the above fixed choice of gains has the drawback of generating too large control efforts. In those cases, a more tailored set of eigenvalues can be assigned scheduling their placement as a function of the physical data of robot inertias and joint stiffnesses.

- When compared to the *computed torque* method for rigid robots, the feedback linearization control for trajectory tracking given by (13.45, 47, 48, 49) requires the inversion of the inertia matrix $\mathbf{M}(\mathbf{q})$ and

the additional evaluation of derivatives of the inertia matrix and of other terms in the dynamic model.

- The feedback linearization approach can also be applied without any changes in the presence of viscous (or otherwise smooth) friction at the motor and link side. The inclusion of spring damping leads instead to a third-order decoupled differential relation between the auxiliary input v and q , leaving thus a N -dimensional unobservable but asymptotically stable dynamics in the closed-loop system. In this case, only input–output (and not full-state) linearization and decoupling is achieved.

We conclude with some considerations on exact linearization/decoupling for the general model (13.7) of robots with elastic joints. Unfortunately, due to the presence of the inertial coupling matrix $S(q)$ between links and rotors, the above control design can no longer be applied. Consider as an illustration the case of a constant S in (13.7), with the associated model simplifications. Solving for $\ddot{\theta}$ from the motor equations, $\ddot{\theta} = B^{-1}(\tau - \tau_J - S^\top \ddot{q})$, and substituting into the link equations leads to

$$\begin{aligned}[M(q) - SB^{-1}S^\top]\ddot{q} + n(q, \dot{q}) - (I + SB^{-1})\tau_J \\ = -SB^{-1}\tau.\end{aligned}$$

In this case, the input torque τ appears already in the expression for the link acceleration \ddot{q} . Using (13.6), the expression of the decoupling matrix is then

$$A(q) = -[M_L(q) + M_R(q)]^{-1}SB^{-1},$$

which is never full rank in view of the structure (13.5) of S . As a consequence, the necessary condition for obtaining (at least) input–output linearization and decoupling by static state feedback fails to hold.

However, by resorting to the use of a larger class of control laws, it is still possible to obtain an exact linearization and decoupling result. For this purpose, consider a *dynamic* state feedback controller of the form

$$\begin{aligned}\tau &= \alpha(q, \dot{q}, \theta, \dot{\theta}, \xi) + \beta(q, \dot{q}, \theta, \dot{\theta}, \xi)v, \\ \dot{\xi} &= \gamma(q, \dot{q}, \theta, \dot{\theta}, \xi) + \delta(q, \dot{q}, \theta, \dot{\theta}, \xi)v,\end{aligned}\quad (13.50)$$

where $\xi \in \mathbb{R}^v$ is the state of the dynamic compensator, α , β , γ , and δ are suitable nonlinear vector functions, and $v \in \mathbb{R}^N$ is (as before) an external input used for trajectory-tracking purposes. It is possible to show in general that a dynamic compensator (13.50) of order at most $v = 2N(N - 1)$ can be designed so as to yield

a closed-loop system that is globally described by

$$q^{[2(N+1)]} = v,$$

in place of (13.46). Note the coincidence of this differential order with the one found for exact reproducibility of a desired trajectory $q_d(t)$ in Sect. 13.1.2. The tracking problem is then solved by a direct generalization of the linear stabilization design of (13.49).

It is interesting to give a physical interpretation for this control result. The structural obstruction to input–output decoupling of the model (13.7) is that the motion of a link attached to an elastic joint is affected *too soon* (at the second differential level) by torques originating at other elastic joints. This is due to the inertial couplings present between the motors and links. The addition of dynamics (i.e., of integrators) in the controller slows down these low-energy paths and allows for the high-energy effects of the elastic torque at the local joint (a fourth-order differential path) to come into play. This dynamic balancing allows both input–output decoupling and exact linearization of the extended system (having the robot and the controller states).

Linear Control Design

The feedback linearization approach to trajectory tracking gives rise to a rather complex nonlinear control law. Its main advantage of globally enforcing a linear and decoupled behavior on the trajectory error dynamics can be traded off with a control design that achieves only local stability around the reference trajectory, but is much simpler to implement (and may run at higher sampling rates).

For this, the inverse dynamics results of Sect. 13.1.2 can be used, assuming either the reduced or the complete robot model and with or without dissipative terms. Given a sufficiently smooth desired link trajectory $q_d(t)$, we have seen that it is always possible to associate:

1. the nominal torque $\tau_d(t)$ needed for its exact reproduction, and
2. the reference evolution of all other state variables (e.g., $\theta_d(t)$, as given by (13.13), or $\tau_{J,d}(t)$).

These signals define a sort of steady-state operation for the system.

A simpler tracking controller combines a model-based feedforward term with a linear feedback term using the trajectory error: the linear feedback locally stabilizes the system around the reference state trajectory, whereas the feedforward torque is responsible for maintaining the robot along the desired motion when the error has vanished.

Using full-state feedback, two possible controllers of this kind are

$$\begin{aligned}\tau = \tau_d + K_{P,\theta}(\theta_d - \theta) + K_{D,\theta}(\dot{\theta}_d - \dot{\theta}) \\ + K_{P,q}(q_d - q) + K_{D,q}(\dot{q}_d - \dot{q})\end{aligned}\quad (13.51)$$

and

$$\begin{aligned}\tau = \tau_d + K_{P,\theta}(\theta_d - \theta) + K_{D,\theta}(\dot{\theta}_d - \dot{\theta}) \\ + K_{P,J}(\tau_{J,d} - \tau_J) + K_{D,J}(\dot{\tau}_{J,d} - \dot{\tau}_J).\end{aligned}\quad (13.52)$$

These trajectory tracking schemes are the most common in the control practice for robots with elastic joints. In the absence of full-state measurements, they can be combined with an observer of the unmeasurable quantities. An even simpler realization is

$$\tau = \tau_d + K_P(\theta_d - \theta) + K_D(\dot{\theta}_d - \dot{\theta}), \quad (13.53)$$

which uses only motor measurements and relies on the results obtained for the regulation case.

The different gain matrices used in (13.51, 52, 53) have to be tuned using a linear approximation of the robot system. This approximation may be obtained at a fixed equilibrium point or around the actual reference trajectory, leading respectively to a linear time-invariant or to a linear time-varying system. While the existence of (possibly time-varying) stabilizing feedback matrices is guaranteed by the controllability of these linear approximations, the validity of the approach is only *local* in nature and the region of convergence will depend both on the given trajectory and on the robustness of the designed linear feedback.

It should be mentioned that such a control approach to trajectory tracking problems can also be used for robots with flexible links. Once the inverse dynamics problem has been solved (for the case of link flexibility, this typically results in a noncausal solution), a controller of the form (13.53) (or (13.51), with link deflection δ and deflection rate $\dot{\delta}$ replacing, respectively, q and \dot{q}), can be directly applied.

13.1.5 Further Reading

This section contains the main references for the part of this chapter on robots with joint flexibility. In addition, we indicate to a larger bibliography for topics that have not been included here.

Early interest in problems arising from the presence of flexible transmissions in robot manipulators dates back to [13.1, 2], with first experimental findings on the GE P-50 arm. Relevant mechanical considerations involved in the design of robot arms and in the evaluation of their compliant elements can be found in [13.3].

One of the first studies on the inclusion of joint elasticity in the dynamic modeling of robot arms is due to [13.4]. The detailed analysis of the model structure presented in Sect. 13.1.1 comes from [13.5], with some updates from [13.6]. The simplifying assumption leading to the reduced model was introduced in [13.7]. The special case of motors mounted on the driven links is considered in [13.8]. The observation that joints with limited elasticity lead to a singularly perturbed dynamic model was first recognized in [13.9]. Symbolic manipulation programs for the automatic generation of dynamic models of robots with elastic joints were also developed very early [13.10].

The inverse dynamics computations in Sect. 13.1.2 can be traced back to [13.11]. The use of programs such as Modelica for the numerical evaluation of inverse dynamics is highlighted in [13.6].

The first specific control designs were based on decentralized linear controllers, see, e.g., [13.12] and [13.13], where a fourth-order dynamics local to each elastic joint was used. However, schemes with proved global convergence characteristics appeared only later.

In Sect. 13.1.3, the PD controller with constant gravity compensation is a contribution of [13.14]. This was also extended to the case of robots with flexible links in [13.15]. The two versions of regulation control with online gravity compensation are due, respectively, to [13.16] and [13.17]. Both these control laws were extended to Cartesian compliance schemes in [13.18] and [13.19]. A general regulation framework based on energy shaping has been proposed in [13.20]. In the absence of any information on gravity, a PID regulator with semiglobal stability properties has been presented in [13.21], while a global learning scheme was proposed in [13.22].

The presentation of a full-state feedback design for regulation (and tracking) follows the idea used in [13.23]. Special interest has been devoted over the years to joint torque feedback, from the placement of torque sensors on transmission shafts [13.24] or within harmonic drives [13.25] to their use for achieving robust control performance [13.26].

The fact that the reduced model of robots with elastic joints can always be feedback linearized via static state feedback was shown for the first time in [13.7]. A previous similar result for a specific robot kinematics had been found in [13.27]. The discrete-time implementation of the feedback linearization approach has been studied in [13.28], while its robustness properties were analyzed in [13.29]. Feedback linearization and input-output decoupling were also considered for the case of

viscoelastic joints in [13.30], and for robots with joints of mixed type, some rigid and some elastic, in [13.31]. The same idea of inversion control, leading to input–output decoupling and linearization, has also been successfully applied to the tracking problem of joint-level trajectories in robots with flexible links [13.32].

For the general model of robots with elastic joints, the use of dynamic state feedback was first proposed in [13.33]. A comparative study of the errors induced by neglecting the motor–link inertia couplings (thus, for robots that are not linearizable by static state feedback) was carried out in [13.34]. The general algorithm for constructing the dynamic linearizing feedback is presented in [13.35].

Other control design methodologies available for trajectory tracking, which were not discussed in Sect. 13.1.4, are based on singular perturbation, backstepping, or passivity. Nonlinear controllers based on the two-time scale separation property were proposed by [13.36] and [13.37]. These corrective controllers are an outcome of the singular perturbation model form and should be preferred in the case of very stiff joints, as they do not generate high-gain laws in the limit. Backstepping is based on the idea of considering the joint elastic torque [13.38] or the motor position [13.39] as an intermediate fictitious input to

be used to control the link equations, and then to design the actual torque input in the motor equations so as to follow the reference behavior for the previous intermediate input. The main advantage is that this design may be easier to be transformed into an adaptive version. Adaptive control results for robots with elastic joints include the high-gain (approximate) scheme [13.40] and the global (but very complex) solution obtained in [13.41], both analyzed using only the reduced dynamic model. Moreover, robust control schemes have been proposed in [13.42], based on sliding mode techniques, and in [13.43], using iterative learning on repetitive tasks.

Different state observers have been presented, starting from an approximate one in [13.44] up to the exact ones in [13.45] and [13.5], in which a tracking controller based on the estimated state was also tested. In all cases, link position or link position and velocity measurements are assumed. More recently, the use of motor position and link acceleration has been shown to be a feasible alternative for robust state reconstruction [13.46].

Finally, the force control problem in constrained tasks for robots with elastic joints has been tackled following a singular perturbation technique [13.47, 48], an inverse dynamics approach [13.49], or an adaptive strategy [13.50].

13.2 Robots with Flexible Links

Arm flexibility is a dynamic behavior in which kinetic energy interacts with elastic potential energy. Kinetic energy is stored in moving inertia, and potential energy is stored in compliant members. Flexible links provide both the inertia and compliance distributed throughout the member. Flexibility manifests itself as mechanical oscillations and static deflections, greatly complicating the motion control of a mechanical arm. If the time to settle the oscillations is significant relative to the cycle time of the overall task, flexibility will be a major consideration in the arm design.

13.2.1 Design Issues

We will deal with these issues in a modular way, separating link flexibility and joint flexibility. The first topic of link flexibility deals with the inherent spatial distribution of compliance and inertia, perhaps with both effects existing in the same element of material. The links of a manipulator arm can usually be stiffened by adding structural mass or by improving the material properties

or distribution over the links. At some points the links may be treated as rigid. The designer must realize that an arm with heavy rigid links and flexible joints may be more flexible dynamically than a lighter arm with more link flexibility and less inertia. The consequences are predicted by the natural frequency of the first flexible mode of motion, with the joint actuators locked, which can be approximated by

$$\omega_1 = \sqrt{\frac{k_{\text{eff}}}{I_{\text{eff}}}} \quad (13.54)$$

where k_{eff} is the effective spring constant and I_{eff} is the effective inertia. For the elastic joint case k_{eff} and I_{eff} are directly available from the elastic joint parameters and mass properties of the arm. The *effective* values applicable to a simple beam in bending, for example, would result from boundary conditions that are clamped at one end and free at the other and would be selected to yield a good approximation to the natural frequency. This natural frequency is readily available from handbooks on

vibration in this case as $\omega_1 = 3.52\sqrt{EI/m^4}$. (The variables are used in (13.55) and (13.56) and defined below.) More-complex geometries can be evaluated by various means, including the transfer matrix method discussed in Sect. 13.2.2 on modeling. The arm should be considered flexible when this frequency is low enough to interfere with the design of controllers based on rigid assumptions. The common proportional-derivative (PD) control of a single joint on a flexible link can only achieve adequate damping of a closed-loop design when the magnitude of the closed loop poles is less than about $\frac{1}{3}$ of ω_1 [13.51].

A distillation of the key aspects of the mechanics of materials is now in order. In some cases static compliance effects represent a member sufficiently, whereas in other cases the true distributed nature of compliance and mass and its dynamics must be modeled. A long structural member with forces f and moments M perpendicular to its long axis is subject to bending. Static bending relates the moment at the axial location x to the displacement w

$$M(x) = EI(x) \frac{\partial^2 w}{\partial x^2}, \quad (13.55)$$

where E is the elastic modulus of the material, and $I(x)$ is the area moment of inertia about the neutral axis of the cross section. The deflection at any point is obtained by integrating this equation from a reference point to a desired point, such as the end of the link.

This is a description of compliance that can be used when mass is isolated from elasticity. If mass is distributed throughout the beam with material mass density per unit volume ρ , the time t must be incorporated so that

$$m(x) \frac{\partial^2 w(x, t)}{\partial t^2} + \frac{\partial^2}{\partial x} \left(EI(x) \frac{\partial^2 w(x, t)}{\partial x^2} \right) = 0. \quad (13.56)$$

Here $m(x)$ is the mass density per unit length, incorporating the material properties and the cross-sectional area at x . Assumptions implicit in this equation, which is called the Bernoulli–Euler equation, include the minimal impact of shear distortion and rotational inertia of the cross section of the beam, which is valid for long beams. The Timoshenko beam model relaxes these assumptions but is not included here.

Torsional deflection of an angle θ results if a twisting moment T about the long beam axis occurs, such that, in the static case

$$\theta = \frac{Tl}{JG} = \alpha_{\theta T} T, \quad (13.57)$$

where G is the the shear modulus of the material, and J is the polar area moment of inertia about the neutral axis of the beam. Again, the addition of a distributed mass and considering the dynamics produces a partial differential equation with independent variables in space and time:

$$\mu \frac{\partial^2 \theta}{\partial t^2} = GJ \frac{\partial^2 \theta}{\partial x^2}, \quad (13.58)$$

where $\mu(x)$ is the rotary mass moment of inertia per unit length of the shaft. While (13.58) is potentially appropriate for links, the smaller rotational mass moment of inertia of a long slender shaft relative to the links it drives results in the static compliance effects of torsion given by (13.57) being of most importance.

Tension and compression effects should also be acknowledged, although they tend to be the least significant. Here, with deflection in the x -direction, the long axis of the member results in a compliance of

$$\delta = \frac{F_a L}{A E} = \alpha_{XF} F_a \quad (13.59)$$

and a dynamic flexibility of

$$\rho \frac{\partial^2 \xi}{\partial t^2} = E \frac{\partial^2 \xi}{\partial x^2}. \quad (13.60)$$

Note that these effects are special cases of the more general elastic behavior of a member subject to acceleration and external loading, specialized to the member with one long axis. The same general phenomena apply to joint structures (e.g., bearings and couplings) and drive-train components (e.g., gears and cables). The functional constraints on the structural design of these members may be more severe and limit the designer's ability to make them more rigid by adding more material. Under this constraint the combined compliance of the fixed joint design and the rigidized link design results in inferior performance of the combination. A less rigid link with less inertia will raise the lowest natural frequency. Thus the design of the link and the joint must be coordinated.

Flexibility is only one of several link design constraints. Static compliance is obviously another based on the above discussion. Buckling and strength are two more considerations that constrain some of the same design parameters. While it has been shown that flexibility is a dominant constraint for typical arm design regimes [13.52], a simple optimization of bending stiffness of a beam with a tubular geometry illustrates the fallacy of ignoring buckling. If the radius of the tube is varied to maximize bending stiffness with constrained total mass, the radius increases without bound, producing a thin shell of infinitesimal thickness and infinite

radius that lacks robustness. The true constraint becomes local buckling of the tube under slight perturbations of the applied load. A thin metal can illustrates this behavior as it crushes. Strength is another applicable constraint. Various materials differ in their strength, typically represented by their elastic limit or endurance limit on the stress at a point in the member. A sufficiently stiff member may fail due to stress, particularly at points of stress concentration.

In this presentation of options to overcome flexibility, and link flexibility in particular, radically different operational and design strategies should be recognized even though they are not the core of the treatment. The elastic modulus relates stress to strain, but physically the strain rate is sometimes a relevant term, providing structural damping to augment the joint or control-based damping. Composite materials have substantially more damping inherent in their behavior. Damping can be enhanced with passive damping treatments, with constrained layer damping having particularly pronounced effects [13.53]. Smart materials can also be configured to enhance damping [13.54]. An operational strategy known as *bracing* can be combined with redundant actuation to achieve a large workspace for a flexible arm that provides gross motion and a smaller precision workspace after docking the large arm with a stationary structure, as described in [13.55].

The implication above is that flexibility was always due to the moving parts of the arm. However, the arm base itself may be a source of significant flexibility. If the base is stationary, the analysis may be almost identical to that of the flexible links of an arm. However, if the arm is mounted on a vehicle, tires or tracks may be the source of flexibility and empirical evaluation of these new elements might be the best solution. The vehicle could be a boat, aircraft or space vehicle. Here there is no elastic connection to an inertial reference frame and some fundamental changes in approach will be needed. These changes are not unexplored and in some cases are simple extensions of the following approaches.

13.2.2 Modeling of Flexible Link Arms

Mathematical models of link flexibility trade accuracy for ease of use. It is therefore key to determine the effects that are important to represent accurately. The techniques presented here will assume linear elasticity with light damping. Rotational motions must be of modest angular rate so that centrifugal stiffening can be ignored. Small deflections will generally be assumed. These are reasonable assumptions for most robotic devices, but can

be violated in more exotic applications, requiring reevaluation of the assumptions and more tortuous modeling approaches.

Four model types will be examined:

1. lumped-element models having compliance or inertia but not both in a given member
2. finite-element models, which will be only briefly addressed
3. assumed mode models which readily include nonlinear dynamic behavior
4. transfer matrix models that incorporate the true distributed intermingling of compliance and inertia and consequently the infinite-dimensional nature of flexible link arms

With the limited space available here, the discussion will be preliminary but should enable the reader to pursue one or more alternatives knowledgably.

For lumped elements one may build on the rigid kinematics presented in the section on fundamentals of kinematics (Chap. 1) that establishes rigid transformation matrices A_i . The 4×4 homogenous transformations that describe position can be used to describe deflection as well. Assuming small motions and static behavior (or negligible member mass), the transformation produced by elastic bending, torsion, and compression is

$$E_i = \begin{pmatrix} 1 & -\alpha_{\theta Fi} F_{Yi}^i - \alpha_{\theta Mi} M_{Zi}^i & & \\ \alpha_{\theta Fi} F_{Yi}^i + \alpha_{\theta Mi} M_{Zi}^i & 1 & & \\ \alpha_{\theta Fi} F_{Zi}^i - \alpha_{\theta Mi} M_{Yi}^i & & \alpha_{Ti} M_{Xi}^i & \\ 0 & & & 0 \end{pmatrix}, \quad (13.61)$$

where

α_{Ci} = coefficient in compression,
displacement/force,

α_{Ti} = coefficient in torsion, angle/moment,

$\alpha_{\theta Fi}$ = coefficient in bending, angle/force,

$\alpha_{\theta Mi}$ = coefficient in bending, angle/moment,

α_{XFi} = coefficient in bending, displacement/force,

α_{XMi} = coefficient in bending,
displacement/movement,

F_{Xi}^j = the force at the end of link i in the X direction of coordinate frame j ,

F_{Yi}^j = the force at the end of link i in the Y direction of coordinate frame j ,

F_{Zi}^j = the force at the end of link i in the Z direction of coordinate frame j ,

M_{Xi}^j = the moment at the end of link i in the X direction of coordinate frame j ,

M_{Yi}^j = the moment at the end of link i in the Y direction of coordinate frame j ,

M_{Zi}^j = the moment at the end of link i in the Z direction of coordinate frame j .

The listed coefficients depend on the construction of the element and are readily found for a slender beam from simple strength of materials. In other cases a finite-element model or empirical measurements may be more readily used.

Alternating transformations for the undeformed and deformed aspects of N members (links or joints) produces the position vector of the end of arm (EOA):

$$\mathbf{p}^0 = (A_1 E_1 A_2 E_2 \cdots A_i E_i A_{i+1} E_{i+1} \cdots A_N E_N) \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \quad (13.62)$$

If the massless elements connect rigid lumped masses a linear spatial model is readily obtained, as described in [13.56]. Servo-controlled joints can also be inserted into this model. This analysis proceeds by examining the deflection of the elastic members produced by joint motion and the resulting forces and moments on the rigid inertias at the ends of the chain of links. The reference concentrates on the special case of only two inertias at each end of the chain but the technique is easily extended to inertias in the middle of the chain as well. The results are six linear second-order equations for each inertia and one first-order equation for each joint.

If the compliance and inertia properties are both to be treated as distributed throughout the same element, the partial differential equations (PDE) introduced in the previous section for bending, torsion, and compression must be employed. Still insisting on a linear treatment, the general solution of these equations can be found in terms of each element with adjoining elements, i.e. the boundary conditions on the PDE. The convenient approach of Laplace transformation of these linear equa-

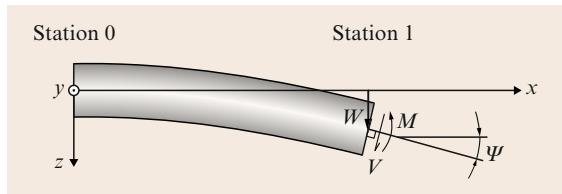

Fig. 13.9 State vector for the bending transfer matrix

tions into the frequency domain, followed by factoring out the boundary conditions into a matrix–vector product, results in a technique known as the transfer matrix method (TMM) [13.57]. This method has been applied productively to general elastomechanics problems as well as specifically to flexible arms [13.58].

The transfer matrix relates variables at two stations along the arm with the number of variables depending on the model complexity. For the planar bending deflection of the beam shown in Fig. 13.9

$$\begin{aligned} \mathbf{z}_1 &= \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_1 = \begin{pmatrix} \text{displacement} \\ \text{angle} \\ \text{moment} \\ \text{shear force} \end{pmatrix}_{\text{at station 1}} , \\ \mathbf{z}_0 &= T \mathbf{z}_1 \end{aligned} \quad (13.63)$$

where T is the appropriate element transfer matrix.

If the element is a simple rotary spring with constant k and a damper with constant b then the angle of rotation θ is related to the moment by a differential equation with the following Laplace-domain representation:

$$\begin{aligned} M &= -L(k\theta + b\dot{\theta}) = k\Theta(s) + bs\Theta(s) = M_0 = M_1 , \\ W_0 &= W_1 , \\ V_0 &= V_1 , \\ \Psi_0 &= \Psi_1 - \Theta(s) = \Psi_1 - \frac{1}{k+bs} M_1 . \end{aligned}$$

Note that the only variable changed across the element is the angle related to the moment. The transfer matrix representation conventionally uses zero initial conditions and converts to the Fourier representation with $s = i\omega$. This leads to the transfer function

$$T = C(i\omega) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & \frac{1}{k+b(i\omega)} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} ,$$

which has the same form of the joint controller shown in equation (13.64).

The beam model is much more complex, and the Euler–Bernoulli model gives

$$\mathbf{B} = \begin{pmatrix} c_0 & lc_1 & ac_2 & alc_3 \\ \beta^4 c_3/l & c_0 & ac_1/l & ac_2 \\ \beta^4 c_2/a & \beta^4 lc_3/a & c_0 & lc_1 \\ \beta^4 c_1/al & \beta^4 c_2/a & \beta^4 c_3/l & c_0 \end{pmatrix}, \quad (13.64)$$

where

$$\beta^4 = \omega^2 l^4 \mu / (EI); \quad a = l^2 / (EI),$$

$$c_0 = (\cosh \beta + \cos \beta) / 2,$$

$$c_1 = (\sinh \beta + \sin \beta) / (2\beta),$$

$$c_2 = (\cosh \beta - \cos \beta) / (2\beta^2),$$

$$c_3 = (\sinh \beta - \sin \beta) / (2\beta^3),$$

$$\mu = \text{density/unit length},$$

$$\omega = \text{circular frequency of vibration},$$

$$E = \text{elastic modulus},$$

$$I = \text{cross-sectional area moment of inertia}.$$

The spatial variable has been transformed to the spatial Laplace variable but no longer appears explicitly. The Laplace time variable remains and is designated by s or by the frequency variable $\omega = -is$, where $i = \sqrt{-1}$. The other transfer matrices needed for a simple planar model are as follows.

For a rotation in the plane of angle ϕ

$$\mathbf{A} = \begin{pmatrix} 1/\cos \phi & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ m_s \omega^2 \sin \phi \tan \phi & 0 & 0 & \cos \phi \end{pmatrix}, \quad (13.65)$$

where m_s is the sum of all outboard masses from the angle to the end of the arm. This is an approximation resulting from ignoring compression elasticity. These

elements appear as an additional mass to the extent they are translated with beam compression.

For a rigid mass, simply applying Newton's laws and collecting term yields

$$\mathbf{R} = \begin{pmatrix} 1 & l & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -m\omega^2 l/2 & -I\omega^2 + m\omega^2 l/2 & 1 & l \\ m\omega^2 & -m\omega^2 l/2 & 0 & 1 \end{pmatrix}, \quad (13.66)$$

where m is the mass of the body, I is the mass moment of inertia about an axis through the center of mass and perpendicular to the plane of the arm, l is the length of the mass (the distance between the points of attachment at stations i and $i+1$), and $l/2$ is the distance to the center of mass from station i .

For a controlled joint with the controller transfer function (joint torque/joint angle) = $k(i\omega)$

$$\mathbf{C} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1/k(i\omega) & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (13.67)$$

When combined to represent the planar arm with two joints shown in Fig. 13.10 this analysis yields a composite transfer matrix that relates the four state variables at the two ends of the arm. Further analysis results from imposing the known boundary conditions at these ends.

The transfer matrix representation of an arm presented in [13.59] and pictured in Fig. 13.10 is shown in (13.68).

$$\begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_0 = \mathbf{R}_1 \mathbf{B}_2 \mathbf{R}_3 \mathbf{A}_4 \mathbf{C}_5 \mathbf{B}_6 \mathbf{R}_7 \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_7. \quad (13.68)$$

In the example the left end is pinned and the right end is free, yielding

$$z_0 = \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_0 = \begin{pmatrix} u_{11} & u_{12} & u_{13} & u_{14} \\ u_{21} & u_{22} & u_{23} & u_{24} \\ u_{31} & u_{32} & u_{33} & u_{34} \\ u_{41} & u_{42} & u_{43} & u_{44} \end{pmatrix} \begin{pmatrix} -W \\ \Psi \\ M \\ V \end{pmatrix}_7,$$

$$\begin{pmatrix} u_{11} & u_{12} \\ u_{31} & u_{32} \end{pmatrix} \begin{pmatrix} -W \\ \Psi \end{pmatrix}_7 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \quad (13.69)$$

The determinant of the 2×2 matrix must be zero when ω is a natural frequency, or a system eigenvalue if it is

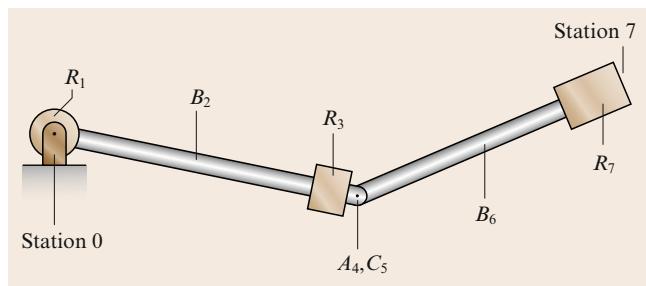

Fig. 13.10 Transfer matrix representation of an arm

complex. This can be found by a numerical search. Evaluating variables (position, angle, shear, and moment) along the length of the arm with the eigenvalues used for the values of ω yields the eigenfunctions. If boundary conditions are not zero but known for given frequencies, the frequency response of the system can be obtained. Hence Bode plots are readily obtained for boundary condition forcing. Interior forcing can be handled using an extended state vector as described in [13.57], which was applied to arms in [13.51] and most recently updated with modern programming techniques in [13.58]. Inverse fast Fourier transform (FFT) will produce a time-domain response from the frequency response.

The creation of a state-space model in the time domain is attractive because it enables the use of powerful state-space design techniques and is compatible with the nonlinear behavior of arms undergoing large motion and experiencing centrifugal and Coriolis forces. The assumed modes method allows such a model to be constructed efficiently. The presentation here follows the early introduction of a recursive manner to calculate these equations introduced in [13.60]. The flexible kinematics of the links must be expressed as a sum of basis functions also known as assumed modes (shapes) $\phi_i(x)$ with time-variable amplitudes $\delta_i(t)$.

$$w(x, t) = \sum_{i=1}^{\infty} \delta_i(t) \phi_i(x). \quad (13.70)$$

The amplitudes and their derivatives become the states of the model. Compatible joint angle variables and their derivatives are also included as the rigid state variables. Joint angles tangent to the ends of the flexible links are compatible with mode shapes based on the clamped boundary conditions at one end and free boundary conditions at the other. This choice is generally chosen for simulation and the rigid coordinates are directly measured by standard joint angle transducers. If rigid coordinates are angles measured between lines connecting successive joint axes, the end of arm is known in terms of rigid coordinates alone and pinned-pinned boundary conditions are consistent. This produces advantages for inverse dynamics calculations as seen shortly.

The flexible and rigid kinematics combined describes the position and velocity of every point on the arm and can be used to express the kinetic energy \mathcal{T} and the potential energy \mathcal{V} . These expressions are used in the conservative form of Lagrange's equation:

$$\frac{d}{dt} \frac{\partial \mathcal{T}}{\partial \dot{q}_i} - \frac{\partial \mathcal{T}}{\partial q_i} + \frac{\partial \mathcal{V}}{\partial q_i} = F_i, \quad (13.71)$$

where F_i is the force that does work as q_i is varied.

The kinematics of the deflection are again described by 4×4 transformation matrices, but this time the assumed mode shapes j are summed to give the position of link i .

$$\mathbf{h}_i^j(\eta) = \begin{pmatrix} \eta \\ 0 \\ 0 \\ 1 \end{pmatrix} + \sum_{j=i}^{m_i} \delta_{ij} \begin{pmatrix} x_{ij}(\eta) \\ y_{ij}(\eta) \\ z_{ij}(\eta) \\ 0 \end{pmatrix}, \quad (13.72)$$

where x_{ij} , y_{ij} , and z_{ij} are the x_i , y_i , and z_i displacement components of mode j of link i 's deflection, respectively, δ_{ij} is the time-varying amplitude of mode j of link i , and m_i is the number of modes used to describe the deflection of link i .

$$\mathbf{E}_i = \left(\mathbf{H}_i + \sum_{j=i}^{m_i} \delta_{ij} \mathbf{M}_{ij} \right), \quad (13.73)$$

where

$$\mathbf{H}_i = \begin{pmatrix} 1 & 0 & 0 & l_i \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (13.74)$$

and

$$\mathbf{M}_{ij} = \begin{pmatrix} 0 & -\theta_{zij} & \theta_{yij} & x_{ij} \\ \theta_{zij} & 0 & -\theta_{xij} & y_{ij} \\ -\theta_{yij} & \theta_{xij} & 0 & z_{ij} \\ 0 & 0 & 0 & 0 \end{pmatrix}. \quad (13.75)$$

This description is used in the formation of the potential and kinetic energy contributions of each element of mass. The integral over the link accumulates the total energy for that link and the sum over all links gives the energy of the arm system. Interchanging the order of integration and summation allows key invariant parameters to be identified, such as the *modal mass* that multiplies the second derivative of modal amplitude and the *modal stiffness* that multiplies the amplitude itself. The intermediate steps are aimed at the evaluation of Lagrange's equations, which separate into derivatives related to the rigid variables and the flexible variables. If the rigid variables $\boldsymbol{\theta}$ are the joint variables, two groups of equations result:

$$1. \quad \frac{d}{dt} \left(\frac{\partial \mathcal{K}}{\partial \dot{\theta}_j} \right) - \frac{\partial \mathcal{K}}{\partial \theta_j} + \frac{\partial \mathcal{V}_e}{\partial \theta_j} + \frac{\partial \mathcal{V}_g}{\partial \theta_j} = F_j \quad (13.76)$$

$$2. \quad \frac{d}{dt} \left(\frac{\partial \mathcal{K}}{\partial \dot{\delta}_{jf}} \right) - \frac{\partial \mathcal{K}}{\partial \delta_{jf}} + \frac{\partial \mathcal{V}_e}{\partial \delta_{jf}} + \frac{\partial \mathcal{V}_g}{\partial \delta_{jf}} = 0, \quad (13.77)$$

where the subscript ‘e’ indicates elasticity, ‘g’ indicates gravity, and δ indicates the amplitude of a mode shape.

The simulation form of the equations is achieved by grouping all second derivatives of the rigid and flexible coordinates, which yields

$$\begin{aligned} & \begin{pmatrix} M_{rr}(q) & M_{rf}(q) \\ M_{fr}(q) & M_{ff} \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{\delta} \end{pmatrix} \\ &= - \begin{pmatrix} 0 & 0 \\ 0 & K_s \end{pmatrix} \begin{pmatrix} \theta \\ \delta \end{pmatrix} + N(q, \dot{q}) + G(q) \\ &= R(q, \dot{q}, Q), \end{aligned} \quad (13.78)$$

where θ is a vector of rigid coordinates, usually the joint variables, δ are the flexible coordinates, $q = [\theta^\top \delta^\top]^\top$, M_{ij} is the mass matrix for rigid and flexible coordinates corresponding to the rigid ($i, j = r$) or flexible ($i, j = f$) coordinates and equations, $N(q, \dot{q})$ contains the nonlinear Coriolis and centrifugal terms, $G(q)$ captures gravity effects, Q represents the externally applied forces, and R captures the effect of external forces and all other nonconservative forces including friction.

On the other hand, the inverse dynamics form of the equations is

$$\begin{aligned} Q &= \begin{pmatrix} M_{rr}(q) & M_{rf}(q) \\ M_{fr}(q) & M_{ff} \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{\delta} \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & K_s \end{pmatrix} \begin{pmatrix} \theta \\ \delta \end{pmatrix} \\ &\quad - N(q, \dot{q}) - G(q). \end{aligned} \quad (13.79)$$

In general Q is dependent on the vector T of motor torques or forces at the joints, and the distribution of these effects is such that

$$Q = \begin{pmatrix} B_r \\ B_f \end{pmatrix} T, \quad (13.80)$$

where T has the same dimensionality as q_r . By rearranging the inverse dynamics equation we obtain

$$\begin{pmatrix} B_r & -M_{rf} \\ B_f & -M_{ff} \end{pmatrix} \begin{pmatrix} T \\ \ddot{\delta} \end{pmatrix} = \begin{pmatrix} M_{rr} \\ M_{rf} \end{pmatrix} \ddot{\theta} + N(q, \dot{q}) + G(q) \quad (13.81)$$

which is arranged with a vector of unknowns on the left-hand side of the equation and the prespecified rigid and solvable flexible coordinates on the right. This is at least approximately true, with the caveat that the nonlinear and gravity terms have a weak influence on the immediate flexible coordinates, which are not simultaneously known but which can be estimated for the next time step.

One consequence of the distributed flexibility is non-minimum-phase behavior. This can occur for other cases

where the excitation is separated from the output point by mass and flexibility, a condition known as noncollocation. These systems are characterized by a step response in which the initial movement is opposite in sign from the final movement. This is simply characterized for linear systems as a transfer function zero in the right half-plane.

13.2.3 Control

Sensors for Flexibility Control

Appropriate reaction to flexible dynamics requires appropriate sensors. While a Kalman filter can theoretically observe flexible link states from joint measurements, it is based on back driving the joint from the various modes of flexible dynamics. More-reliable indications of flexibility include strain gauges, accelerometers, and optical sensors.

The strain of a beam element is a direct indication of curvature, which is the second spatial derivative of beam deflection, as indicated in (13.55). Modern semiconductor strain gauges have high gauge factors producing a good signal-to-noise ratio. The second spatial derivative relationship means that a slight change in location can result in a large change in the reading, but once affixed to the arm this is not a problem. More of a problem is the relatively short lifetime of a strain gauge subject to wear and tear if not carefully protected. By suitably placing strain gauges, good measurements of multiple assumed modes are possible.

Optical measurement of deflection can be very versatile but is subject to interference between a target measurement point and the sensor, particularly if the sensor is stationary. If the sensor is mounted on the link this difficulty is reduced but optical measurements are then usually a complex combination of the rotation of the optical axis of the sensor and the deflection of the target. Machine vision senses a wide field of view but typically with less precision. Multiple points can be detected, which is attractive in measuring multiple modes. Machine vision requires considerable processing and, even for enhanced targets or retroreflective fiducials, sample rates can be slow relative to some modes of control interest.

Accelerometers are attractive transducers in that they do not require explicit grounding to a fixed frame. Microelectromechanical systems (MEMS) accelerometers provide the required low-frequency sensitivity and are very inexpensive. However, they are subject to orientation in a gravity field, which must be compensated for by knowing the orientation of the sensor. If one is

interested in position, accelerometers require two integrations and are consequently subject to drift in position measurement. Consequently the combined use of sensors is appealing. For example, vision sensors, which are relatively slow but give direct position information for the end of a flexible member, can be combined with accelerometers, which give information about the same point at high sample rates but with noise and drift problems. The two sensor readings can be combined with a Kalman filter or other fusion scheme.

Issues Related to Model Order

Realizing that the theoretical order of a flexible arm is infinite, one should be prepared to deal with certain issues related to model order. The first of these is possible aliasing problems arising from finite sampling rates. Anti-aliasing filters should be employed, and even more effective is the use of analog damping by materials, damping treatments, or the back electromotive force (emf) of actuators to provide an inherent damping of the system under digital control. A more subtle problem is that of measurement and control spill over.

Control of Special Configurations: Macro/Microredundancy

Several special configurations have been proposed to enable improved controlled performance of flexible link arms. The problem with noncollocation noted above is a case in point. In some cases a large range of motion and high accuracy cannot be achieved with a single set of actuators. Redundant degrees of freedom can then be employed with the macro degrees of freedom that provide large range of motion but with inherent lack of precision or accuracy. Vibrations are particularly difficult to eliminate with a long arm, and construction accuracy and even thermal drift can exceed the tolerance limits. If the gross motion is completed quickly, residual vibrations may remain and be very lightly damped. Actuators constructed for gross motions of large axes do not have the bandwidth capabilities to damp these vibrations actively, but small motion axes typically do. This has been illustrated in several instances for long-reach manipulators when exploring nuclear waste cleanup solutions [13.61–64]. Using the inertial forces generated at the end of the arm also has the advantage of creating forces collocated with the measurements being used for control, assuming the base of the micro arm is at the end of the macro arm and the location of sensors. Loper [13.63] and George [13.65] have shown that this control is possible based on accelerometers in multiple degrees of freedom. It is also possible to excite unde-

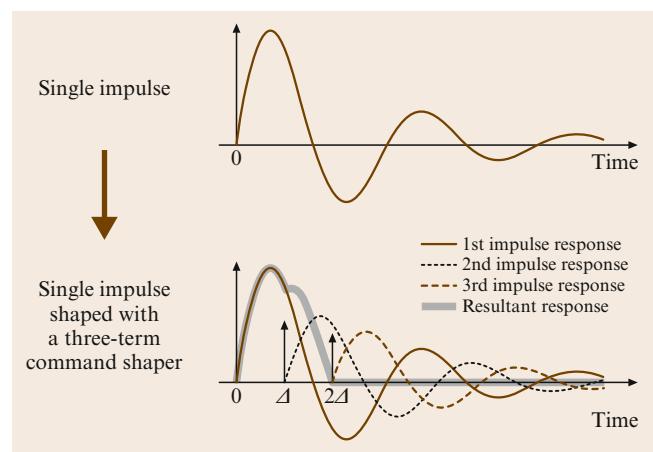

Fig. 13.11 Impulse response of a shaper and the effect on a vibratory system. Time is normalized by the intersample time T_s and T_d , chosen such that $\Delta = T_d/T_s$ is an integer

sired modes which have not been accounted for. If the full six degrees of freedom are used it is possible to argue stability based on a simple passive analogy. Generating prescribed forces at the base of an articulated micromanipulator is a challenging task, requiring the solution of a new type of inverse dynamics problem, which solves for motions or joint torques to produce the prescribed base forces and moments.

Command Generation for Flexible Link Arms

The trajectory undertaken by a flexible arm can dramatically affect the consequences of flexibility. Purely open-loop anticipation of the flexible dynamics has been used to create motion profiles wherein the motion cancels the incipient oscillation that had been created by earlier motions. This strategy is referred to as command shaping. A more complicated strategy to implement is a true inverse-dynamics-based trajectory wherein the

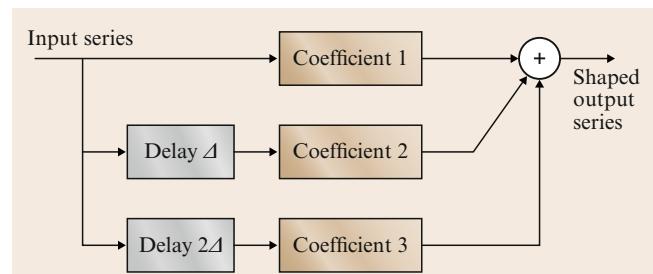

Fig. 13.12 Block diagram representation of the command shaping algorithm

rigid and flexible states are all orchestrated to arrive at the desired point in state space, typically at a static equilibrium. The high order of the flexible model is further complicated by the non-minimum-phase nature of the non-collocated system and noncausal inverse is necessary to produce a physically realizable trajectory.

Time delay command shaping is a variation of the deadbeat control introduced by [13.66, 67]. It can be couched in terms of a finite impulse response filter with a simple impulse response as depicted in Fig. 13.11 with a single input impulse producing a small number (typically two to four) of output impulses with appropriate time spacing and amplitudes. Extensions by *Singer* and *Seering* [13.68] and *Singhose* [13.69] have produced more-robust varieties under the trademark Input Shaping. The robustness is enhanced by using more output impulses and appropriate selection of the impulse spacing. The optimal arbitrary time-delay

Fig. 13.13 A large flexible linking arm with command shaping

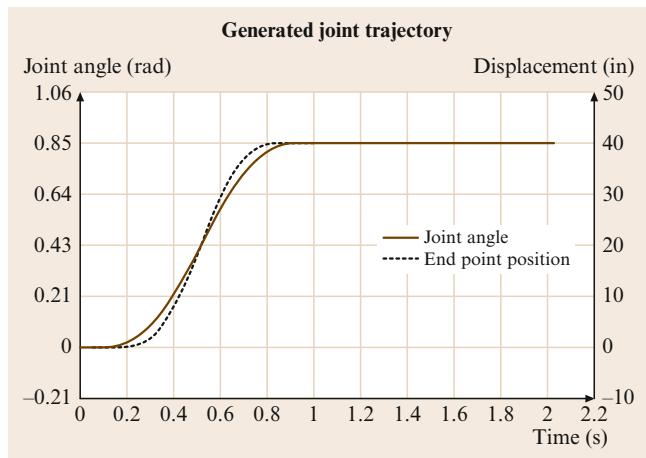

Fig. 13.14 Inverse dynamics driven motion of a single-link flexible arm

(OAT) filter [13.70, 71] reduces this selection to a simple formula for linear vibrations that depends on the natural frequency and damping ratio of those modes to be eliminated from the response. The simplicity of implementation is illustrated in Fig. 13.12, where the relationships between the filter parameters and the mode parameters are

$$\text{coefficient 1} = 1/M$$

$$\text{coefficient 2} = -(2 \cos \omega_d T_d e^{-\zeta \omega_n T_d})/M$$

$$\text{coefficient 3} = (e^{-2\zeta \omega_n T_d})/M$$

$$M = 1 - 2 \cos \omega_d T_d e^{-\zeta \omega_n T_d} \\ + e^{-2\zeta \omega_n T_d}$$

$$\omega_d = \omega_n \sqrt{1 - \zeta^2} = \text{damped natural frequency}$$

$$\omega_n = \text{undamped natural frequency}$$

$$\zeta = \text{damping ratio}$$

$$T_d = \text{time delay selected, an integer number of samples} = \Delta$$

(13.82)

Note that the formulation here is oriented towards digital systems with fixed sampling intervals such that the time delay of the filter is adjusted to an integer number of sampling intervals. Command shaping has been applied to a wide range of flexible systems including disk drives, cranes, and large robot arms, such as the example by CAMotion shown in Fig. 13.13. Note that this example contains a flexible drive belt, effectively a flexible joint, as well as flexible links that contribute to the compliance of the lowest mode that is quenched with an OAT filter.

Adaptive versions of command shaping have also been demonstrated. A version oriented towards repetitive motion applications is presented in [13.72].

In contrast to the scant system knowledge required for command shaping, the inverse dynamics of a flexible arm requires a great deal of knowledge about the system. The creation of an appropriate model was discussed above. An assumed modes model, for example, is well adapted to inverse dynamics if the rigid coordinates are not the joint angles, but the angles between lines connecting the joint axes (where it is assumed that joints are rotational). In this case the desired end-of-arm motion can be expressed solely in terms of rigid variables, that is, the same variables q_d used in the flexible joint case, and the desired flexible variables are found from the second-order equations driven by the known rigid positions and velocities. The re-

maining difficulty is the unstable zero dynamics of the system.

For the purposes of introduction, only the linear situation will be treated here in the fashion of [13.73]. First, the rigid coordinates and their derivatives are found from the desired end-of-arm motion profile. The flexible equations are separated into causal stable zeros and anticausal unstable zeros, and the stable inverse is solved forward in time. Physically the motion response responds after the torque inputs. The computational input however is the response and the torque is calculated as an output, so no physical laws are violated in solving the anticausal portion beginning at the final time when flexible coordinates are specified to be zero and proceeding to the initial time and beyond. In fact the exact solution extends from negative infinity (where the anticausal solution decays) to positive infinity (where the causal solution decays). For realistic dynamics the necessary time for the input is only slightly more than the motion time for the end of the arm because the zeros are often quite far from the origin in both directions. If the end-of-arm motion begins at time zero, shortly before that, the joint torques begin to *pre-shape* the flexible links without moving the end of arm. Similarly, when the end of the arm reaches its final position, the joint torques must release the arm deflection in a manner that is not seen from the end of arm (or any other chosen output location). Figure 13.14 shows the example from Kwon [13.74] for a single-link arm.

Feedback Control of Flexible Links

Flexibility in the links is in some cases controlled in the same way as concentrated flexibility in joints. Herein the focus is on approaches that apply specifically to link flexibility; consequently the use of Kalman filtering to estimate tip position and other broadly used techniques are not reexamined. A long history of research on this topic exists. Cannon and Schmitz [13.75], Truckenbrot [13.76], and others showed that these techniques work for flexible link arms and that the non-collocated nature of the system aggravates the sensitivity to modeling errors.

Strain measurements provide a valuable indication of the state of a flexible link, and strain rate, obtained from filtered differentiation of the typically noisy strain signal, was shown by Hastings [13.77] to be an appropriate way of overcoming the limitations imposed by purely joint feedback control. Yuan [13.78] produced an adaptive version of strain-rate feedback.

Strain measurements readily lend themselves to calculation of the modal amplitudes, and the number of

appropriately placed strain gage measurements N can be equal to the number of mode amplitudes to be evaluated. In this case no estimation algorithm is necessary, although filtering is usually needed. If the mode shape ϕ_i of a beam is known, strain is proportional to the second derivative of ϕ_i ,

$$\alpha_{ij} = \left. \frac{\partial^2 \phi_i}{\partial x^2} \right|_{x_j} . \quad (13.83)$$

By inverting the coefficient matrix thus formed it is simple to obtain the amplitude of N modes. Additional attention is necessary if beam torsion is a significant part of the mode deflection, but the principle still applies. Active control of high-frequency modes may not be warranted, and feedback of the one or two lowest-frequency modes can be managed by classical or state-space design

Fig. 13.15 Robotic arm large and flexible (RALF) used in EOA feedback experiments

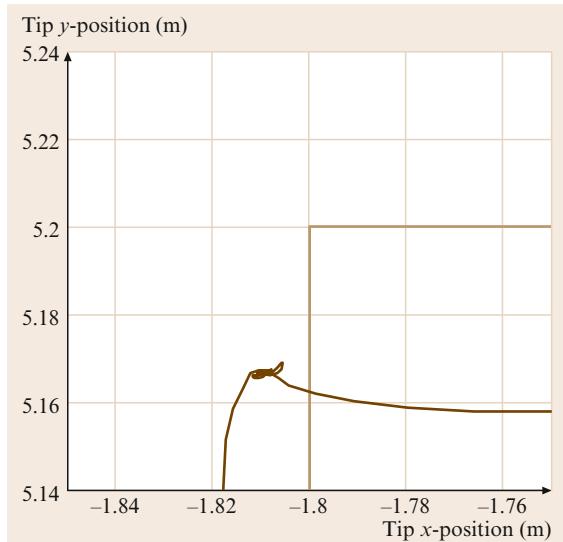

Fig. 13.16 Path followed without EOA position feedback. (Commanded trajectory is a *square* partially shown in *light brown*. Actual trajectory shown in *dark brown*.)

techniques to increase the damping of that mode

$$\begin{pmatrix} \delta_1 \\ \delta_2 \\ \vdots \\ \delta_N \end{pmatrix} = \begin{pmatrix} \alpha_{11} & \alpha_{12} & \dots & \alpha_{1N} \\ \alpha_{21} & \alpha_{22} & \dots & \alpha_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_{N1} & \alpha_{N2} & \dots & \alpha_{NN} \end{pmatrix}^{-1} \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_N \end{pmatrix}. \quad (13.84)$$

The use of the measurement of the end-of-arm position has perpetual appeal and is very effective for rigid arms for the elimination of variability due to arm distortion and the change over time of arm calibration. Machine vision can eliminate uncertainty in the target position as well as the arm position. These approaches are plagued by the non-collocated and hence non-minimum-phase dynamics of link flexibility, however, and may require particular caution. Wang [13.79] proposed an alternative formulation of EOA measurements in the control formulation that he called the reflected tip position. For a rotating link of angle θ and length l the deflected position is $l\theta + \delta$ while the reflected tip position $l\theta - \delta$ is minimum phase. This combination of joint and tip measurements produced the desired undeflected position but would not serve for EOA tracking control. Oberfell [13.80] synthesized an output based on strain feedback combined with EOA position that allowed tracking control as well. He first

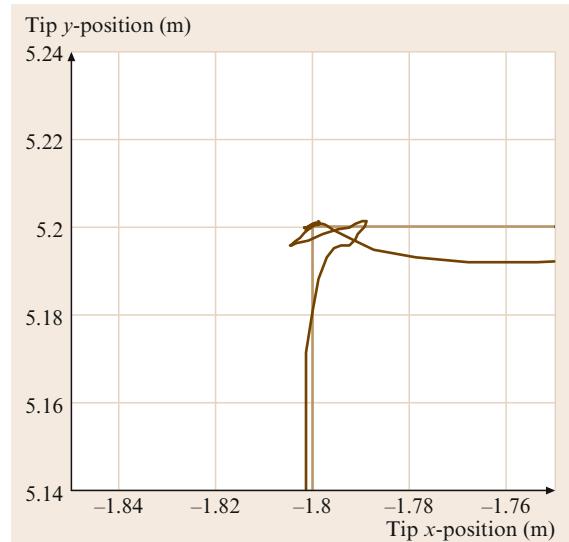

Fig. 13.17 Path followed with EOA feedback from camera. (Commanded trajectory is a *square* partially shown in *light brown*. Actual trajectory shown in *dark brown*.)

produced a passive system with deflection feedback obtained from optical measurements of the link deflection, and then devised a traditional feedback control of the tip position measured by machine vision of the large two link arm shown in Fig. 13.15. Figures 13.16 and 13.17 compare the path for a large square traced in a plane with only the deflection feedback and with both deflection and EOA position feedback.

13.2.4 Further Reading

The topic of flexible link robot control is widely covered with papers on modeling and control. The reader wishing to probe further may want to begin with a paper giving some perspective on the nature of the problem. This was the goal of Book in [13.81]. Progress to date in this field from the theoretical perspective is significant and has been collected by *Canudas de Witt et al.* in [13.82]; this reference includes a wide range of research approaches, but the examples of the practical application of this theory are more limited. The German Aerospace Center has produced lightweight space arms [13.83] and deployed them in space. The startup CAMotion Inc. [13.84] has produced large lightweight industrial robots using the command-shaping approach to improve cycle time. High-speed arms such as the FlexPicker [13.85] achieve a light weight and avoid flexibility because of their parallel structure, but suffer

the usual disadvantages of parallel actuation: restricted workspace considering the space occupied by the robot structure.

Trautt and *Bayo*'s early exploration of non-minimum-phase inverses is described in [13.86]. This is a particularly interesting variation of the work by *Kwon* [13.73, 74] in that it uses the frequency domain and deals with nonzero initial conditions. The concept of using two time scales, a fast time scale for the flexible dynamics and a slow time scale for the rigid dynamics, can be found in *Siciliano* and *Book* [13.87]. The singular per-

turbation approach was used earlier by *Spong* for elastic joint arms. *Ghorbel* and *Spong* also consider flexible links and contact with a rigid environment in [13.88]. Achieving robustness is a problem, particularly with end-point sensors. Sliding mode control [13.89] and passivity-based control [13.90] address this problem in effective but widely varying ways. While these seem to be the more promising methods of control, one will find many more approaches to this challenging control problem. H_∞ , adaptive, fuzzy, and other controllers have all been applied with varying degrees of success.

Model Identification

John Hollerbach, Wisama Khalil, Maxime Gautier

This chapter discusses how to determine the kinematic parameters and the inertial parameters of robot manipulators. Both instances of model identification are cast into a common framework of least-squares parameter estimation, and are shown to have common numerical issues relating to the identifiability of parameters, adequacy of the measurement sets, and numerical robustness. These discussions are generic to any parameter estimation problem, and can be applied in other contexts.

For kinematic calibration, the main aim is to identify the geometric Denavit–Hartenberg (**DH**) parameters, although joint-based parameters relating to the sensing and transmission elements can also be identified. Endpoint sensing or endpoint constraints can provide equivalent calibration equations. By casting all calibration methods as closed-loop calibration, the calibration index categorizes methods in terms of how many equations per pose are generated.

Inertial parameters may be estimated through the execution of a trajectory while sensing one or more components of force/torque at a joint. Load estimation of a handheld object is simplest because of full mobility and full wrist force–torque sensing. For link inertial parameter estimation,

restricted mobility of links nearer the base as well as sensing only the joint torque means that not all inertial parameters can be identified. Those that can be identified are those that affect joint torque, although they may appear in complicated linear combinations.

14.1 Overview

There are many different kinds of models in robotics, whose accurate identification is required for precise control. Examples from the previous chapters include sensor models, actuator models, kinematic models, dynamic models, and flexibility models. System identification is the general field concerned with the process of identifying models from measurements. Generally speaking, there are two types of models: parametric and non-

parametric models. Parametric models are described by a few parameters, which are adequate to characterize the accuracy of a model throughout the working range. Examples include sensor gain and offset, the **DH** parameters for links, and rigid-body inertial parameters. Parametric models are particularly appropriate for robotics, whose components are manmade and whose properties are controlled and understood.

Nonparametric models include the impulse response and the Bode plot for linear systems, and Wiener and Volterra kernels for nonlinear systems [14.1]. A nonparametric model can be used as a stepping stone towards identifying a parametric model; for example, a Bode plot (graph of amplitude and phase versus input frequency) is often used to decide on model order, such as whether an actuator should be modeled as a second- or third-order system. Otherwise, nonparametric models are required when the system's properties are so complicated that a few lumped parameters do not suffice. This is particularly true for biological systems.

This chapter will describe the parametric calibration of the following kinds of models.

1. Kinematic parameters. Kinematic calibration is the process of locating coordinate systems of objects relative to each other. These objects may be isolated from each other, or they may be linked by joints. Examples include
 - locating a robot relative to a global reference frame
 - locating a stereo vision system relative to a robot
 - locating a grasped object relative to the manipulator's gripper frame
 - locating neighboring coordinate systems of links of a robot manipulator
2. Rigid-body inertial parameters. These parameters are required to predict the driving forces and torques to move objects and manipulators.

Suppose there are N_{par} parameters combined into an $N_{\text{par}} \times 1$ parameter vector $\boldsymbol{\phi} = \{\phi_1, \dots, \phi_{N_{\text{par}}}\}$. The parameters may appear linearly or nonlinearly in the model.

$$\text{Linear model: } \mathbf{y}^l = \mathbf{A}^l \boldsymbol{\phi}, \quad (14.1)$$

$$\text{Nonlinear model: } \mathbf{y}^l = \mathbf{f}(\mathbf{x}^l, \boldsymbol{\phi}), \quad (14.2)$$

where $\mathbf{y}^l = \{y_1^l, \dots, y_M^l\}$ is the $M \times 1$ vector of output variables and $\mathbf{x}^l = \{x_1^l, \dots, x_n^l\}$ is the vector of input variables. For the linear model, \mathbf{A}^l is an $M \times N_{\text{par}}$ matrix whose entries A_{ij}^l are functions of the input variables \mathbf{x}^l . Any entry A_{ij}^l may be a complicated nonlinear function of \mathbf{x}^l , but it evaluates to just a number. For the nonlinear model, an explicit equation is shown in which the input variables appear in a nonlinear function $\mathbf{f} = \{f_1, \dots, f_M\}$. Implicit nonlinear models $\mathbf{f}(\mathbf{y}^l, \mathbf{x}^l, \boldsymbol{\phi}) = \mathbf{0}$ may also appear in calibration [14.2]; they are handled similarly to explicit nonlinear models (Sect. 14.2.2). There may be P different measurements;

a particular measurement is indicated by the superscript $l = 1, \dots, P$.

For linear models, information from different measurements is combined by stacking the P equations (14.1):

$$\mathbf{y} = \mathbf{A} \boldsymbol{\phi}, \quad (14.3)$$

where $\mathbf{y} = \{y^1, \dots, y^P\}$ is an $MP \times 1$ vector of all output measurements and $\mathbf{A} = \{\mathbf{A}^1, \dots, \mathbf{A}^P\}$ is $MP \times N_{\text{par}}$. The parameters are estimated by ordinary least squares:

$$\boldsymbol{\phi} = (\mathbf{A}^\top \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{y}. \quad (14.4)$$

In statistics, the matrix \mathbf{A} is called the regressor matrix and the least-squares solution is called regression [14.3]. An example of a linear model is the rigid-body model for inertial parameters.

The Gauss–Newton method [14.3] is typically employed to estimate the nonlinear model (14.2). First, absorb the input variables \mathbf{x}^l (which can be considered as a number of constants) into the nonlinear function \mathbf{f}^l , now given a superscript. The model is linearized through a Taylor series expansion at a current estimate $\boldsymbol{\phi}^k$ of the parameters at iteration k :

$$\begin{aligned} \mathbf{y}_c^l &= \mathbf{f}^l(\boldsymbol{\phi}^k + \Delta\boldsymbol{\phi}) \\ &= \mathbf{f}^l(\boldsymbol{\phi}^k) + \left. \frac{\partial \mathbf{f}^l(\boldsymbol{\phi})}{\partial \boldsymbol{\phi}} \right|_{\boldsymbol{\phi}=\boldsymbol{\phi}^k} \Delta\boldsymbol{\phi} \\ &\quad + \text{higher order terms} \\ &\approx \mathbf{f}^l(\boldsymbol{\phi}^k) + \mathbf{A}^l \Delta\boldsymbol{\phi}, \end{aligned} \quad (14.5)$$

where \mathbf{y}_c^l are the computed values of the output variables and $\mathbf{A}^l = \partial \mathbf{f}^l / \partial \boldsymbol{\phi}$ is a Jacobian matrix evaluated at $\boldsymbol{\phi}^k$. Higher-order terms in the Taylor series are ignored, yielding the linearized form (14.5). The bold assumption is now made that a correction $\Delta\boldsymbol{\phi}$ to the parameter estimate $\boldsymbol{\phi}^k$ causes the computed output variables to equal the measurements: $\mathbf{y}_c^l = \mathbf{y}^l$. Defining $\Delta\mathbf{y}^l = \mathbf{y}^l - \mathbf{f}^l(\boldsymbol{\phi}^k)$ as the error between the output measurement and the predicted output with the current model $\boldsymbol{\phi}^k$, the linearized equation (14.5) becomes

$$\Delta\mathbf{y}^l = \mathbf{A}^l \Delta\boldsymbol{\phi}. \quad (14.6)$$

The linearized equation is then stacked for P measurements for the estimation form:

$$\Delta\mathbf{y} = \mathbf{A} \Delta\boldsymbol{\phi}. \quad (14.7)$$

A correction $\Delta\boldsymbol{\phi}$ to the parameter estimates is now found by ordinary least squares

$$\Delta\boldsymbol{\phi} = (\mathbf{A}^\top \mathbf{A})^{-1} \mathbf{A}^\top \Delta\mathbf{y}. \quad (14.8)$$

This process is iterated with a new estimate $\phi^{k+1} = \phi^k + \Delta\phi$ until the error $\Delta\phi$ becomes sufficiently small. The Gauss–Newton method has quadratic convergence, which is very fast, provided that there is a good initial estimate ϕ^0 of the parameters and the nonlinearity is not too severe. An example of a nonlinear model is the kinematic model containing the DH parameters. The nonlinearity is mild because it is due to sines and cosines, so the Gauss–Newton method usually has good convergence properties.

Both for linear and nonlinear estimation, however, rank deficiencies and numerical ill-conditioning may cause problems in inverting $A^\top A$. Rank deficiencies may result from two problems.

1. Inadequate data. The quality of the data for estimating the parameters can be quantified by an observability index, such as the condition number [14.4] of the regressor matrix A . A different choice of data to maximize the observability index might result in more robust estimates. Examples are choosing different poses for kinematic calibration, or different trajectories for inertial parameter estimation.
2. Unidentifiable parameters. Perhaps no set of data from an experiment can identify some of the parameters. A procedure has to be found to eliminate or circumvent the unidentifiable parameters. Parameter elimination is usually done by using the singular value decomposition of A , while circumvention can be achieved by using a priori values and ridge regression. This does not mean that the parameters are intrinsically identifiable, only that the experimen-

tal setup precludes their determination; for example, only one of the 10 inertial parameters of the first link of a robot manipulator can be identified if the base of the manipulator is stationary. A different experimental setup involving accelerating the base of the manipulator and measuring the reaction forces and torques at the base would allow other parameters to be identified [14.5].

Ill-conditioning may result from poor scaling of measurements or parameters.

1. The least-squares estimation minimizes the error between the predicted and measured output vector. Components y_j^l of the output vector y^l may have different units and magnitudes, such as radians versus meters, in pose measurements for kinematic calibration. Moreover, not all components may be measured to the same level of accuracy. Normalizing the output vectors with an appropriately chosen weighting matrix may result in a better conditioned estimate.
2. The parameters may also have different units and different magnitudes. This can cause problems both in terms of convergence criteria and in terms of deciding which parameters to eliminate. Again, a weighting matrix for the parameters may be introduced to improve the conditioning.

These numerical issues are generic to any parameter estimation problem, and are discussed at the end of this chapter. The next sections discuss individual robot models and issues in putting them into parameter estimation form.

14.2 Kinematic Calibration

In general, the relative location between coordinate systems requires six geometric parameters to be calibrated (position plus orientation). If there are mechanical constraints between the relative movement of the coordinate systems, such as connection by a joint, fewer parameters are required. For a rotary joint connecting two links, whose axis is a line-bound vector, four geometric parameters are required. For a prismatic joint, whose axis is a free vector, only two geometric parameters describing orientation are required.

In addition, nongeometric parameters are required to model sensors and mechanical deflection.

- Joint angle sensors may require a gain and offset determination.
- Camera calibration using an undistorted pinhole camera model may require the determination of the focal length and an image sensor offset.
- Joint flexibility from gears leads to angle change due to gravity loading and the manipulator's own weight.
- Base flexibility results from nonrigid attachment of the robot to the environment. Depending on how the manipulator is outstretched, there will be a varying effect on endpoint location.
- Thermal effects and vibration may need to be modeled for very fine positioning control.

This section focuses on determining the geometric parameters and the sensor-based nongeometric parameters.

14.2.1 Serial-Link Robot Manipulators

The modified Denavit–Hartenberg (DH) parameters (Fig. 14.1) serve as the main geometric parameters (Sect. 1.4); the link transformation matrix is

$$\begin{aligned} {}^{i-1}\mathbf{T}_i \\ = \text{Rot}(\mathbf{x}, \alpha_i)\text{Trans}(\mathbf{x}, a_i)\text{Trans}(\mathbf{z}, d_i)\text{Rot}(\mathbf{z}, \theta_i). \end{aligned} \quad (14.9)$$

- For an n -joint manipulator with rotary joint $i = 1, \dots, n$, whose axis \mathbf{z}_i is a line in space, all four parameters a_i , d_i , α_i , and θ_i have to be calibrated.
- For a prismatic joint i , whose axis \mathbf{z}_i is a free vector, only two parameters describing its orientation (α_i and θ_i) are required. In principle, the axis \mathbf{z}_i can be positioned anywhere in space. This means two DH parameters are arbitrary. One possibility is to intersect \mathbf{z}_i with O_{i+1} [14.6, 7], which sets $d_{i+1} = 0$ and $a_{i+1} = 0$. While kinematically correct, this placement is nonintuitive in that it doesn't correspond to the physical location of the prismatic mechanism. It is possible to set a_{i+1} with a_i or θ_i to values that position \mathbf{z}_i in the middle of the prismatic joint's mechanical structure.

In the case of nearly parallel neighboring axes, the common normal is poorly defined and the calibration is ill-conditioned. For this case, Hayati [14.7] introduced an extra rotational parameter β_i about the \mathbf{y}_{i-1} axis (Fig. 14.2).

Let \mathbf{x}'_{i-1} lie along a line from O_i to axis \mathbf{z}_{i-1} , such that \mathbf{x}'_{i-1} is perpendicular to \mathbf{z}_i ; the intersection point defines the origin O_{i-1} . Two rotations are required to

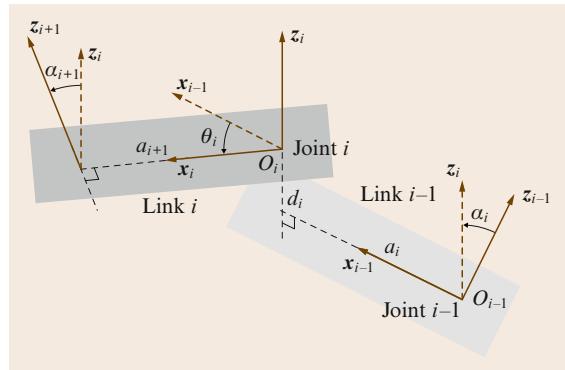

Fig. 14.1 The modified DH parameters

relate \mathbf{z}_{i-1} to $\mathbf{z}_i = \mathbf{z}'_{i-1}$: a rotation α_i about \mathbf{x}'_{i-1} maps \mathbf{z}'_{i-1} to \mathbf{z}_i , and a rotation β_i about $\mathbf{y}_{i-1} = \mathbf{y}''_{i-1}$ maps \mathbf{z}_{i-1} to \mathbf{z}''_{i-1} . The angle θ_i is now from \mathbf{x}'_{i-1} to \mathbf{x}_i about \mathbf{z}_i . The link transformation is

$$\begin{aligned} {}^{i-1}\mathbf{T}_i \\ = \text{Rot}(\mathbf{y}, \beta_i)\text{Rot}(\mathbf{x}, \alpha_i)\text{Trans}(\mathbf{x}, a_i)\text{Rot}(\mathbf{z}, \theta_i). \end{aligned} \quad (14.10)$$

- For a rotary joint, the parameter β_i is calibrated instead of d_i .
- For a prismatic joint, the joint variable d_i has to be retained. As before, position \mathbf{z}_i at some convenient location on link i , by specifying two parameters relative to the coordinate system $i + 1$. Then proceed with the construction of the Hayati parameters for $d_i = 0$. As d_i changes, axis \mathbf{x}_i is displaced along \mathbf{z}_i relative to \mathbf{x}'_{i-1} (not shown). The link transformation is:

$$\begin{aligned} {}^{i-1}\mathbf{T}_i = \text{Rot}(\mathbf{y}, \beta_i)\text{Rot}(\mathbf{x}, \alpha_i)\text{Trans}(\mathbf{x}, a_i) \\ \text{Trans}(\mathbf{z}, d_i)\text{Rot}(\mathbf{z}, \theta_i). \end{aligned} \quad (14.11)$$

Although there are five parameters in this transformation, the process of setting the Hayati parameters for $d_i = 0$ is tantamount to setting the value of d_{i-1} to locate O_{i-1} , so there is no net increase in the number of parameters.

The procedures above set the coordinate systems in the intermediate links of a serial manipulator. Coordinate systems also have to be set in the base and end links, but the procedure for doing so depends on the external metrology system and on any physical constraints on the end link pose. The last frame may be n or $n + 1$, while the first frame may be 0 or -1 (to keep consecutive numbers); examples appear below. Collect the unknown kinematic parameters into the vectors \mathbf{a} , \mathbf{d} , $\boldsymbol{\alpha}$, $\boldsymbol{\theta}$, and $\boldsymbol{\beta}$,

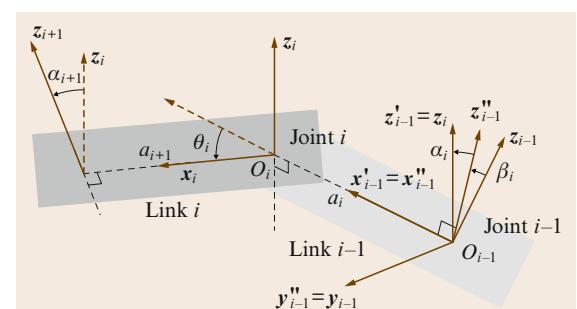

Fig. 14.2 The additional parameter β_i about \mathbf{y}_{i-1} is employed for nearly parallel axes

and thence into the parameter vector $\phi = \{a, d, \alpha, \theta, \beta\}$. The parameters ϕ predict the position and orientation of the last coordinate system relative to the first, such as ${}^0T_{n,c}$.

Not all six components of pose are necessarily used for calibration; the number can vary from one to six. Calibration proceeds by observing the error in the prediction of a certain number of pose components, then employing the nonlinear calibration method (14.7). There are two general methods for observing error.

- *Open-loop calibration* utilizes an external metrology system to measure the pose components. Because the manipulator is not in contact with the environment during this process, the method is termed open loop.
- *Closed-loop calibration* utilizes physical constraints on the end link pose to substitute for measurements. Deviations from the physical constraint represent the prediction error. Because of the contact with the physical constraint, the manipulator forms a closed loop with the ground.

Open-Loop Kinematic Calibration

The calibration literature contains a variety of metrology systems, which can be categorized based on the number of pose components measured [14.8].

1 component: The distance to a single point on the end link can be measured in a variety of ways, such as an instrumented ball bar [14.9], wire potentiometer [14.10], or laser displacement meter [14.11].

2 components: A single theodolite has been employed to provide two orientation measurements [14.12]. A reference length had to be sighted for scaling.

3 components: Laser tracking systems provide accurate three-dimensional (3-D) measurements by reflecting a beam off a retroreflector mounted on the end effector. The beam provides length information, while the gimbal drive for laser steering provides two orientation measurements [14.13]. Since the least precise part of this setup is the angle sensing, another approach is to employ three laser tracking systems and use only the length information. Commercial 3-D stereo-camera motion tracking systems also provide high-accuracy measurements of position.

5 components: Lau et al. [14.14] presented a steerable laser interferometer with steerable reflector. With pitch and yaw measurements, the steerable interferometer yields all three components of position, while the steerable reflector yields two components of orientation.

6 components: Full pose can be inferred from the 3-D position of multiple points on the last link measured with a stereo-camera system. A coordinate system fit to the cloud of points yields position plus orientation [14.15].

Vincze et al. [14.16] measured full pose with a single-beam laser tracking system, by fitting the robot with a retroreflector mounted on a universal joint. Position is measured using interferometry, as usual. The novel aspect is orientation measurement, by imaging of the diffraction pattern of the edges of the retroreflector.

Examples are given for calibrating with three pose components and with all six pose components measured.

Point Measurement. The 3-D position of a particular point on the end link can be conveniently located by some form of stereo camera system. The camera system defines a global coordinate system relative to which frame 1 of the robot is located. To provide enough parameters, an intermediate coordinate system has to be introduced; this intermediate coordinate system has index 0, while the camera system is given index -1 to keep consecutive numbers. Two of the eight parameters are arbitrary. Figure 14.3 shows one possibility: z_0 is made

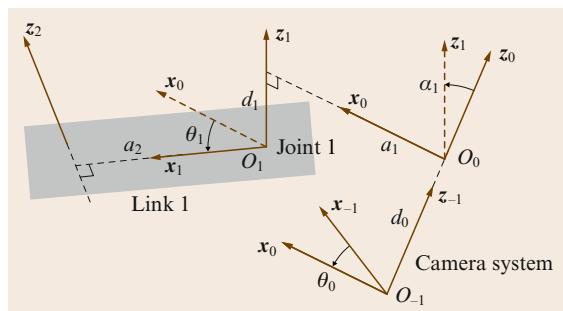

Fig. 14.3 A camera system (index -1) is located relative to the manipulator coordinate system 1 via an intermediate coordinate system 0

parallel ($\alpha_0 = 0$) and coincident ($a_0 = 0$) with z_{-1} . The calibrated parameters are $d_0, \theta_0, a_1, d_1, \alpha_1$, and θ_1 . In the case that z_{-1} is nearly parallel to z_0 , the measurement coordinate system can be simply redefined to avoid using Hayati parameters; for example, y_{-1} can be redefined as z_{-1} .

In the end link, the origin O_n and axis x_n are unspecified, as are the associated parameters d_n and θ_n . Locating the measured point requires only three parameters, so the addition of a single coordinate system $n+1$ is required to provide an additional parameter. The measured point is defined as the origin O_{n+1} of the new coordinate system, and the normal from z_n that intersects O_{n+1} defines the x_n axis (Fig. 14.4). Three parameters are arbitrary; a simple choice is to make z_{n+1} parallel to z_n ($\alpha_{n+1} = 0$) and x_{n+1} collinear with x_n ($\theta_{n+1} = 0$) and $d_{n+1} = 0$). The calibrated parameters are a_{n+1}, d_n , and θ_n .

From the transformation ${}^{-1}\mathbf{T}_{n+1} = {}^{-1}\mathbf{T}_0 \dots {}^n\mathbf{T}_{n+1}$, the position ${}^{-1}\mathbf{p}_{n+1}$ of the measured point relative to the camera frame is extracted. Collect the unknown kine-

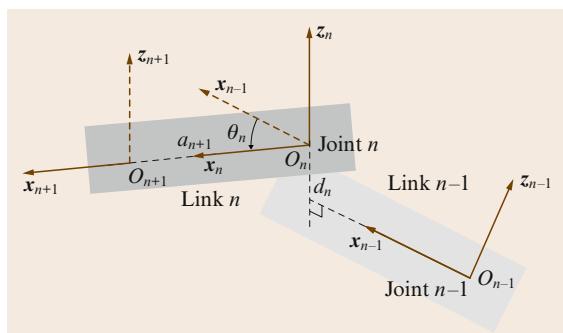

Fig. 14.4 A measured point O_{n+1} is located on the end link by adding a coordinate system $n+1$

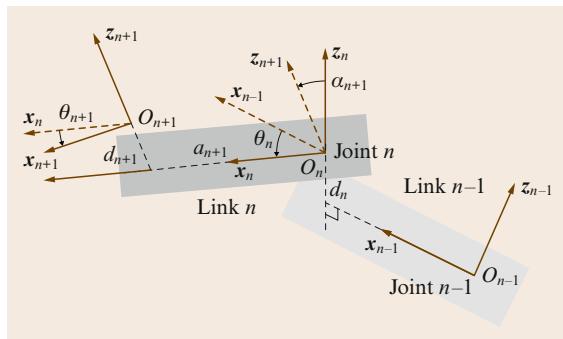

Fig. 14.5 Full pose measurement of coordinate system $n+1$ in the end link

matic parameters into vectors \mathbf{a} , \mathbf{d} , $\boldsymbol{\alpha}$, $\boldsymbol{\theta}$, and $\boldsymbol{\beta}$, and thence into the parameter vector $\boldsymbol{\phi} = \{\mathbf{a}, \mathbf{d}, \boldsymbol{\alpha}, \boldsymbol{\theta}, \boldsymbol{\beta}\}$. The nonlinear kinematic model analogous to (14.2) is

$${}^{-1}\mathbf{p}_{n+1}^l = \mathbf{f}(\mathbf{q}^l, \boldsymbol{\phi}), \quad l = 1, \dots, P, \quad (14.12)$$

where \mathbf{q}^l is the vector of joint variables for pose l . To linearize this equation into estimation form (14.6), the associated Jacobians for each parameter type are calculated:

$$\Delta {}^{-1}\mathbf{p}_{n+1}^l = {}^{-1}\mathbf{p}_{n+1}^l - {}^{-1}\mathbf{p}_{n+1,c}^l = \mathbf{J}^l \Delta \boldsymbol{\phi} \\ = \left(\mathbf{J}_a^l \ \mathbf{J}_d^l \ \mathbf{J}_\alpha^l \ \mathbf{J}_\theta^l \ \mathbf{J}_\beta^l \right) \begin{pmatrix} \Delta \mathbf{a} \\ \Delta \mathbf{d} \\ \Delta \boldsymbol{\alpha} \\ \Delta \boldsymbol{\theta} \\ \Delta \boldsymbol{\beta} \end{pmatrix}, \quad (14.13)$$

where a typical column i for each individual parameter Jacobian is derived from the screw parameters as if each parameter represented an active joint (Sect. 1.8.1):

$$\mathbf{J}_{a_i}^l = \begin{cases} {}^{-1}\mathbf{x}_{i-1}^l & \text{DH} \\ {}^{-1}\mathbf{x}_{i-1}^l & \text{Hayati} \end{cases}, \quad (14.14)$$

$$\mathbf{J}_{d_i}^l = {}^{-1}\mathbf{z}_i^l, \quad (14.15)$$

$$\mathbf{J}_{\alpha_i}^l = \begin{cases} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l & \text{DH} \\ {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l & \text{Hayati} \end{cases}, \quad (14.16)$$

$$\mathbf{J}_{\theta_i}^l = {}^{-1}\mathbf{z}_i^l \times {}^{-1}\mathbf{d}_{i,n+1}^l, \quad (14.17)$$

$$\mathbf{J}_{\beta_i}^l = {}^{-1}\mathbf{y}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l, \quad (14.18)$$

where ${}^{-1}\mathbf{d}_{i,n+1}^l = {}^{-1}\mathbf{R}_i^l \mathbf{p}_{n+1}$ refers the interorigin vector to coordinate system -1 . Equations (14.13) are stacked for all the poses for the final estimation form

$$\Delta {}^{-1}\mathbf{p}_{n+1} = \mathbf{J} \Delta \boldsymbol{\phi}, \quad (14.19)$$

which corresponds to (14.7) and which is solved for $\Delta \boldsymbol{\phi}$ by least squares and for $\boldsymbol{\phi}$ by iteration.

Full Pose Measurement. Suppose that coordinate system $n+1$ in link n is measured (Fig. 14.5). Coordinate system n is completed in the usual way, and the six calibrated parameters to locate coordinate system $n+1$ are $d_n, \alpha_n, \theta_n, a_{n+1}, d_{n+1}$, and θ_{n+1} . If z_{n+1} is nearly parallel to z_n , this axis may simply be permuted with other axes, such as y_{n+1} , to avoid using the Hayati parameters.

In addition to the position equations (14.12), orientation equations of coordinate system $n+1$

$${}^{-1}\mathbf{R}_{n+1}^l = \mathbf{F}(\mathbf{q}^l, \boldsymbol{\phi}), \quad l = 1, \dots, P \quad (14.20)$$

are extracted from ${}^{-1}\mathbf{T}_{n+1}$, where \mathbf{F} is a matrix function. Linearization of this equation yields:

$$\begin{aligned} \Delta^{-1}\mathbf{R}_{n+1}^l &= {}^{-1}\mathbf{R}_{n+1}^l - {}^{-1}\mathbf{R}_{n+1,c}^l \\ &= \Delta^{-1}\boldsymbol{\rho}_{n+1}^l \times {}^{-1}\mathbf{R}_{n+1,c}^l \\ \mathbf{S}(\Delta^{-1}\boldsymbol{\rho}_{n+1}^l) &= ({}^{-1}\mathbf{R}_{n+1}^l - {}^{-1}\mathbf{R}_{n+1,c}^l)({}^{-1}\mathbf{R}_{n+1,c}^l)^T, \end{aligned} \quad (14.21)$$

where $\Delta^{-1}\boldsymbol{\rho}_{n+1}^l$ are differential orthogonal rotations which are the finite-difference counterpart to the angular velocity vector. Continuing with this analogy, a Jacobian \mathbf{J} similar to that for spatial velocities (Sect. 1.8) is employed to represent the combined effect of parameter variations $\Delta\boldsymbol{\phi}$ on changes in position $\Delta^{-1}\mathbf{p}_{n+1}^l$ and orientation $\Delta^{-1}\boldsymbol{\rho}_{n+1}^l$:

$$\begin{pmatrix} \Delta^{-1}\mathbf{p}_{n+1}^l \\ \Delta^{-1}\boldsymbol{\rho}_{n+1}^l \end{pmatrix} = \mathbf{J}^l \Delta\boldsymbol{\phi}. \quad (14.22)$$

Compared to (14.13), the Jacobian \mathbf{J}^l now has six rows, as do the individual parameter Jacobians:

$$\mathbf{J}_{a_i}^l = \begin{cases} \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \\ \mathbf{0} \\ {}^{-1}\mathbf{x}_{i-1}^l \\ \mathbf{0} \end{pmatrix} & \text{DH} \\ \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \\ \mathbf{0} \end{pmatrix} & \text{Hayati} \end{cases}, \quad (14.23)$$

$$\mathbf{J}_{d_i}^l = \begin{pmatrix} {}^{-1}\mathbf{z}_i^l \\ \mathbf{0} \end{pmatrix}, \quad (14.24)$$

$$\mathbf{J}_{\alpha_i}^l = \begin{cases} \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \end{pmatrix} & \text{DH} \\ \begin{pmatrix} {}^{-1}\mathbf{x}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{x}_{i-1}^l \end{pmatrix} & \text{Hayati} \end{cases}, \quad (14.25)$$

$$\mathbf{J}_{\theta_i}^l = \begin{pmatrix} {}^{-1}\mathbf{z}_i^l \times {}^{-1}\mathbf{d}_{i,n+1}^l \\ {}^{-1}\mathbf{z}_i^l \end{pmatrix}, \quad (14.26)$$

$$\mathbf{J}_{\beta_i}^l = \begin{pmatrix} {}^{-1}\mathbf{y}_{i-1}^l \times {}^{-1}\mathbf{d}_{i-1,n+1}^l \\ {}^{-1}\mathbf{y}_{i-1}^l \end{pmatrix}. \quad (14.27)$$

As before, $\Delta\boldsymbol{\phi}$ is found by least squares and $\boldsymbol{\phi}$ by iteration.

Closed-Loop Calibration

Physical constraints on end-effector position or orientation can substitute for measurements. The location of

a physical constraint defines the reference coordinate system; the *measurement* of endpoint position or orientation is therefore defined as zero. The deviation from the physical constraint due to an incorrect kinematic model is cast as a displacement from the reference coordinates. Analogous to point measurement and full pose measurement, there are closed-loop methods using point constraints and full pose constraints.

Point Constraint. Suppose that the end-effector holds a stylus that makes contact with a fixed point in the environment. The orientation of the stylus can be changed by varying the joint angles, as long as the point of contact is not changed. Before, the measurement system for point measurement defined the reference coordinate system -1 (Fig. 14.3), and there was an end effector coordinate system $n+1$ whose origin O_{n+1} was measured (Fig. 14.4). Now the reference coordinate origin O_0 has index 0 and is collocated with O_{n+1} (Fig. 14.6). An extra coordinate system -1 is not required because a point is located relative to coordinate system 1 with only three parameters: a_1 , d_1 , and θ_1 . The arbitrary choice $\alpha_1 = 0$ is made, i.e., z_0 is made parallel to z_1 .

Different poses while maintaining the point contact can be generated manually, or they can be generated automatically if there is a force control capability. In comparison to (14.13), the *measured* position ${}^0\mathbf{p}_{n+1}^l = 0$ by definition and the linearized calibration equation is simply:

$$\Delta^{-1}\mathbf{p}_{n+1}^l = -{}^{-1}\mathbf{p}_{n+1,c}^l = \mathbf{J}^l \Delta\boldsymbol{\phi}. \quad (14.28)$$

The set of poses that may be generated is limited relative to open-loop calibration, which may affect identifiability.

Full Pose Constraint. Analogous to full pose measurement (Fig. 14.5), the end link may be fully constrained

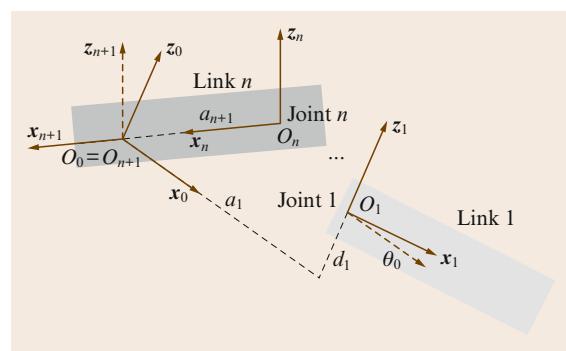

Fig. 14.6 Fixed point contact, setting $O_0 = O_{n+1}$

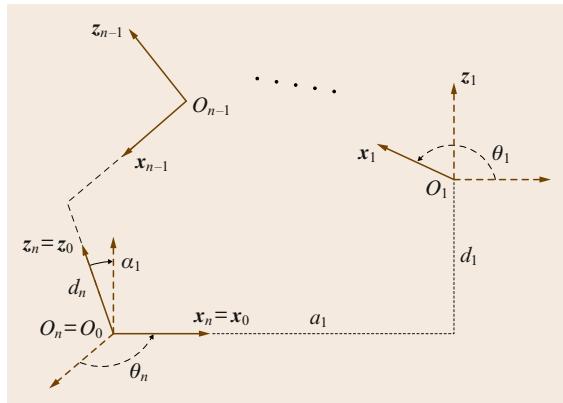

Fig. 14.7 Fully constrained end link, setting $O_0 = O_n$

by rigidly gripping the environment. If the manipulator is redundant (Chap. 11), then poses can be generated through self motion. Generating such poses would require endpoint force/torque sensing or joint torque sensing to be accomplished.

The end link can be considered part of the ground due to rigid attachment, and therefore one fewer coordinate system is required than for the fixed point case. Figure 14.7 shows one way of setting up coordinate systems 0 and n for calibration. Axis z_0 is set equal and coincident with axis z_n . The common normal between z_0 and z_1 sets the origin O_0 and the axis x_0 . Coordinate system n is completed by defining $O_n = O_0$ and $x_n = x_0$. Six parameters result for calibration, as they must relate coordinate system n to coordinate system 0: θ_n , d_n , α_1 , a_1 , d_1 , and θ_1 .

Similar to (14.28) after index adjustment, the measured position ${}^0\mathbf{p}_n^l = 0$ by definition and the linearized position calibration equation is:

$$\Delta {}^0\mathbf{p}_n^l = -{}^0\mathbf{p}_{n,c}^l. \quad (14.29)$$

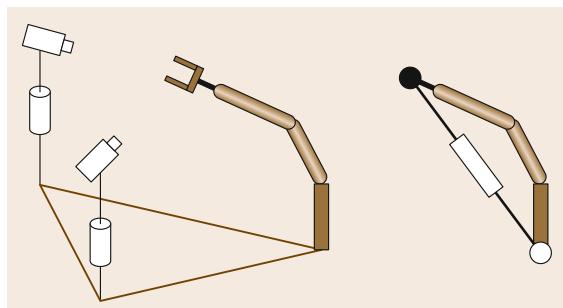

Fig. 14.8 External metrology system modeled as a 6-DOF joint

With regard to the error in orientation (14.21), the measured orientation ${}^0\mathbf{R}_n^l = \mathbf{I}$, the identity matrix, after index adjustment.

$$\mathbf{S}(\Delta {}^0\boldsymbol{\rho}_n^l) = (\mathbf{I} - {}^0\mathbf{R}_{n,c}^l)({}^0\mathbf{R}_{n,c}^l)^\top = ({}^0\mathbf{R}_{n,c}^l)^\top - \mathbf{I}. \quad (14.30)$$

The error equation (14.22) is then applied as for full pose measurement, after index adjustment. The set of poses that may be generated is limited relative to open-loop calibration, which may affect identifiability.

14.2.2 Parallel Manipulator Calibration

Parallel manipulators are comprised of multiple closed loops. The methods of the previous section could readily be extended to calibrate parallel manipulators. Rather than treat parallel and serial manipulators differently, and continue to elaborate the calibration equations on a case-by-case basis that includes different loop arrangements and different sensing arrangements, Hollerbach and Wampler [14.8] presented a unifying methodology termed the *calibration index*, which views all calibration problems as closed-loop calibration problems.

Open-loop calibration is converted to closed-loop calibration by considering the end effector measurement to form a joint. All measurements, whether from joints or metrology systems, are put on an equal footing, as are all unsensed joints, whether from unsensed components of pose, passive environmental constraints, or joints in the chain without sensors. In the case of parallel linkages, sufficient numbers of loop-closure equations are formulated to characterize the kinematics and are combined at each pose. Because the loop-closure equations are implicit functions of all measurements, Wampler et al. [14.2] called this calibration method the *implicit loop method*.

Figure 14.8 illustrates this idea for a calibrated stereo camera metrology system that measures the 3-D coordinates of a distinguished point on the end-effector of an uncalibrated robot. On the right this camera system has been replaced by a prismatic leg, which stylistically represents a six-degree-of-freedom (6-DOF) joint that provides equivalent 3-D coordinate measurements. The result is a closed-loop mechanism.

The kinematic loop closure equations f for the i th pose ($i = 1, \dots, P$) are formed as

$$f^i(\boldsymbol{\phi}) \equiv f(\mathbf{x}^i, \boldsymbol{\phi}) = \mathbf{0}, \quad (14.31)$$

where $\boldsymbol{\phi}$ is a vector of robot parameters to be calibrated, \mathbf{x}^i is a vector of joint sensor readings and possibly external sensor readings, and f^i absorbs the sensor readings

x^i and so is given an index. Combining (14.31) for the P poses into a single matrix equation

$$\mathbf{f}(\phi) = \left(\mathbf{f}^1^\top \dots \mathbf{f}^P^\top \right)^\top = \mathbf{0}. \quad (14.32)$$

Linearize (14.32) around the nominal values of the parameters

$$\Delta f = \frac{\partial \mathbf{f}}{\partial \phi} \Delta \phi = A \Delta \phi, \quad (14.33)$$

where Δf is the deviation of the computed loop closure equations from zero, J is the identification Jacobian, and $\Delta \phi$ is the correction to be applied to the current parameter estimate. The calibration problem is then solved by minimizing Δf via iterative least squares.

The Calibration Index

The basis for kinematic calibration is to compute the error in positioning a manipulator using the current kinematic model. The error may be relative to measurements by an external metrology system (open-loop methods), or relative to a physical constraint such as contact with a plane (closed-loop methods). An external metrology system may measure all six components of pose or fewer components such as a point on the end link (three components). Likewise, a physical constraint can limit between one and six components of pose. Constraints and measurements may be mixed. The number of measurements and constraints determine how many scalar equations per pose are available for calibration.

The calibration index C quantifies the number of equations per pose. While this analysis is rather straightforward for serial linkages, for parallel linkages it can be difficult to infer the number of independent equations per pose

$$C = S - M, \quad (14.34)$$

where S is the sensor index and M is the mobility index. The mobility index [14.17] characterizes the degrees of freedom in the calibration setup.

$$M = 6n - \sum_{i=1}^{N_J} n_i^c, \quad (14.35)$$

where n is the number of links, N_J is the number of joints, and n_i^c is the number of constraints at joint i . n includes any extra links attached to the robot to constrain or measure its motion. N_J includes joints of any additional linkages added for calibration. For a rotational or prismatic joint $n_i^c = 5$, while for a ball or spherical joint $n_i^c = 3$. For an external measurement system for a freely

moving end-effector $n_{N_J}^c = 0$, while for rigid attachment of the endpoint $n_{N_J}^c = 6$. While generally correct, there are exceptions to (14.35) due to special or degenerate mechanisms that have to be analyzed on a case-by-case basis (Chap. 12).

The sensor index S is the total number of sensors in the joints:

$$S = \sum_{i=1}^{N_J} S_i, \quad (14.36)$$

where S_i is the number of sensed degrees in joint i . Usually $S_i = 1$ for the lower-order pairs typical of actuated joints, while $S_{N_J} = 6$ for full pose measurement of the end-effector joint N_J . For an unsensed joint, such as in passive environment kinematics, $S_i = 0$.

If P is the number of poses, then CP is the total number of equations for the calibration procedure. Clearly a larger C means that fewer poses are required, other things being equal. For the single-loop case consisting of a series of sensed lower-order robot joints ($S_i = 1, n_i^c = 5, i = 1, \dots, N_J - 1$) with a final joint ($S_{N_J}, n_{N_J}^c$) connecting the end-effector to ground, one has from (14.34–14.35)

$$C = S_{N_J} + n_{N_J}^c. \quad (14.37)$$

According to the calibration index, using full endpoint constraints is an equivalent kinematic calibration method to using full pose measurements. There is potentially a problem with the smaller range of poses available with the endpoint constrained, but otherwise the mathematics are the same.

Categorization of Serial Link Calibration Methods

A great variety of calibration methods have been proposed, varying in the manner of pose measurement or endpoint constraints. These are categorized below according to the calibration index C and the values of $n_{N_J}^c$ and S_{N_J} .

$C = 6$: $n_{N_J}^c = 0$ and $S_{N_J} = 6$ corresponds to full pose measurement. $n_{N_J}^c = 6$ and $S_{N_J} = 0$ corresponds to rigid endpoint attachment.

$C = 5$: $n_{N_J}^c = 0$ and $S_{N_J} = 5$ corresponds to 5-DOF pose measurement [14.14]. $n_{N_J}^c = 5$ and $S_{N_J} = 0$ corresponds to 5-DOF endpoint constraints, such as manipulation of an unsensed passive hinge joint [14.18].

$C = 4$: No published method exists for $C = 4$.

$C = 3$: $n_{N_J}^c = 0$ and $S_{N_J} = 3$ corresponds to 3-DOF pose measurement. $n_{N_J}^c = 3$ and $S_{N_J} = 0$ corresponds to 3-DOF endpoint constraints.

$C = 2$: $n_{N_J}^c = 0$ and $S_{N_J} = 2$ corresponds to 2-DOF pose measurements, such as is provided by a single theodolite [14.12]. $n_{N_J}^c = 2$ and $S_{N_J} = 0$ corresponds to 2-DOF endpoint constraints. Motion along a line provides two constraints [14.19].

$C = 1$: $n_{N_J}^c = 0$ and $S_{N_J} = 1$ corresponds to measurement of just 1-DOF pose, provided by a linear transducer such as an linear variable differential transformer (LVDT) [14.9] or wire potentiometer [14.10]. $n_{N_J}^c = 1$ and $S_{N_J} = 0$ corresponds to a plane constraint [14.20].

Categorization of Parallel-Link Calibration Methods

To calibrate parallel robots, a loop-closure equation is written for each loop j :

$$\mathbf{0} = f_j(\phi). \quad (14.38)$$

The equations for all the loops are combined. One problem is to eliminate unsensed degrees of freedom. The calibration index is now applied based on the number of loops.

2 loops: A two-loop mechanism has three arms or legs, attached to a common platform. An example is the RSI Research Ltd. Hand Controller [14.21], which employs three 6-DOF arms with three sensed joints each. The mobility of this mechanism is $M = 6$. As $S = 9$, therefore $C = 3$ and closed-loop calibration is possible.

4 loops: Nahvi et al. [14.22] calibrated a spherical shoulder joint, driven redundantly by four

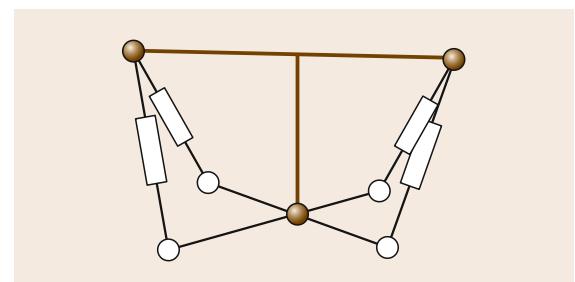

Fig. 14.9 Redundant parallel drive shoulder joint

prismatic legs (Fig. 14.9). In addition, the platform is constrained to rotate about a spherical joint; with the four legs, four kinematic loops are formed. For this system, $M = 3$ and $S = 4$, so that $C = 1$. Hence self-calibration is possible. Without the extra leg and the sensing it provides, one would have $C = 0$ and calibration would not be possible.

5 loops: Wampler et al. [14.2] calibrated the six-legged Stewart platform ($M = 6$) via a closed-loop procedure. In addition to leg length measurements, all angles on one of the legs were measured ($S = 11$). The reason for the extra sensors is to yield a unique forward kinematics solution, but a side benefit is that, with $C = 5$, closed-loop calibration is possible. For a regular Stewart platform without the instrumented leg, $S = 6$ and hence $C = 0$. External pose measurement is required; for example, with full pose measurement $S = 12$ and $C = 6$; full pose measurement was utilized in [14.23].

14.3 Inertial Parameter Estimation

A rigid body i has 10 inertial parameters: mass m_i , center of mass \mathbf{r}_{0i} relative to an origin O_0 , and symmetric inertia matrix $\tilde{\mathbf{I}}_i$ referred here to the origin O_i (Fig. 14.11). The rigid body may be a load held by the end effector, or it can be one of the manipulator's own links. By generating a trajectory and measuring forces or torques in combination with velocity and acceleration, some or all of the inertial parameters can be estimated.

14.3.1 Load Inertial Parameter Estimation

Beginning with load inertial parameter estimation sets the stage for link inertial parameter estimation. It is as-

sumed that there is a wrist-mounted six-axis force/torque sensor, and that suitable filters have been designed to estimate the velocity $\dot{\theta}_i$ and acceleration $\ddot{\theta}_i$ at each joint i . The procedure involves

1. formulating the Newton–Euler equations of the load dynamics to reveal a linear dependence on the inertial parameters, and
2. estimating the parameters using ordinary least squares.

Load Dynamics

Kinematically, the force-torque sensor is part of the last link n , mounted near the joint axis \mathbf{z}_n and origin O_n . The

sensor provides readings relative to its own coordinate system, called $n + 1$ (Fig. 14.10). The remainder of the last link is attached to the shaft of the force-torque sensor, and so the force-torque sensor is measuring the loads on the last link excluding itself. The acceleration of the force-torque sensor reference frame would have to be calculated based on the amount of offset from O_n , but we will ignore that complication here and assume that the sensor origin O_{n+1} is coincident with O_n .

The center of mass of link n is defined as C_n , located relative to the base origin O_0 by $\mathbf{r}_n = C_n - O_0$ and relative to link n 's origin O_n by $\mathbf{c}_n = C_n - O_n$. All vectors and matrices are expressed in coordinate system n , in which the center of mass location \mathbf{c}_n and the inertia matrix $\bar{\mathbf{I}}_n$ about origin O_n are constant. The force-torque sensor measures the spatial force \mathbf{f}_n at O_n in the coordinate system of the sensor, but the readings are presumed to be converted to the link n coordinates.

From (2.33) in Chap. 2, the Newton–Euler equations referred to O_n are

$$\mathbf{f}_n = \mathbf{I}_n \mathbf{a}_n + \mathbf{v}_n \times \mathbf{I}_n \mathbf{v}_n . \quad (14.39)$$

Substituting for the spatial inertia \mathbf{I}_n , the spatial acceleration \mathbf{a}_n , and the spatial velocity \mathbf{v}_n , the first term on the right evaluates to:

$$\begin{aligned} \mathbf{I}_n \mathbf{a}_n &= \begin{pmatrix} \bar{\mathbf{I}}_n & m_n \mathbf{S}(\mathbf{c}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^\top & m_n \mathbf{I} \end{pmatrix} \begin{pmatrix} \dot{\mathbf{w}}_n \\ \dot{\mathbf{v}}_n \end{pmatrix} \\ &= \begin{pmatrix} \bar{\mathbf{I}}_n \dot{\mathbf{w}}_n + m_n \mathbf{S}(\mathbf{c}_n)(\ddot{\mathbf{d}}_{0n} - \mathbf{w}_n \times \mathbf{v}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^\top \dot{\mathbf{w}}_n + m_n (\ddot{\mathbf{d}}_{0n} - \mathbf{w}_n \times \mathbf{v}_n) \end{pmatrix}, \end{aligned}$$

where $\dot{\mathbf{v}}_n = \ddot{\mathbf{d}}_{0n} - \mathbf{w}_n \times \mathbf{v}_n$ has been substituted. The second term on the right evaluates to:

$$\begin{aligned} \mathbf{v}_n \times \mathbf{I}_n \mathbf{v}_n &= \begin{pmatrix} \mathbf{S}(\mathbf{w}_n) & \mathbf{S}(\mathbf{v}_n) \\ \mathbf{0} & \mathbf{S}(\mathbf{w}_n) \end{pmatrix} \\ &\quad \times \begin{pmatrix} \bar{\mathbf{I}}_n & m_n \mathbf{S}(\mathbf{c}_n) \\ m_n \mathbf{S}(\mathbf{c}_n)^\top & m_n \mathbf{I} \end{pmatrix} \begin{pmatrix} \mathbf{w}_n \\ \mathbf{v}_n \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{S}(\mathbf{w}_n) \bar{\mathbf{I}}_n \mathbf{w}_n + m_n \mathbf{S}(\mathbf{c}_n) \mathbf{S}(\mathbf{w}_n) \mathbf{v}_n \\ \mathbf{S}(\mathbf{w}_n) m_n \mathbf{S}(\mathbf{c}_n)^\top \mathbf{w}_n + \mathbf{S}(\mathbf{w}_n) m_n \mathbf{v}_n \end{pmatrix}. \end{aligned}$$

Combining and simplifying,

$$\mathbf{f}_n = \begin{pmatrix} \bar{\mathbf{I}}_n \dot{\mathbf{w}}_n + \mathbf{S}(\mathbf{w}_n) \bar{\mathbf{I}}_n \mathbf{w}_n - \mathbf{S}(\ddot{\mathbf{d}}_{0n}) m_n \mathbf{c}_n \\ m_n \ddot{\mathbf{d}}_{0n} + \mathbf{S}(\dot{\mathbf{w}}_n) m_n \mathbf{c}_n + \mathbf{S}(\mathbf{w}_n) \mathbf{S}(\mathbf{w}_n) m_n \mathbf{c}_n \end{pmatrix}, \quad (14.40)$$

where the mass moment $m_n \mathbf{c}_n$ appears as a quantity to be estimated in combination. However, since the mass m_n

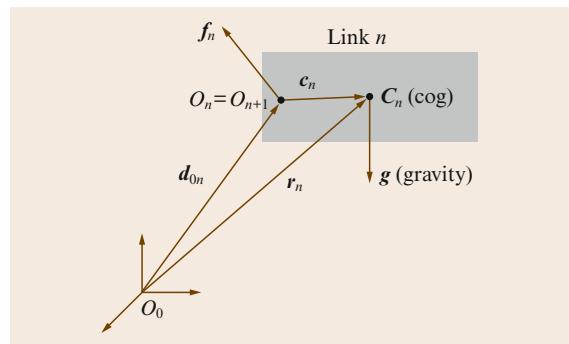

Fig. 14.10 Dynamics of the last link

is separately estimated from the $m_n \ddot{\mathbf{d}}_{0n}$ term, the center of mass \mathbf{c}_n can be extracted. To account explicitly for gravity \mathbf{g} , we substitute $\ddot{\mathbf{d}}_{0n} - \mathbf{g}$ for $\ddot{\mathbf{d}}_{0n}$ subsequently.

To formulate an estimation algorithm, the force and torque measured by the wrist sensor must be expressed in terms of the product of known geometric parameters and the unknown inertial parameters. Elements of the inertia matrix are vectorized as $\mathbf{L}(\bar{\mathbf{I}}_n)$ according to the following notation:

$$\bar{\mathbf{I}}_n \boldsymbol{\omega}_n = \begin{pmatrix} I_{11} & & & & & \\ \omega_1 & \omega_2 & \omega_3 & 0 & 0 & 0 \\ 0 & \omega_1 & 0 & \omega_2 & \omega_3 & 0 \\ 0 & 0 & \omega_1 & 0 & \omega_2 & \omega_3 \end{pmatrix} \begin{pmatrix} I_{12} \\ I_{13} \\ I_{22} \\ I_{23} \\ I_{33} \end{pmatrix} \equiv \mathbf{L}(\boldsymbol{\omega}_n) \mathbf{I}(\bar{\mathbf{I}}_n),$$

where $\mathbf{L}(\boldsymbol{\omega}_n)$ is a 3×6 matrix of angular velocity elements and

$$\bar{\mathbf{I}}_n = \begin{pmatrix} I_{11} & I_{12} & I_{13} \\ I_{12} & I_{22} & I_{23} \\ I_{13} & I_{23} & I_{33} \end{pmatrix}.$$

Using these expressions, (14.40) can be written as:

$$\begin{aligned} \mathbf{f}_n &= \begin{pmatrix} \mathbf{0} & -\mathbf{S}(\ddot{\mathbf{d}}_{0n}) & \mathbf{L}(\dot{\mathbf{w}}_n) + \mathbf{S}(\boldsymbol{\omega}_n) \mathbf{L}(\boldsymbol{\omega}_n) \\ \ddot{\mathbf{d}}_{0n} & \mathbf{S}(\dot{\mathbf{w}}_n) + \mathbf{S}(\boldsymbol{\omega}_n) \mathbf{S}(\boldsymbol{\omega}_n) & \mathbf{0} \end{pmatrix} \\ &\quad \times \begin{pmatrix} m_n \\ m_n \mathbf{c}_n \\ \mathbf{L}(\bar{\mathbf{I}}_n) \end{pmatrix} \end{aligned}$$

or more compactly,

$$\mathbf{f}_n = \mathbf{A}_n \boldsymbol{\phi}_n, \quad (14.41)$$

where A_n is a 6×10 matrix, and ϕ_n is the vector of the 10 unknown inertial parameters which appear linearly.

Estimating the Parameters

The quantities inside the A_n matrix are computed by direct kinematics computation from the measured joint angles, and from the estimated joint velocities and accelerations. The estimation is typically done by bandpass filtering of the joint angle data [14.24]. The elements of the f_n vector are measured directly by the wrist force sensor. For robust estimates in the presence of noise, a larger number of data points are obtained by moving the manipulator through a suitable trajectory. Augment f_n and A_n as:

$$A = \begin{pmatrix} A_n^1 \\ \vdots \\ A_n^P \end{pmatrix}, \quad f = \begin{pmatrix} f_n^1 \\ \vdots \\ f_n^P \end{pmatrix}, \quad (14.42)$$

where P is the number of data points. The least-squares estimate for ϕ is given by

$$\hat{\phi} = (A^\top A)^{-1} A^\top f. \quad (14.43)$$

Equation (14.43) can also be formulated in a recursive form for online estimation.

For object recognition, it may be desired to derive the inertia about the center of mass, which can be done with the parallel axis theorem. An eigenvalue analysis can diagonalize the inertia matrix to reveal the principal axes and inertia.

14.3.2 Link Inertial Parameter Estimation

By treating each link i of a manipulator as a load, the previous formulation can be extended to the link estimation problem. Unlike load estimation, the only sensing is one component of joint torque. This lack of full force/torque sensing, along with the restricted movement near the base, makes it impossible to find all the inertial parameters of the proximal links. The missing parameters are unimportant, since they have no effect on the control of the arm.

For geared electric drives, joint torque may either be measured by joint torque sensors (Sect. 19.2.4) or estimated from the motor current by using an electric motor model (Sect. 6.3). Most robots do not have joint torque sensors, in which case joint friction needs to be taken into account. Joint friction typically consumes a large fraction of the torque that the motor produces. Coulomb and viscous friction are the most important components of a friction model, although Stribeck friction may need to

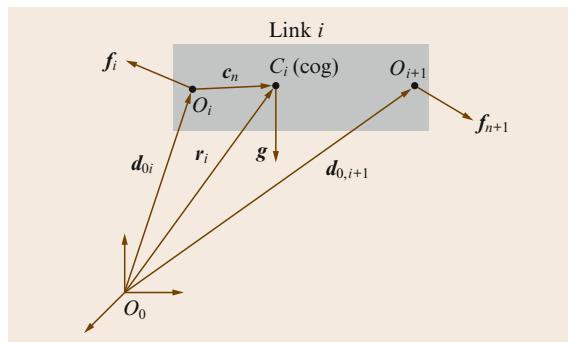

Fig. 14.11 Location of the center of gravity for an intermediate link i , and the constraint forces and torques

be modeled for low joint velocities [14.25, 26]. A friction model is estimated through a process of moving one joint at a time, and relating motor torque to velocity. Ripple torque, due either to uncompensated inhomogeneities of the magnetic field in the motor [14.27, 28], or to positional dependencies of gear tooth interaction [14.25], may need to be modeled.

Consider a manipulator with n joints (Fig. 14.11). (Only manipulators with revolute joints will be considered, since handling prismatic joints requires only trivial modifications to the algorithm.) Define f_{ij} as the spatial force at joint i due to movement of link j alone. Then f_{ii} is the spatial force at joint i due to movement of its own link, and is the same as (14.41) with i substituted for n in the A_n matrix

$${}^i f_{ii} = {}^i A_i \phi_i, \quad (14.44)$$

where ϕ_i is the vector of unknown link i inertial parameters. Superscript i has been added to indicate that vectors are expressed in terms of link i coordinates, so that the center of mass ${}^i c_i$ and the inertia matrix ${}^i I_i$ are constant.

The total spatial force ${}^i f_i$ at joint i is the sum of the spatial forces ${}^i f_{ij}$ for all links j distal to joint i :

$${}^i f_i = \sum_{j=i}^n {}^i f_{ij}. \quad (14.45)$$

Each spatial force ${}^i f_{ij}$ at joint i is determined by transmitting the distal spatial force ${}^j f_{jj}$ across intermediate joints. Using the spatial force transform matrix ${}^i X_j^F$,

$${}^i f_{i+1} = {}^i X_{i+1}^F {}^{i+1} f_{i+1, i+1} = {}^i X_{i+1}^F {}^{i+1} A_{i+1} \phi_{i+1}. \quad (14.46)$$

For convenience, we note that ${}^i X_i^F = I_{6 \times 6}$. To obtain the forces and torques at the i -th joint due to the movements

of the j -th link, these matrices can be cascaded:

$$\begin{aligned} {}^i f_{ij} &= {}^i \mathbf{X}_{i+1}^F {}^{i+1} \mathbf{X}_{i+2}^F \cdots {}^{j-1} \mathbf{X}_j^F {}^j f_{jj} \\ &= {}^i \mathbf{X}_j^F \mathbf{A}_j \boldsymbol{\phi}_j. \end{aligned} \quad (14.47)$$

An upper-diagonal matrix expression for a serial kinematic chain can be derived from (14.45) and (14.47):

$$\begin{aligned} &\begin{pmatrix} {}^1 f_1 \\ {}^2 f_2 \\ \vdots \\ {}^n f_n \end{pmatrix} \\ &= \begin{pmatrix} {}^1 \mathbf{X}_1^F \mathbf{A}_1 & {}^1 \mathbf{X}_2^F \mathbf{A}_2 & \cdots & {}^1 \mathbf{X}_n^F \mathbf{A}_n \\ \mathbf{0} & {}^2 \mathbf{X}_2^F \mathbf{A}_2 & \cdots & {}^2 \mathbf{X}_n^F \mathbf{A}_n \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & {}^n \mathbf{X}_n^F \mathbf{A}_n \end{pmatrix} \begin{pmatrix} \boldsymbol{\phi}_1 \\ \boldsymbol{\phi}_2 \\ \vdots \\ \boldsymbol{\phi}_n \end{pmatrix}. \end{aligned} \quad (14.48)$$

This equation is linear in the unknown parameters, but the left-hand side is composed of a full force-torque vector at each joint. Since only the torque τ_i about the joint rotation axis z_i can usually be measured, each spatial force ${}^i f_i$ must be projected onto the joint rotation axis, reducing (14.48) to

$$\boldsymbol{\tau} = \mathbf{K} \boldsymbol{\phi}, \quad (14.49)$$

where

$$\begin{aligned} \tau_i &= \begin{pmatrix} z_i \\ \mathbf{0} \end{pmatrix} \cdot f_i, \\ \mathbf{K}_{ij} &= \begin{pmatrix} z_i \\ \mathbf{0} \end{pmatrix} \cdot {}^i \mathbf{X}_j^F \mathbf{A}_j, \quad \boldsymbol{\phi} = \begin{pmatrix} \boldsymbol{\phi}_1 \\ \vdots \\ \boldsymbol{\phi}_n \end{pmatrix} \end{aligned}$$

and $\mathbf{K}_{ij} = \mathbf{0}_{1 \times 10}$ if $i > j$. For an n -link manipulator, $\boldsymbol{\tau}$ is an $n \times 1$ vector, $\boldsymbol{\phi}$ is a $10n \times 1$ vector, and \mathbf{K} is an $n \times 10n$ matrix.

Equation (14.49) represents the dynamics of the manipulator for one sample point. As with load identification, (14.49) is augmented using P data points:

$$\mathbf{K} = \begin{pmatrix} \mathbf{K}^1 \\ \vdots \\ \mathbf{K}^P \end{pmatrix}, \quad \boldsymbol{\tau} = \begin{pmatrix} \boldsymbol{\tau}^1 \\ \vdots \\ \boldsymbol{\tau}^P \end{pmatrix},$$

where $\boldsymbol{\tau}$ is now an $nP \times 1$ vector and \mathbf{K} is now $nP \times 10n$.

Unfortunately, one cannot apply simple least-squares estimation because $\mathbf{K}^\top \mathbf{K}$ is not invertible due to the loss of rank from restricted degrees of freedom at the

proximal links and the lack of full force-torque sensing. Some inertial parameters are completely unidentifiable, while some others can only be identified in linear combinations. The general topic of identifiability of parameters, and how to handle unidentifiable parameters, is discussed next.

An issue with geared electric drives is the rotor inertia. If not known, the rotor inertia can be added to the list of 10 inertial parameters to be identified for a link [14.29]. For large gear ratios, the rotor inertia can dominate the other components of link inertia.

14.3.3 Link Parameter Estimation for More Complex Structures

In this section we present the dynamic identification model for kinematic tree (spanning tree) robots and kinematic closed-loop robots including parallel robots. These models are linear in the inertial parameters and can be represented by a model similar to (14.49), thus these parameters can be identified using the same techniques.

Tree-Structured Robots

For an n -link manipulator with a kinematic tree structure, the dynamic identification model equations (14.48) must be modified to take into account that the inertial parameters of link j have no effect on the dynamics of links which do not belong to the chain from the base to that link. For such structures, the link on which link j is articulated is denoted by $p(j)$ (parent of j – see Chap. 2). It could be a link with any number i , such that $i < j$. Thus the nonzero elements of the column of the matrix representing the coefficients of the inertial parameters of link j in (14.48) would be:

$${}^j \mathbf{X}_j^F \mathbf{A}_j, {}^{p(j)} \mathbf{X}_j^F \mathbf{A}_j, {}^{p(p(j))} \mathbf{X}_j^F \mathbf{A}_j, \dots, {}^b \mathbf{X}_j^F \mathbf{A}_j, \quad (14.50)$$

where b is the first link of the chain connecting link 0 to link j , thus $p(b) = 0$.

Consequently, in (14.49) of a tree robot we obtain: $\mathbf{K}_{ij} = \mathbf{0}_{1 \times 10}$ if $i > j$ or if link i does not belong to the branch connecting link 0 to link j . This means that some elements of the upper-right submatrix of \mathbf{K} will be zero.

We note that a serial structure is a particular case of a tree structure where $p(j) = j - 1$. Thus any link m such that $m < j$ will belong to the chain from the base to link j .

Closed-Loop Robots

The dynamic model of a closed-loop structure can be obtained by considering first an equivalent spanning tree

by opening one joint at each closed loop, and then using the principle of virtual work such that:

$$\boldsymbol{\tau} = \mathbf{G}^\top \mathbf{K}_{\text{tr}} \boldsymbol{\phi}, \quad \mathbf{G} = \left(\frac{\partial \mathbf{q}_{\text{tr}}}{\partial \mathbf{q}_a} \right) \quad (14.51)$$

with \mathbf{q}_a an $N \times 1$ vector of N active joint angles (N differs from n , the total number of joints), and \mathbf{q}_{tr} an $n \times 1$ vector of the joints of the spanning tree structure.

Parallel Robots

A parallel robot is a particular case of closed-loop robots (Chap. 12). It is composed of a moving platform, representing the terminal link, that is connected to the base by m parallel legs. The dynamic model of parallel robots can be given by [14.30]

$$\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{A}_p \boldsymbol{\phi}_p + \sum_{i=1}^m \left(\frac{\partial \mathbf{q}_i}{\partial \mathbf{q}_a} \right)^\top \mathbf{K}_i \boldsymbol{\phi}_i, \quad (14.52)$$

where $\mathbf{K}_i \boldsymbol{\phi}_i$ represents the dynamic model of leg i with \mathbf{K}_i a function of $(\mathbf{q}_i, \dot{\mathbf{q}}_i, \ddot{\mathbf{q}}_i)$, \mathbf{q}_i is the vector of joint angles of leg i , $\mathbf{A}_p \boldsymbol{\phi}_p$ is the Newton–Euler spatial force of the platform calculated in terms of the Cartesian variables of the mobile platform using (14.41), and \mathbf{J} is the Jacobian matrix of the parallel manipulator. We can obtain (14.52) from (14.51) by supposing that the span-

ning tree structure is obtained by separating the mobile platform from the legs.

Equation (14.52) can be rewritten as

$$\begin{aligned} \boldsymbol{\tau} &= \left(\mathbf{J}^\top \mathbf{A}_p \left(\frac{\partial \mathbf{q}_1}{\partial \mathbf{q}_a} \right)^\top \mathbf{K}_1 \cdots \left(\frac{\partial \mathbf{q}_m}{\partial \mathbf{q}_a} \right)^\top \mathbf{K}_m \right) \boldsymbol{\phi}_{\text{par}} \\ &= \mathbf{K}_{\text{par}}(\boldsymbol{\omega}_p, \dot{\mathbf{v}}_p, \dot{\boldsymbol{\omega}}_p, \mathbf{q}_i, \dot{\mathbf{q}}_i, \ddot{\mathbf{q}}_i) \boldsymbol{\phi}_{\text{par}}, \end{aligned} \quad (14.53)$$

where $\boldsymbol{\phi}_{\text{par}}$ is the vector of the inertial parameters of the robot (the legs and the platform).

$$\boldsymbol{\phi}_{\text{par}} = \begin{pmatrix} \boldsymbol{\phi}_p \\ \boldsymbol{\phi}_1 \\ \vdots \\ \boldsymbol{\phi}_m \end{pmatrix}.$$

In the common case where the legs are identical and their inertial parameters are denoted by $\boldsymbol{\phi}_{\text{leg}}$, the identification model can be rewritten by the following equation, which considerably reduces the number of inertial parameters to be identified:

$$\boldsymbol{\tau} = \left(\mathbf{J}^\top \mathbf{A}_p \sum_{i=1}^m \left(\frac{\partial \mathbf{q}_i}{\partial \mathbf{q}_a} \right)^\top \mathbf{K}_i \right) \begin{pmatrix} \boldsymbol{\phi}_p \\ \boldsymbol{\phi}_{\text{leg}} \end{pmatrix}. \quad (14.54)$$

The identification of the orthoglide parallel robot is given in [14.31].

14.4 Identifiability and Numerical Conditioning

That some inertial parameters in (14.49) are unidentifiable does not mean that they are intrinsically identifiable, only that the experimental setup does not allow them to be identified. Limited motion near the base could be fixed by placing the whole manipulator on a six-axis moving platform such as a Stewart–Gough platform. In fact, for mobile manipulators mounted on high-mobility vehicles such as satellites, it may be necessary to know the full inertial model of the manipulator. Additional sensors could be added, for example a six-axis force-torque sensor to the base of the robot [14.5], to identify some additional (but not all) inertial parameters.

A similar situation may arise in kinematic calibration, where for example joint models might be augmented to include gear eccentricities, transmission and coupling coefficients of gears, joint elasticity, link elasticity, and base deflection [14.32]. By instrumenting the robot with additional sensors, for example, by placing joint angle sensors before and after the gears

to measure joint deflection, it may be possible to identify additional parameters of interest. Additional sensing with a theodolite was done to measure base deflection in [14.12].

Given that the experimental setup is what it is, there may be no recourse but to deal with unidentifiable parameters, treated in the next section. Another problem is that parameters might in principle be identifiable, but numerical conditioning prevents their accurate determination. Issues such as adequacy of the collected data, and the effect of different units and magnitudes of parameters, are treated subsequently.

14.4.1 Identifiability

There are two main approaches towards handling unidentifiable parameters, depending on whether the goal is a structural model or a prediction model. For a structural model, the goal is to find the minimum

parameter set that provides a meaningful physical description of the system by eliminating parameters until all are identifiable. This is done by careful evaluation of the effect of each parameter of the original model.

For a prediction model, the goal is to match the outputs to the inputs as closely as possible, and is more of a curve-fitting approach. The resulting parameter values are not necessarily physically meaningful or accurate.

Structural Model

It may be possible in the initial model formation to avoid including redundant or unidentifiable parameters. At other times, it is not possible to determine a priori what the minimal parameter set is, because of system complexity or because of numerical difficulties such as measurement error or limitations in the collected data.

A Priori Parameter Elimination. In the initial model formation, the choice of representation can immediately dictate whether the model is redundant or minimal. For kinematic calibration, the minimal parameter set includes four parameters for a rotary joint and two parameters for a prismatic joint. The detailed presentation in Sect. 14.2.1 of how to set up the DH/Hayati parameters for different kinematic and sensing arrangements has the advantage that the parameter set is minimal (excepting joint models). Once done, the application to any manipulator is somewhat formulaic.

Five- and six-parameter joint models have also been proposed, either for the convenience of locating link coordinate systems or for the ease of model formation [14.13, 29, 33]. With such redundant parameter sets, extra steps must be taken to handle the numerical difficulties caused by the redundancy, such as by reducing the number of parameters in a postprocessing step. When there are complicated joint models that include gearing effects as mentioned above, the resultant large numbers of parameters make the parameter elimination problem more difficult. Determining the minimal set of inertial parameters offers a different sort of complexity, because large numbers of parameters are not identifiable or are identifiable only in linear combinations. Again, model reduction is one approach to handle this problem.

Two approaches towards determining a minimal or base parameter set are

1. numerical identification of the unidentifiable parameters or linear combinations of parameters
2. symbolic determination

Numerical identification involves rank reduction through matrix manipulation of the regressor, either

through QR decomposition or singular value decomposition [14.4]. If the kinematic or dynamic model is known exactly, then a simulation using exactly generated *data* will yield a noise-free regressor matrix \mathbf{A} in (14.3). For QR decomposition, the regressor matrix is factored as:

$$\mathbf{A} = \mathbf{Q} \begin{pmatrix} \mathbf{R} \\ \mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}} \end{pmatrix}, \quad (14.55)$$

where \mathbf{Q} is an $M \times MP$ orthogonal matrix, \mathbf{R} is an $N_{\text{par}} \times N_{\text{par}}$ upper-triangular matrix, and $\mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}}$ is the zero matrix with dimensions $MP - N_{\text{par}} \times N_{\text{par}}$. Theoretically, the unidentifiable parameters ϕ_i are those whose corresponding diagonal elements R_{ii} of matrix \mathbf{R} are zero. In practice, $|R_{ii}|$ is considered to be zero if it is less than the numerical zero ζ :

$$\zeta = MP\epsilon \max_i |R_{ii}|, \quad (14.56)$$

where ϵ is the computer precision [14.34]. Other parameters may appear in linear combinations depending on how many nonzero elements there are in row j of \mathbf{R} . Resolving these linear combinations is arbitrary. One approach is to zero all elements in the linear combination save one. The result is a prediction model rather than a structural model.

Symbolic determination of the base inertial parameters has been proposed in [14.35, 36]. Using an energy formulation, the total energy of link j is expressed as $\mathbf{h}_j \phi_j$, where \mathbf{h}_j is a row vector termed the total energy function whose elements are kinematic expressions of the angular and linear velocity of link j plus gravity. A recursive relation between neighboring links is developed as

$$\mathbf{h}_j = \mathbf{h}_{j-1}^{j-1} \lambda_j + \dot{q}_j \boldsymbol{\eta}_j, \quad (14.57)$$

where the elements of the 10×10 matrix ${}^{j-1}\lambda_j$ are functions of the DH parameters defining frame j , and the elements of the 1×10 row vector $\boldsymbol{\eta}_j$ depend on the linear and angular velocities. The details of these expressions can be found in [14.35, 36]. Grouping rules are then developed to find the precise linear combinations of parameters.

The minimum inertial parameters for a tree structure can be obtained using a closed-form solution similar to the serial structure case [14.36].

The term $\mathbf{K}_{\text{tr}} \boldsymbol{\phi}$ in (14.51) shows that the minimum parameters of the spanning tree structure can be used to calculate the dynamics of the closed structure, giving by this a first reduction and grouping of the inertial parameters. However extra parameters can be eliminated

or grouped when considering the matrix \mathbf{G} . The case of parallelogram loops can be treated symbolically using closed-form relations [14.36]. For general closed loops, the minimum parameters must be determined using numerical methods such as QR decomposition.

In the case of parallel robots, we deduce from (14.52) that the minimum parameters of the legs can be used to calculate $\mathbf{K}_l \boldsymbol{\phi}_l$, giving a first reduction of the inertial parameters. However, some other parameters can be grouped with the parameters of the platform. The minimum parameters of the Gough–Stewart robot are given in [14.37].

Data-Driven Parameter Elimination. The singular value decomposition of the regressor matrix can show which parameters are unidentifiable, weakly identifiable, or identifiable only in linear combination. For N_{par} parameters, P data points, and M -dimensional output measurements at each data point, the regressor matrix \mathbf{A} (14.3) or (14.7) can be decomposed as

$$\mathbf{A} = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^\top, \quad (14.58)$$

where \mathbf{U} is an $MP \times MP$ orthogonal matrix, \mathbf{V} is an $N_{\text{par}} \times N_{\text{par}}$ orthogonal matrix, and $\boldsymbol{\Sigma}$ is the $MP \times N_{\text{par}}$ matrix of singular values

$$\boldsymbol{\Sigma} = \begin{pmatrix} \mathbf{S} \\ \mathbf{0}_{MP-N_{\text{par}}, N_{\text{par}}} \end{pmatrix}, \quad (14.59)$$

where $\mathbf{S} = \text{diag}(\mu_1, \dots, \mu_r, 0, \dots, 0)$ is the $N_{\text{par}} \times N_{\text{par}}$ matrix of ordered singular values, with μ_1 the largest and μ_r the smallest nonzero singular value. There may be $N_{\text{par}} - r$ zero singular values $\mu_{r+1} = \dots = \mu_{N_{\text{par}}} = 0$.

Especially when complex joint models are assumed that include flexibility, backlash, and gear eccentricity, it is not clear that all parameters can be identified. Retaining poorly identifiable parameters will degrade the robustness of the calibration; such parameters are indicated by zero or very small singular values. The expansion of (14.7) in terms of (14.58) is:

$$\Delta \mathbf{y} = \sum_{j=1}^r \mu_j (\mathbf{v}_j^\top \Delta \boldsymbol{\phi}) \mathbf{u}_j, \quad (14.60)$$

where \mathbf{u}_j and \mathbf{v}_j are the j -th columns of \mathbf{U} and \mathbf{V} . For zero or small singular values μ_j , the projection $\mathbf{v}_j^\top \Delta \boldsymbol{\phi}$ of the parameters onto the column vector \mathbf{v}_j in general represents a linear combination of parameters. It is also possible that only a single parameter results from the projection.

To proceed, it is first necessary to scale the parameters and the output measurements so that the

singular values are comparable. Scaling is discussed in Sect. 14.4.3. Small singular values signal that there are parameters that are poorly identifiable and that should be eliminated. By small singular values, Schröer [14.32] suggests the heuristic that the *condition number* of a well-conditioned regressor matrix should be less than 100:

$$\kappa(\mathbf{A}) = \frac{\mu_1}{\mu_r} < 100. \quad (14.61)$$

This heuristic derives from experience of their statistical community. If the condition number is above 100, the singular values are examined, beginning with the smallest one, which may be a zero singular value.

If the condition number is above 100, the linear sums (14.60) corresponding to the smallest singular value μ_r are examined. The elements of column \mathbf{v}_r are in one-to-one correspondence with the elements of $\Delta \boldsymbol{\phi}$. If there is an element j of \mathbf{v}_r that is much larger than the others, then the parameter ϕ_j corresponding to that column element is a candidate for elimination. This procedure will tend to pinpoint parameters that are totally unidentifiable. Isolating the largest element of \mathbf{v}_r is once again meaningful if the parameters have been previously scaled.

Once the parameter is eliminated, the condition number of the reduced regressor is computed again. The procedure iterates until the condition number of the regressor is below 100.

The previous procedure can be carried out using QR decomposition as in (14.55), by replacing ϵ representing the computer precision in (14.56) by a greater value function of the noise level.

Prediction Model

If there are several largest elements of \mathbf{v}_r that are roughly comparable in magnitude, then these parameters may only be identifiable in linear combination. There will be the same number of singular values which are too small. By examining several columns \mathbf{v}_j corresponding to the small singular values, these linear combinations can become apparent. The linear combinations can be resolved arbitrarily, i.e., all parameter elements in the linear combination save one can be set to zero. The result of zeroing some parameters is that the model is no longer a structural model, but rather a prediction model.

One may also proceed without first removing parameters. It can be shown by substituting the singular value decomposition that

$$(\mathbf{A}^\top \mathbf{A})^{-1} \mathbf{A}^\top = \mathbf{V} \left(\mathbf{S}^{-1} \mathbf{0}_{N_{\text{par}}, MP-N_{\text{par}}} \right) \mathbf{U}^\top. \quad (14.62)$$

Consequently the solution to (14.8) can be expressed as [14.38]

$$\Delta\phi = \sum_{j=1}^{N_{\text{par}}} \frac{\mathbf{u}_j^\top \Delta\mathbf{y}}{\mu_j} \mathbf{v}_j. \quad (14.63)$$

One can see that poorly identifiable parameters corresponding to small singular values μ_j greatly perturb the estimates, because the weighting is $1/\mu_j$. The strategy is to remove their influence. If μ_j is zero or very small relative to the largest singular value μ_1 , then set $1/\mu_j = 0$.

Parameters that cannot be identified well are simply ignored in this procedure, which automatically converges to an identifiable parameter set. The resulting parameters can then be used for the model. A disadvantage is that the resulting parameters may not correspond to real model parameters.

Incorporating A Priori Parameter Estimates

Least squares treats parameter values as completely unknown, i.e., they could be anywhere in the range from $-\infty$ to $+\infty$. Yet often a fairly good initial estimate of the parameters is available, for example, from a manufacturer's specifications or in the case of a recalibration. It makes sense to incorporate such an a priori preference into the least-squares optimization [14.39].

Suppose there is a preference for a solution near $\phi = \phi_0$. Express the preference as $I\phi = \phi_0$, where I is the identity matrix, and append it as additional rows to (14.3) that reflect this preference

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{I} \end{pmatrix} \phi = \begin{pmatrix} \mathbf{y} \\ \phi_0 \end{pmatrix}. \quad (14.64)$$

To proceed with the solution, we can treat ϕ_0 as a constant. Redefine the parameter vector as $\tilde{\phi} = \phi - \phi_0$, which we expect to be close to zero. Then

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{I} \end{pmatrix} \tilde{\phi} = \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix}, \quad (14.65)$$

where $\tilde{\mathbf{y}} = \mathbf{y} - \mathbf{A}\phi_0$. We may not know ϕ_0 perfectly well, so we add a weighting parameter λ to express the confidence in this value

$$\begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{I} \end{pmatrix} \tilde{\phi} = \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix}. \quad (14.66)$$

The larger is λ , the more confidence we have in our a priori estimate. The least-squares solution is therefore

$$\begin{aligned} \tilde{\phi} &= \left((\mathbf{A}^\top \lambda \mathbf{I}) \begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{I} \end{pmatrix} \right)^{-1} (\mathbf{A}^\top \lambda \mathbf{I})^\top \begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{0} \end{pmatrix} \\ &= (\mathbf{A}^\top \mathbf{A} + \lambda^2 \mathbf{I})^{-1} \mathbf{A}^\top \tilde{\mathbf{y}}. \end{aligned} \quad (14.67)$$

This solution is called *damped least squares*, where λ is the damping factor. Expanding this solution in terms of the singular value decomposition,

$$\tilde{\phi} = \sum_{j=1}^{N_{\text{par}}} (\mathbf{u}_j^\top \tilde{\mathbf{y}}) \frac{\mu_j}{\mu_j^2 + \lambda^2} \mathbf{v}_j. \quad (14.68)$$

Hence a very small μ_j is counteracted by the larger λ value; then the a priori information about parameter values dominates the information from the data, i.e., the data are ignored. Thus for damped least squares, no explicit action on the singular values is required, because the damping factor modifies the singular values. The solution will be perturbed over the normal least-squares solution by the magnitude of the λ choice.

Confidence Measure of Parameter Estimates

After calibration, an estimate $\hat{\mathbf{M}}$ of the covariance of the parameter estimates can be derived from the data [14.3]. Assume that the task variables $\Delta\mathbf{y}$ have previously been scaled for equal uncertainty, that there is no bias, and that the errors are uncorrelated. Then

$$\hat{\mathbf{M}} = \sigma^2 (\mathbf{A}^\top \mathbf{A})^{-1}. \quad (14.69)$$

An estimate of the standard deviation σ after running the calibration procedure is obtained from the χ^2 statistic [14.38, 40]:

$$\chi^2 = (\Delta\mathbf{y} - \mathbf{A}\Delta\hat{\phi})^\top (\Delta\mathbf{y} - \mathbf{A}\Delta\hat{\phi}). \quad (14.70)$$

An unbiased estimator for σ^2 is $\hat{\sigma}^2 = \chi^2/v$, where $v = MP - N_{\text{par}}$ is called the statistical *degrees of freedom*; v subtracts from the total number of measurements MP the number N_{par} of parameters estimated, since some of the measurements went into determining ϕ .

The estimate $\hat{\mathbf{M}}$ can be used as a basis for eliminating parameters, by choosing those with the largest variances.

14.4.2 Observability

The measurements that are taken will influence the accuracy of parameter estimation. In kinematic calibration, the quality of the pose set has been measured by an *observability index*. In inertial parameter estimation, the

quality of the identification trajectory has been termed *persistent excitation* [14.41]. Regardless of whether data is collected statically as in kinematic calibration or dynamically as in inertial parameter estimation, the result is just a bunch of numbers that go into the regressor matrix, and so common terminology is appropriate.

In statistics, optimal experimental design theory has given rise to several data measures termed *alphabet optimality* [14.42]. Some of the most prominent are the following.

| | |
|--------------|---------------------------------------------------------------------------------------------------------------|
| A-optimality | minimizes the trace of $(A^\top A)^{-1}$ to obtain regression designs. |
| D-optimality | maximizes the determinant of $(A^\top A)^{-1}$. |
| E-optimality | maximizes the minimum singular value of $(A^\top A)^{-1}$. |
| G-optimality | minimizes the maximum prediction variance, and does not have a simple expression in terms of singular values. |

Although ties to the experimental design literature have not typically been made [14.43], several of the proposed observability indexes for robot calibration have an alphabet-optimality counterpart. A-optimality does not have a counterpart in the robot calibration literature, and conversely a few proposed observability indexes do not have an alphabet-optimality counterpart. In [14.43], it is proved that E-optimality and G-optimality are equivalent for exact design.

Born and Menq [14.44, 45] proposed an observability index (here termed O_1 and numbered consecutively below) that maximizes the product of all of the singular values

$$O_1 = \frac{\sqrt{\mu_1 \cdots \mu_r}}{\sqrt{P}}. \quad (14.71)$$

This is similar to D-optimality. The rationale is that O_1 represents the volume of a hyperellipsoid in Δy , defined by (14.7) when $\Delta\phi$ defines a hypersphere, and the singular values represent the lengths of axes. Therefore maximizing O_1 gives the largest hyperellipsoid volume, and hence a good aggregate increase of the singular values. One can also derive O_1 from the well-known relation $\sqrt{\det(A^\top A)} = \mu_1 \cdots \mu_r$.

Minimizing the condition number of A as a measure of observability has been proposed in [14.35, 46, 47]:

$$O_2 = \frac{\mu_1}{\mu_r}. \quad (14.72)$$

O_2 measures the eccentricity of the hyperellipsoid rather than its size. The intermediate singular values are not

considered to be that pertinent, because minimizing the condition number automatically makes all singular values become more similar in magnitude and makes the hyperellipsoid closer to a hypersphere.

Nahvi et al. [14.22] argue for maximizing the minimum singular value μ_r as an observability measure:

$$O_3 = \mu_r. \quad (14.73)$$

This is similar to E-optimality. The rationale is to make the shortest axis as long as possible, regardless of the other axes, that is to say, to improve the worst case. Consider the following standard result [14.4]

$$\mu_r \leq \frac{\|\Delta y\|}{\|\Delta\phi\|} \leq \mu_1 \quad (14.74)$$

or more particularly

$$\mu_r \|\Delta\phi\| \leq \|\Delta y\|. \quad (14.75)$$

Then maximizing μ_r ensures that a given size of parameter errors $\|\Delta\phi\|$ has the largest possible influence on the pose errors $\|\Delta y\|$.

Nahvi and Hollerbach [14.48] proposed the noise amplification index O_4 , which can be viewed as combining the condition number O_2 with the minimum singular value O_3 :

$$O_4 = \frac{\sigma_r^2}{\sigma_1}. \quad (14.76)$$

The rationale is to measure both the eccentricity of the ellipse through O_2 as well as the size of the ellipse through O_3 . The noise amplification index was argued to be the most sensitive to measurement error and modeling error.

Hollerbach and Lokhorst [14.21] found experimentally that the condition number and the minimum singular value gave about the same good result: their relative magnitudes were almost proportional to the root-mean-square (RMS) errors of the final parameter errors. The observability index O_1 was not as sensitive and not directly related to parameter errors. [14.43] derived general relations among the observability indexes and alphabet optimality

$$O_1 \geq \text{A-optimality} \geq O_3. \quad (14.77)$$

They further showed that if $\mu_1 \geq 1$, then $O_3 \geq O_2$, and if $\mu_r \leq 1$, then $O_2 \geq O_4$. They also argued that O_3 (D-optimality) is in general the best index, because it minimizes the variance of the parameters and also minimizes the uncertainty of the end-effector pose.

Optimal Experimental Design

An observability index is typically used to decide how many data points to collect. As one begins to add data points, the observability increases, then plateaus. Adding additional data does not then improve the quality of the estimates. For kinematic calibration, data may be added through random selection, or optimal design methods can be employed that can drastically reduce the amount of data required [14.49, 50]. Optimal experimental designs work by measuring the effect of adding or exchanging data points [14.51].

Exciting Trajectories

For inertial parameter estimation, data points are not independent because they result from a trajectory rather than isolated poses. Therefore the issue is what type of trajectory to generate. Industrial robots usually have joint position point-to-point trajectory generators. A continuous and smooth trajectory is calculated by interpolating between these points, assuming zero initial and final velocity and acceleration at each point, and using polynomial interpolators. Excitation trajectories are obtained by minimizing an observability index, using nonlinear optimization techniques to calculate the polynomial coefficients, under the constraints of the joint positions, velocities, and accelerations limits [14.46].

It is possible to facilitate the optimization by proceeding to a sequential excitation procedure. Specific trajectories, which structurally excite a small number of parameters, are easier to optimize. For example, moving one joint at a time with constant velocities excites friction and gravity parameters. In this approach, sequential identification is avoided. However, it is better to collect all the data and to proceed to a globally weighted least-squares estimation [14.24]. This procedure avoids the accumulation of estimation errors and allows the calculation of the confidence intervals [14.69].

Specific trajectories have been proposed like sinusoidal interpolators [14.52], or periodic trajectories obtained from a spectral analysis of the contribution function of the parameters [14.53]. This is a general planning trajectory strategy, which is very important to get accurate experimental identification [14.54].

14.4.3 Scaling

The numerical conditioning of parameter estimation can be improved by scaling both the output measurements (task variable scaling) and the parameters.

Task Variable Scaling

When performing a least-squares analysis on the endpoint pose error, position errors and orientation errors have to be combined (14.22):

$$\|\Delta \mathbf{y}^i\|^2 = \|\Delta^{-1} \mathbf{p}_{n+1}^l\|^2 + \|\Delta^{-1} \boldsymbol{\rho}_{n+1}^l\|^2. \quad (14.78)$$

However, position error and orientation error have different units, and so are not comparable. Furthermore, not all position or orientation components may be measured with equal accuracy.

Ordinary least squares (14.8) weighs all task variables equally. To weigh these variables differently, the general solution is left multiplication of (14.7) by a scaling matrix \mathbf{G} [14.39],

$$\begin{aligned} \mathbf{G}\Delta\mathbf{y} &= \mathbf{G}\mathbf{A}\Delta\phi, \\ \Delta\tilde{\mathbf{y}} &\equiv \tilde{\mathbf{A}}\Delta\phi, \end{aligned} \quad (14.79)$$

where $\Delta\tilde{\mathbf{y}} = \mathbf{G}\Delta\mathbf{y}$ is the scaled output vector and $\tilde{\mathbf{A}} = \mathbf{G}\mathbf{A}$ is the scaled regressor matrix. The weighted least-squares solution is

$$\Delta\phi = (\tilde{\mathbf{A}}^\top \tilde{\mathbf{A}})^{-1} \tilde{\mathbf{A}}^\top \Delta\tilde{\mathbf{y}} = (\mathbf{A}^\top \mathbf{W}\mathbf{A})^{-1} \mathbf{A}^\top \mathbf{W}\Delta\mathbf{y}, \quad (14.80)$$

where $\mathbf{W} = \mathbf{G}^\top \mathbf{G}$. Often \mathbf{W} is a diagonal matrix.

One approach to scaling position error versus orientation error is to equalize the effect of a parameter error $\Delta\phi_i$ on either position error or orientation error. Curiously, for human-sized robot arms the effect is equal without scaling due to an accident of metric units. If θ is the joint angle resolution, then $s = r\theta$ is the resulting endpoint position resolution. For human-sized arms, $r = 1$ m and hence $s = \theta$. Thus meters and radians are directly comparable after all. Thus using no scaling factors for the pose parameters makes some sense, and may explain why the general disregard for scaling in the robotics community has not had more consequences. If linkages are much smaller (like fingers) or much larger (like excavators) then the situation is different.

A more general way of choosing the weighting matrix \mathbf{W} is to use a priori information about acceptable relative errors. Such information might arise from specifications of the measurement apparatus. Suppose that the output variables are subject to independent Gaussian noise, such that σ_j^y is the standard deviation in task variable measurement component Δy_j^i , for $j = 1, \dots, m$ pose components. Then the individual diagonal weights are $w_{jj} = 1/\sigma_j^y$, and define

$$\mathbf{R}^i = \text{diag}[(\sigma_1^y)^2, \dots, (\sigma_m^y)^2],$$

$$\mathbf{R} = \text{diag}(\mathbf{R}^1, \dots, \mathbf{R}^P),$$

where the weighting matrix $\mathbf{W} = \mathbf{R}^{-1}$, and \mathbf{R} is called the *covariance matrix*.

The weighted least-squares estimate is

$$\Delta\boldsymbol{\phi} = (\mathbf{A}^\top \mathbf{R}^{-1} \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{R}^{-1} \Delta\mathbf{y}. \quad (14.81)$$

The resulting scaled output variable $\Delta\tilde{y}_j^l = \Delta y_j^l / \sigma_j^y$ is dimensionless. The larger the uncertainty σ_j^y , the less this variable influences the least-squares solution relative to other variables. The standard deviations σ_j^y are not necessarily the same as endpoint measurement accuracy, because model errors and input noise also contribute to output errors.

The weighted least-squares solution using standard deviations is variously called the Gauss–Markov estimate, the generalized least-squares estimate, or the best linear unbiased estimator (BLUE) [14.3]. It is the minimum covariance estimate (on the parameter error) of all unbiased estimators. A significant point is that the standard deviations of the scaled components of $\Delta\tilde{y}$ are all about the same size, or the covariance $\hat{\mathbf{R}} = \text{cov}(\Delta\tilde{y}) = \mathbf{I}$, the identity matrix. Hence the Euclidean norm of the error vector $\Delta\tilde{y}$ is a reasonable measure of its size.

Often we do not know the covariance matrix \mathbf{R} that well. An estimate of the standard deviations after running the calibration procedure is obtained from the χ^2 statistic [14.38, 40]:

$$\chi^2 = (\Delta\mathbf{y} - \mathbf{A}\Delta\boldsymbol{\phi})^\top \mathbf{R}^{-1} (\Delta\mathbf{y} - \mathbf{A}\Delta\boldsymbol{\phi}). \quad (14.82)$$

This equation is the same as the residual error equation (14.79), with substitution for $\mathbf{W} = \mathbf{R}^{-1}$. χ^2 is nothing more than the weighted residuals after calibration. The expected value of χ^2 is

$$E(\chi^2) \equiv \nu = PK - R, \quad (14.83)$$

where E is the expectation operator. That is to say, the unweighted residuals $(\Delta\mathbf{y} - \mathbf{A}\Delta\boldsymbol{\phi})^2$ should, with enough measurements, approximate the true covariance. We may now uniformly scale an initial estimate of \mathbf{R} after a preliminary calibration, based on the value of χ^2 ,

$$\hat{\mathbf{R}} = \frac{\chi^2}{\nu} \mathbf{R}, \quad (14.84)$$

where $\hat{\mathbf{R}}$ is the revised estimate of the covariance matrix.

Parameter Scaling

Scaling of parameters is important for proper convergence in nonlinear optimization and for singular value decomposition. If parameters have vastly different magnitudes, then the singular values are not directly comparable. Also, parameter scaling can improve the

conditioning of the regressor \mathbf{A} and help to avoid invertibility problems.

Whereas left multiplication of \mathbf{A} in (14.79) results in task variable scaling, right multiplication of \mathbf{A} by a weighting matrix \mathbf{H} results in parameter scaling [14.39]:

$$\Delta\mathbf{y} = (\mathbf{A}\mathbf{H})(\mathbf{H}^{-1} \Delta\boldsymbol{\phi}) \equiv \bar{\mathbf{A}} \Delta\tilde{\boldsymbol{\phi}}, \quad (14.85)$$

where the scaled Jacobian and parameters are $\bar{\mathbf{A}} = \mathbf{A}\mathbf{H}$ and $\Delta\tilde{\boldsymbol{\phi}} = \mathbf{H}^{-1} \Delta\boldsymbol{\phi}$. The least-squares solution is not changed by parameter scaling, whereas it is by task variable scaling.

The most common approach towards parameter weighting is column scaling, which does not require a priori statistical information. Define a diagonal matrix $\mathbf{H} = \text{diag}(h_1, \dots, h_{N_{\text{par}}})$ with elements

$$h_j = \begin{cases} \|\mathbf{c}_j\|^{-1} & \text{if } \|\mathbf{c}_j\| \neq 0 \\ 1 & \text{if } \|\mathbf{c}_j\| = 0 \end{cases} \quad (14.86)$$

where \mathbf{a}_j is the j th column of \mathbf{A} . Then (14.85) becomes

$$\Delta\mathbf{y} = \sum_{j=1}^{N_{\text{par}}} \frac{\mathbf{a}_j}{\|\mathbf{a}_j\|} \Delta\phi_j \|\mathbf{a}_j\|. \quad (14.87)$$

Suppose that $\Delta\mathbf{y}$ has been previously normalized; then its length is meaningful. Each $\mathbf{a}_j / \|\mathbf{a}_j\|$ is a unit vector, and hence each scaled parameter $\Delta\phi_j \|\mathbf{a}_j\|$ is about the same size and has the same effect on $\Delta\mathbf{y}$.

Schröer [14.32] identified a problem with column scaling, namely that poor identifiability of parameters can result in very small Euclidean norms, which result in very large scaling factors. This results in strong amplification of uncertainties of \mathbf{A} . Instead, Schröer proposed scaling based on the effect on the anticipated error of the robot (as previously discussed under task variable scaling).

In an ideal case, one would have a priori knowledge of the expected value $\boldsymbol{\phi}_0$ of the parameter vector and the standard deviation $\sigma_j^{\boldsymbol{\phi}}$ of each of the parameter vector components. More generally, the parameter distribution would be described by a covariance matrix \mathbf{M} , but usually this information is not available. Instead, the estimate $\hat{\mathbf{M}}$ of the covariance from (14.69) can be used.

If the output measurement covariance \mathbf{R}^{-1} and parameter error covariance \mathbf{M} are both available, one may define a new least-squares optimization criterion that combines output errors with parameter errors to yield a new χ^2 statistic:

$$\begin{aligned} \chi^2 = & (\Delta\mathbf{y} - \mathbf{A}\Delta\boldsymbol{\phi})^\top \mathbf{R}^{-1} (\Delta\mathbf{y} - \mathbf{A}\Delta\boldsymbol{\phi}) \\ & + \Delta\boldsymbol{\phi}^\top \mathbf{M}^{-1} \Delta\boldsymbol{\phi}. \end{aligned} \quad (14.88)$$

Its solution is the minimum-variance estimate, which unlike (14.81) is biased

$$\Delta\phi = (\mathbf{A}^\top \mathbf{R}^{-1} \mathbf{A} + \mathbf{M}^{-1})^{-1} \mathbf{A}^\top \mathbf{R}^{-1} \Delta y. \quad (14.89)$$

The Kalman filter recursively solves the same problem [14.55, 56]; when the state is nonvarying, there is a constant process, and there is no process

noise [14.13, 57]. The Gauss–Markov estimate is the limiting case when \mathbf{M}^{-1} is zero, i.e., there is no a priori information about the parameters. Again, there is an issue of determining the covariances. As for the Gauss–Markov estimate, the expected value of χ^2 can be used to uniformly scale \mathbf{R} and \mathbf{M} post facto [14.58].

14.5 Conclusions and Further Reading

This chapter has presented methods for calibrating the kinematic parameters and the inertial parameters of robot manipulators. Both methods are instances of parameter estimation using least squares. Inertial parameters appear linearly in the equations of motion, and ordinary least squares can be used. Kinematic parameters appear nonlinearly because of sines and cosines, and so nonlinear estimation via the Gauss–Newton method can be applied.

There are domain-specific issues for setting up the calibration equations. For kinematic calibration, Hayati parameters have to be mixed with Denavit–Hartenberg parameters to handle the case of nearly parallel joint axes. The calibration equations have to take into account how the endpoint is measured or constrained. By examining in a detailed fashion the possible joint sequences, including parallel or prismatic joints, a minimal parameterization is achieved that obviates problems of identifiability.

The calibration index has been presented as categorizing all kinematic calibration methods. This index counts the number of equations generated per pose, by calculating the excess of sensing over mobility. A key is that all calibration methods can be viewed as closed-loop methods, where any endpoint sensing system is considered as a joint. Parallel robots are handled by incorporating multiple closed loops.

For inertial parameter estimation, the link estimation problem has been viewed as an instance of load estimation but with restricted sensing and motion at the joints. The recursive Newton–Euler equations lead to a formulation of the regressor matrix as an upper-diagonal matrix. A minimal parameterization is straightforward for serial and spanning robots.

Numerical methods were presented to handle unidentifiable parameters if a minimal parameterization has not been achieved. These methods hinge on

the singular value or QR decomposition of the regressor matrix. The singular values can be examined to decide which parameters are not identifiable and should be eliminated. Alternatively, a small singular value can simply be zeroed to eliminate the effects of poorly identifiable parameters without explicitly eliminating them. The former yields a structural model, while the latter yields a prediction model. A priori estimates of parameters can be taken into account by using damped least squares.

The adequacy of the measurement set for parameter estimation is captured by different proposals for an observability index. This index can be related to the literature on alphabet optimalities in experimental design.

Finally, the scaling of measurements or of parameters is important for a well-conditioned numerical estimation, and is essential in order to compare singular values. When uncertainties in measurements and in parameters are included as weights, the optimal minimum variance estimate can be found, which is related to the Kalman filter. If not known beforehand, these uncertainties can be estimated from the data.

14.5.1 Relation to Other Chapters

Estimation involving least squares and Kalman filtering is discussed in Chap. 4 in a similar context. The problem of estimating properties of the world through sensors is very similar to model identification. Recursive estimation techniques are particularly appropriate when a robot needs to update its world model incrementally. For model identification, employing a recursive formulation is not particularly helpful, as the machinery of recursive updating can obscure numerical issues with the total data.

The singular value decomposition appears in other contexts. Chapters 10 and 11 analyze equal motion capability in different directions by measures similar to the observability indexes: O_1 has a counterpart in the manipulability measure, and O_2 the condition number and O_3 the minimum singular value appear again. By contrast, the concern in calibration is good data in all directions as captured by the singular values. Chapter 11 employs the singular value decomposition to analyze redundant mechanisms. Whereas parameter estimation generally is an overconstrained least-squares problem (many more measurements than parameters), redundant mechanisms are underconstrained (more joint angles than task variables). Instead of signalling identifiability problems, zero singular values indicate the null space of the Jacobian. Damped least squares is used in Chap. 11 to avoid singularities. Just as the true parameters are perturbed by damped least squares in calibration, the trajectory is perturbed in order to get around a numerical conditioning issue.

Sensors involved in positioning a robot can have aspects of their sensor models calibrated as well, such as the gain of a potentiometer. Camera calibration is discussed in Chaps. 23 and 24. Camera models can be determined at the same time as the kinematic models of robot manipulators [14.33, 59], including intrinsic camera parameters such as the pinhole model discussed in Chap. 4 as well as the extrinsic parameters of where the camera is located.

14.5.2 Further Reading

Screw Axis Measurement

An alternative to nonlinear least squares to estimate kinematic parameters is a class of methods which measure the joint axes as lines in space, termed *screw axis measurement* in [14.8]. One approach is *circle point analysis*, which involves moving one joint at a time to generate a circle at a distal measurement point [14.13]. Other approaches measure the Jacobian matrix, which contains as columns the joint screws [14.60]. With knowledge of the joint axes, the kinematic parameters are straightforwardly extracted without nonlinear search. The accuracy of this class of methods may not be as good as the nonlinear least-squares methods.

Total Least Squares

Ordinary least squares assumes that there is only noise in the output measurements, but often there is noise in the inputs as well. Input noise is known to lead to bias errors [14.3]. A framework for handling both input and output noise is total least squares [14.61], also known as orthogonal distance regression [14.62] or errors-in-variables regression [14.63]. Nonlinear total least squares has been applied to robot calibration in [14.2, 64, 65]. In the implicit loop method of [14.2], by treating endpoint measurements equally with joint measurements, no distinction is made between input and output noise.

Robot Hands

Claudio Melchiorri, Makoto Kaneko

Multifingered robot hands have a potential capability for achieving dexterous manipulation of objects by using rolling and sliding motions. This chapter addresses design, actuation, sensing and control of multifingered robot hands. From the design viewpoint, they have a strong constraint in actuator implementation due to the space limitation in each joint. After briefly introducing the overview of anthropomorphic end-effector and its dexterity in Sect. 15.1, various approaches for actuation are provided with their advantages and disadvantages in Sect. 15.2. The key classification is (1) remote actuation or build-in actuation and (2) the relationship between the number of joints and the number of actuator. In Sect. 15.3, actuator and sensors used for multifingered hands are described. In Sect. 15.4, modeling and control are introduced by considering both dynamic effects and friction. Applications and trends are given in Sect. 15.5. Finally, this chapter is closed with conclusions and further reading.

Human hands have great potentiality not only for grasping objects of various shapes and dimensions, but also for manipulating them in a dexterous manner. It is common experience that, by training, one can perform acrobatic manipulation of stick-shaped objects, manipulate a pencil by using rolling or sliding motions, and perform precise operations requiring fine control of small tools or objects. It is obvious that this kind of dexterity cannot be achieved by a simple gripper capable of open/close motion only. A multifingered robot hand can therefore provide a great opportunity for achieving such a dexterous manipulation in a robotic system. Moreover, we have also to consider that human beings do not use hands only for grasping or manipulating objects. Exploration, touch, and perception of physical properties

(roughness, temperature, weight, to mention just a few) are other fundamental tasks that we are usually able to perform thanks to our hands. We expect this type of capabilities also from robotic end-effectors and therefore, by adding quite advanced sensing equipments and proper control strategies, we may improve the interaction capabilities with the environment, achieving, for example, active exploration, detection of sensing surface properties (local friction, impedance, and so on), tasks that are usually very hard or impossible for simple grippers. For these and other reasons the study of multifingered robot hands has greatly interested the research community since the early days of robotics.

It was in late 1970s that *Okada* developed a multifingered robot hand with a tendon driving system

and demonstrated a nut-opening motion [15.1]. In the early 1980s, two major projects on multifingered robot hands have been launched: the Stanford/Jet Propulsion Laboratory (JPL) hand and the Massachusetts Institute of Technology (MIT)/Utah hand [15.2, 3]. These two robot hands still represent a milestone and a term of comparison for the design of new devices. Since then, several multifingered hands have been designed and developed in a number research institutes all over the world. Among the most known, one can mention the Deutsches Zentrum für Luft- und Raumfahrt (DLR) hand, the Mechanical Engineering Laboratory (MEL) hand, the Electro-

Technical Laboratory (ETL) hand, the Darmstadt hand, the Karlsruhe hand, the Bologna hand, the Barrett hand, the Yasukawa hand, the Gifu hand, the U-Tokyo-hand, the Hiroshima hand, and many others [15.4–8].

When designing a multifingered hand, on the basis of its utilization, one should first define the following key issues: number and kinematic configuration of the fingers, anthropomorphic or nonanthropomorphic aspect, built-in or remote actuation, transmission system (in case of remote actuation), sensor assignment, integration with a carrying device (robot arm), and control. All these aspects are considered in this chapter.

15.1 Basic Concepts

Before illustrating the main issues involved in the design and use of a robotic hand, it is necessary to discuss some basic concepts and definitions often encountered when dealing with these devices. In particular, terms like *dexterity* and *anthropomorphism* must be defined, and their implications on robotic hand design specified.

15.1.1 Anthropomorphic End-Effectors

The term *anthropomorphism* denotes the capability of a robotic end-effector to mimic the human hand, partly or totally, as far as shape, size, consistency, and general aspect (including color, temperature, and so on) are considered. As the word itself suggests, anthropomorphism is related to the external perceivable properties, and is not, itself, a measure of what the hand can do. On the contrary, *dexterity* is related to actual functionality and not to shape or aesthetic factors. In this sense anthropomorphism and dexterity are *orthogonal* concepts, whose reciprocal dependence (at least in the robotic field) has been not proved yet.

In fact, we can find in the literature anthropomorphic end-effectors with very poor dexterity level, even though they are called *hands*, as the tasks they can perform are limited to very rough grasping procedures [15.9]. Similarly, we can find smart end-effectors, capable of sophisticated manipulation procedures, without any level of anthropomorphism, e.g., the DxGrip-II [15.10]. Anthropomorphism itself is neither necessary nor sufficient to achieve dexterity, although it is quite evident that the human hand achieves a very high level of dexterity and represents a preferential paradigm for dexterous robotic manipulation.

Anthropomorphism is a desirable goal in the design of robotic end-effectors mainly for the following reasons:

- the end-effector can operate in a human-oriented environment (e.g., servicing robots), where tasks may be executed either by robots or men;
- the end-effector can be teleoperated by a human operator, by means of special-purpose interfaces (e.g., a data glove), directly reproducing the operator's hand behavior;
- for the purposes of entertainment, assistance, and so on, a human-like aspect and behavior may be specifically required, like for humanoid robots;
- for prosthetic devices anthropomorphism is a quite evident design goal. The development of end-effectors for prosthetic purposes [15.11, 12] has recently produced such advanced devices that they can be fully considered robotic systems.

While it is difficult to quantify the effective degree of dexterity of a robotic system, its anthropomorphism can be defined in a precise and objective way. In particular, the main aspects that contribute to determining the anthropomorphism level of a robotic hand are:

- *Kinematics*: the presence of the main morphological elements (principal upper fingers, secondary upper fingers, opposable thumb, and palm);
- *Contact surfaces*: the extension and smoothness of the contact surfaces, an aspect that reflects on the capability to locate contacts with objects all over the surface of the available links and on the presence of external compliant pads;

- *Size*: both referring to the average size of a human hand and the *correct* size ratio between the links.

15.1.2 Dexterity of a Robotic Hand

Besides the *geometrical* reproduction of the human hand, the main target of research remains the emulation of those functionalities that make it such a versatile end-effector.

Two are the main capabilities of a human hand:

- *prehension*: the ability to grasp and hold objects of different size and shape;
- *apprehension*: the ability to understand through active touch.

In this sense, the human hand is both an *output* and *input* device (see [15.13]). As an output device, it can apply forces in order to obtain stable grasps or perform manipulation procedures. As an input device, it is capable of exploring an unknown environment providing information about the state of the interaction with it. The same features are desirable in robot hands. In fact, the application of robotic systems in unknown environments requires dexterous manipulation abilities to execute complex operations in a flexible way.

A widely accepted definition states that the dexterity of a robotic end-effector is a measure of its capability of changing the configuration of the manipulated object from an initial configuration to a final one, arbitrarily chosen within the device workspace. Generally speak-

ing, with the term *dexterity* we intend the capability of the end-effector, operated by a suitable robotic system, to perform autonomously tasks with a certain level of complexity. An exhaustive review of scientific work developed so far about the dexterity of robotic hands, with a quite complete and up-to-date list of references, can be found in [15.14].

Even though the word dexterity itself has a very positive meaning, it may be useful to consider different levels of dexterity, associated with the growing complexity and criticality of performable tasks. The dexterity domain for robotic hands can be roughly divided in two main areas: *grasping* and *internal manipulation*.

Grasping means the capability to constrain objects in a configuration that is substantially invariant with time (the object is fixed with respect to the hand).

Internal manipulation is controlled motion of the grasped object in the hand workspace, with the constraint configuration changing with time.

Further subdivisions of these two domains have been widely discussed in the literature (different grasp topologies [15.15] and different internal manipulation modes based on internal mobility and/or contact sliding or rolling [15.14]).

Although the notion of dexterity is settled, the way to achieve it remains debated. Factors affecting the actual capabilities of a robotic end-effector are so many that often the analysis and above all the synthesis of dexterous hands do not take into proper consideration some of these elements, namely: morphological features, sensory equipment, control algorithms, task planning strategies, and so on.

15.2 Design of Robot Hands

The mechanical design of an articulated robotic hand can be performed according to many possible design concepts and options, even if a kinematical architecture has already been defined and size and shape specifications imposed. One of the main issues is the design of a proper actuation and transmission system. This aspect is crucial because space and dimensions are usually limited, being in general an anthropomorphic aspect and dimension a design goal to be pursued.

Note that, since many solutions and operating concepts can be adopted, what is presented here aims only to illustrate the most significant solutions, and does not pretend to be a complete discussion of all the possible choices.

15.2.1 Actuator Placement and Motion Transmission

In order to actuate the joints of a robot hand, two basic approaches for the placement of the actuators are possible:

- placing the motors as close as possible to each joint, directly in the fingers and sometimes integrating them within the joint itself;
- placing the motors into the palm or in the forearm; in this case motion is transmitted to each joint by means of (complex) kinematic chains.

In-Site Actuation

In-site actuation can be defined as the case in which the actuator is hosted inside one of the two links connected by the actuated joint or is placed directly inside the joint:

- *Direct-drive actuation*: the actuator is placed directly on the joint, without transmission elements.
- *Link-hosted actuation*: the actuator is placed inside one of the two links constituting the actuated kinematic chain.

In-site actuation simplifies the mechanical configuration of the joint, reducing the complexity of the transmission chain. In particular, it has the great advantage that the motion of the joint is kinematically independent with respect to other joints. Usually, the size of the finger is imposed by the dimension of the actuators, and for technological reasons it is quite difficult to obtain both an anthropomorphic size and the same grasp strength of the human hand. Furthermore, the motors occupy a large space inside the finger structure, making it difficult to host other elements, like sensors or compliant skin layers. A further negative aspect is that, since the mass of the actuators is concentrated inside the finger, the dynamic behavior of the system and its response bandwidth are reduced.

Nevertheless, the recent advancement of actuator technology enables us to directly implement a quite powerful actuator with reasonable size in each joint. This built-in actuation has been adopted, e.g., for the DLR hand [15.4, 16], the ETL hand, the Karlsruhe hand, the Yasukawa hand, the Barrett hand, the Gifu hand, the U-Tokyo hand, and the Hiroshima hand. Since this actuation does not include compliant elements such as tendons, we can keep a stiff transmission system, which leads to a stable control system even under a high gain, see Sect. 15.4. An issue is the routing of wires for both power and signal cables. This issue is more serious in distal joints than for the base joint, since the cables in distal joints produce a relatively large torque disturbance on the first joint, and therefore it is difficult to achieve precise torque control for this joint.

Remote Actuation

Remote actuation is an alternative solution to in-site actuation. In remote actuation, the joint is driven by actuators placed outside the links connected by the joint itself. Remote actuation requires a motion transmission system, which must pass through the joints between the motor and the actuated joint. In some way, remote actuation must consider the problem of kinematic coupling between the actuated joint and the previous ones. Re-

mote actuation is prevalent in biological structures (e.g., in the human hand), where the finger joints are moved by muscles placed on the palm or in the forearm. This human-like approach has been adopted in projects of robotic hands like the University of Bologna (UB) hand or the National Aeronautics and Space Agency (NASA) Robonaut hand [15.17, 18].

Remote actuation systems can be classified according to the type of adopted transmission elements, i. e., flexible- or rigid-link transmission.

Flexible-Link Transmission. Flexible-link transmission is based on deformable connections, either flexible or rotational, that can adapt to variations of configuration by changing the transmission path. Linear flexible transmissions are based on flexible elements with translating motion, subject to tension (more frequently) or tension and compression. Two further subcategories can be identified: pulley-routed flexible elements (tendons, chains, belts) or sheath-routed flexible elements (mainly tendon-like elements). Rotational flexible transmissions are based on flexible rotary shafts that can transmit rotational motion inside the finger structure to the joint, where a final transforming mechanism (a bevel gear or a worm gear) can be used to actuate the joint.

Rigid-Link Transmission. Rigid-link transmission is mainly based on articulated linkages or on rolling conjugated profiles (mainly gear trains). A further subdivision can be made between parallel and nonparallel axes gear trains, like bevel gears, worm gears, and so on.

15.2.2 Actuation Architectures

Both in-site and remote actuation can be applied according to different types of organization, i. e., by using one or more actuators for each joint and by making these actuators work in different ways.

In general, we can consider an overall number N of joints for the robotic hand (the wrist joints are not considered) and a number M of actuators that are used to drive, directly or indirectly, the joints. According to different concepts of actuation and transmission, three main categories of actuation schemes can be identified:

- $M < N$: some joints are passive, coupled, or underactuated;
- $M = N$: each joint has its own actuator and there are no passive, coupled or underactuated joints;
- $M > N$: more than one actuator is operating on a single joint.

These architectures strongly depend on the type of motors. In particular, it is possible to recognize two main actuation modalities:

- *Single-acting actuators*: each motor can generate a controlled motion in one direction only; return motion in the opposite direction must be obtained by an external action, which can be a passive (e.g., a spring) or an active system (e.g., an antagonistic actuator); this is the case of tendon-based transmission systems;
- *Double-acting actuators*: each motor can generate a controlled motion in both directions and can be used alone to drive the joint or to cooperate with other actuators; in this case the functional redundancy can allow sophisticated drive techniques, like push-pull cooperation.

Each category can be further subdivided. In the following, a brief description of the most frequently adopted schemes is presented.

Single-Acting Actuators with Passive Return Elements

Passive elements, like springs, can store energy during the actuation phase, restituting it during the return stroke, see Fig. 15.1a. This mechanism leads to a simplification of the actuation scheme, but requires mechanically backdrivable actuators. Other possible drawbacks are related to the loss of available power for the grasp and the limited response bandwidth in case of low spring stiffness.

Agonistic–Antagonistic Single-Acting Actuators

Two actuators drive the same joint, acting in opposition in different directions (agonistic–antagonistic couple), see Fig. 15.2b. This solution leads to an N -joint $2N$ -

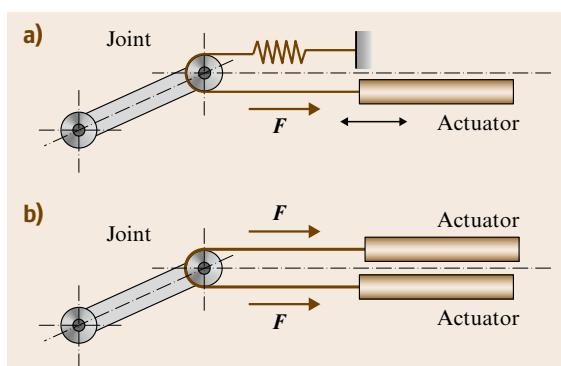

Fig. 15.1 (a) Single-acting actuator with an antagonist passive element and (b) in an agonist–antagonist configuration

actuators scheme and is quite complex since a large number of actuators must be placed in the hand. On the other hand, it may allow sophisticated control procedures, as both actuators can pull at the same time, with different intensity, generating a driving torque on the joint and a pre-loading of the joint itself (co-contraction, typical of tendon-driven joints).

- *Pros*: co-contraction strategies; possibility to change the joint stiffness according to the grasping phase and therefore to limit the influence of friction during fast approaching motions; independent position/tension control on each actuator can allow compensation of different path length in case of remote transmission; it is the most flexible solution for driving a joint;
- *Cons*: backdrivability of actuators is required; difficulty in hosting two actuators for each joint, both in-site and at a remote location; higher control complexity; greater cost.

Single-Acting Actuators Organized According to the Concept of Actuation Net

This is a very interesting case, mimicking biological systems, but has not yet been implemented in robotic hands, except for some preliminary studies. N joints are driven by M actuators, WITH $N < M < 2N$. Each actuator cooperates in moving more than one joint, thanks to proper net-shaped transmissions.

- *Pros*: co-contraction strategies; possibility to change the joint stiffness according to the grasping phase and therefore to limit the influence of friction during fast approaching motions; reduced number of actuators with respect to the $2N$ -actuator scheme.
- *Cons*: backdrivability of actuators is required; high complexity of the kinematic scheme and therefore high complexity in control.

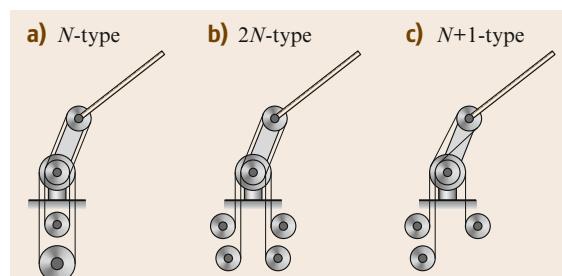

Fig. 15.2a–c Remote actuation (a) N -type (b) $2N$ -type (c) $N+1$ -type

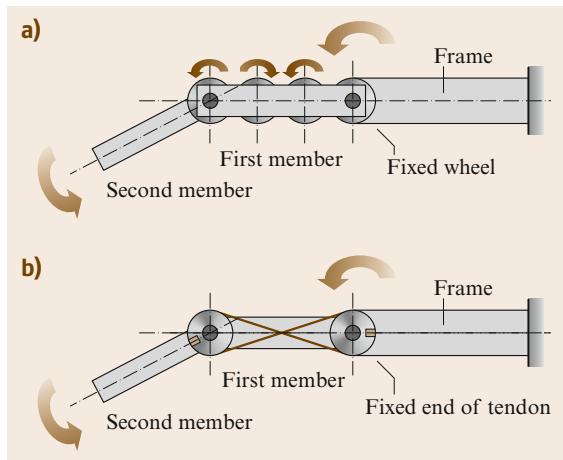

Fig. 15.3 (a) Double-acting actuator with $N = M$ based on gears and (b) tendons

The simplest case of an actuation net is represented by so-called *N+1 actuation* (where N in this case is the number of joints of a finger), frequently adopted in practice, see Fig. 15.2. In this case, all actuators are coupled, and therefore damage to any of them will result in a general failure.

Double-Acting Actuators with $M < N$

In this case, the number of actuators is less than the number of joints. With reference to a single motor and several joints, two main subcases can be defined:

1. the joints are kinematically coupled, in a fixed or variable way, so that the number of degrees of freedom of this subsystems is reduced to one;
2. the joints are selectively actuated by the motor, according to an active or passive selection subsystem.

The former case can be further subdivided.

Joints Kinematically Coupled in a Fixed Way. In this kind of kinematical configuration, each motor can move

more joints connected by rigid mechanisms with fixed transmission ratios. A typical application is obtained with the use of a gear train: the first link is directly actuated by a motor, while a gear transmission between a wheel fixed to the frame and a final wheel connected to the joint generates the relative motion of the second link, see Fig. 15.3a. Should the motion of two parallel fingers be required, their connection could be easily obtained by mounting two gear wheels on the same shaft. Another very common way to obtain this kind of kinematical linkage is to use tendon-driven devices, as shown in Fig. 15.3b. In artificial hand design, the main advantage when using joints driven by fixed-ratio mechanisms is the possibility to know and control the position of the second link. A disadvantage is that this kind of mechanisms does not adapt to the shapes of the grasped objects, and this may cause grasp instability.

Joints Coupled in a Nonfixed Way. This is the case of underactuated mechanisms and deformable passive-driven joints. A mechanism is said to be *underactuated* when the number of actuators is smaller than the number of degrees of freedom. When applied to mechanical fingers, this concept may lead to shape adaptation, i.e., underactuated fingers can envelop the objects to be grasped and adapt to their shape even with a reduced number of actuators. In order to obtain a statically determined system, elastic elements and mechanical limits must be introduced in underactuated systems (a simple linear spring are often used). In the case of a finger closing on an object, for instance, the configuration of the finger is determined by the external constraints associated with the object. An example of an underactuated two-degree-of-freedom finger is shown in Fig. 15.4 [15.19]. The finger is actuated through the lower link, and a spring is used to maintain the finger fully extended. A mechanical limit is used to keep the phalanges aligned under the action of this spring when no external forces are applied on the phalanges. Since the joints cannot be controlled independently, the

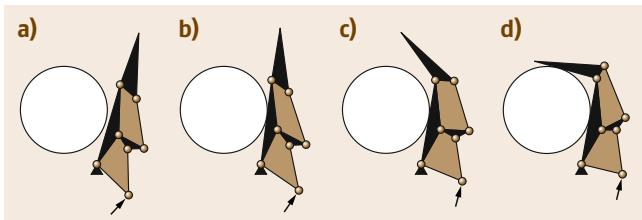

Fig. 15.4 Grasping sequence performed by a finger based on an underactuated mechanism

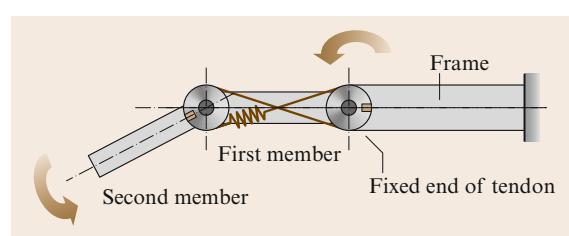

Fig. 15.5 Joints coupled in a nonfixed way

behavior of the finger is determined by the design parameters (i.e., the geometric and the stiffness properties). Hence, the choice of these design parameters is a crucial issue.

Another approach consists of coupling the motion of two adjacent joints by means of deformable linkages. This feature introduces in the kinematical chain the needed compliance to fit to the shapes of the grasped objects. A very simple mechanism of this category is reported in Fig. 15.5. Structurally it is similar to the mechanisms based on a fixed coupling; the only important difference is the addition of a spring to give extensibility to the tendon. This spring allows the motion between the first and second link when an external force is applied to the distal one to be decoupled. This solution is widely used: a well-known example is the DLR hand. The benefits of this solution are mainly due to the possibility to fit to the shapes of objects. A design problem is the choice of the stiffness of the deformable element in order to achieve at the same time a strong grasp and a good shape adaptability.

Joints Selectively Driven by Only One Motor. With this solution, the motion generated by only one (large) motor is transmitted and distributed to several joints. Actuation and control of each joint is obtained by means of

insertion–disinsertion devices like self-acting or commanded clutches.

Double-Acting Actuation, with $M = N$

This is a very common case: each joint is driven in both directions by the same actuator. The achievable performances are therefore similar (equal) in both directions, but particular attention must be paid to backlash, and it is usually necessary to preload the transmission system. In particular, preloading is mandatory in the case of transmission by means of flexible elements such as tendons, see Fig. 15.2a. Furthermore, the adoption of a closed-loop tendon transmission requires that the overall length of the tendon route must be kept constant, according to the concept that wound and unwound parts of the tendon on the motor pulley have the same length; this involves the need for length-compensating mechanisms (e.g., pulley trains, cams) every time that changes in the geometry of the finger cause a differential displacement of the tendons. In spite of this additional complexity, this actuation scheme has been widely used, with simple pulley routing (the UB hand, Okada hand, etc.), or sheath routing (the Salisbury hand, the Dipartimento di Informatica Sistemica e Telematica (DIST) hand), which has a simpler mechanical structure but must face the problem of sheath–tendon friction (the application of a high preload is not convenient in this case).

15.3 Technologies for Actuation and Sensing

In this section, a brief description of the main issues related to technological aspects of actuation and sensing for robot hands is reported. A more general presentation and detailed description of these aspects is given in Part I (Chaps. 3 and 4) and Part C (Chap. 19).

15.3.1 Actuation

Electrical actuators are without doubt the commonest choice for actuating robot hands. As a matter of fact, electric motors have very good performance in terms of position/velocity control, have a reasonable mass/power ratio, and are a very common technology that does not require external devices (such as for hydraulic or pneumatic actuators). However, there are several other possibilities, for example, ultrasonic motors (the Keio hand, [15.20]), chemical actuators, pneumatic actuators as the *McKibben* used in the Shadow hand [15.21]), spring-based actuator (as for the 100G Capturing Robot [15.22]) and others.

In particular, when seeking a quick response, either pneumatic or spring-based actuators may be good solutions, although it should be noted that a braking system with a quick response is essential for achieving good position controllability for this type of actuators.

15.3.2 Sensors

In robot hands, as in other robotic devices, sensors can be classified into two main categories: *proprioceptive* and *exteroceptive* sensors. The first type of sensors measures physical information related to the state of the device itself (e.g., position and velocity), while the second one is devoted to the measurement of data related to the interaction with objects/environment (e.g., applied forces/torques, friction, and shape).

Joint Position/Velocity Sensors

For control purposes, there is the obvious necessity of measuring position/velocity of the actuated joints. A ma-

ajor problem consists in the limitation of the available space, both for the sensors and for the wires. Different technological solutions can be adopted, but a rather common choice is Hall-effect sensors, which are sufficiently small, precise, and reliable for this type of application. In the case of remote actuation, there is the possibility of having two position/velocity sensors for each joint: one located in the actuator (e.g., an encoder) and one placed in the joint itself, often necessary because of the nonlinearities introduced by the transmission system (elasticity, friction, and so on). Quite often, this latter sensor is specifically designed and implemented for the given hand, as commercially available sensors are too large and not suitable for installation in the joints.

Tendon Tension Sensor and Joint Torque Sensor

It is well known that humans can control fingertip compliance as well as fingertip force by controlling voluntary muscles. In remote actuation, it is essential to measure the tendon tension for two main reasons: to compensate for the friction existing in the transmission system, and to measure the external contact force. Figure 15.6 shows a way of measuring the tendon tension in which the tendon is pressed by an elastic plate with a strain gauge. When tension is applied to the tendon, the sensor measures a force composed of axial and bending force components. The displacement of the elastic plate

due to the axial force component is negligibly small compared with that due to the bending force component. As a result, the bending force component generates a bending deformation for the elastic plate. This deformation is transformed into an electric signals by the strain gauges attached on the surface of the plate. Now, suppose N -type actuation with two tension sensors, as shown in Fig. 15.7, where joint torque τ is given. Note that $\tau = r(T_1 - T_2)$, where r , T_1 , and T_2 are the pulley radius and tendon tensions, respectively. Since we can measure e_1 and e_2 corresponding to T_1 and T_2 , τ can be obtained by feeding both e_1 and e_2 into the differential circuit. This approach, however, includes a couple of issues. The main problem is the plastic deformation of the sensor plate under an extreme large pre-tension. Once such a plastic deformation has happened, the sensor will never work appropriately anymore. Another minor issue is that two sensors are always necessary for measuring a joint torque. To cope with these issues, the tension-differential-type torque sensor [15.22] can be used, as shown in Fig. 15.8. The sensor is designed with just a single body and partially includes an elastic part where at least one strain gauge is attached. The working principle of the sensor, shown in Fig. 15.8a, supposes that a torque is applied to the joint. This means that T_1 and T_2 have different values. This difference causes a bending force around the strain gauge. The key is that the bending force is kept to zero even under an extremely large tension as long as no joint torque is applied. Therefore,

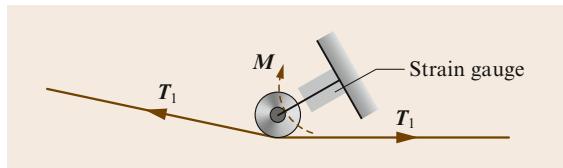

Fig. 15.6 Tendon tension sensing

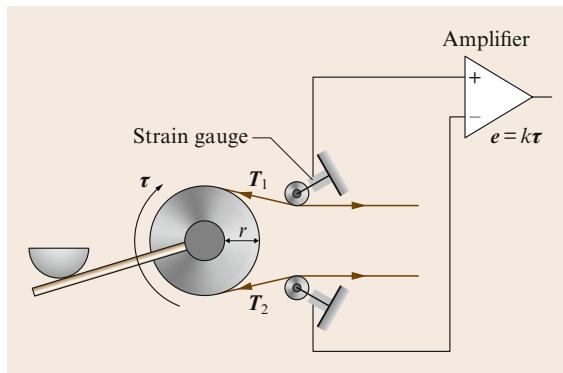

Fig. 15.7 Tension-sensor-based torque sensing

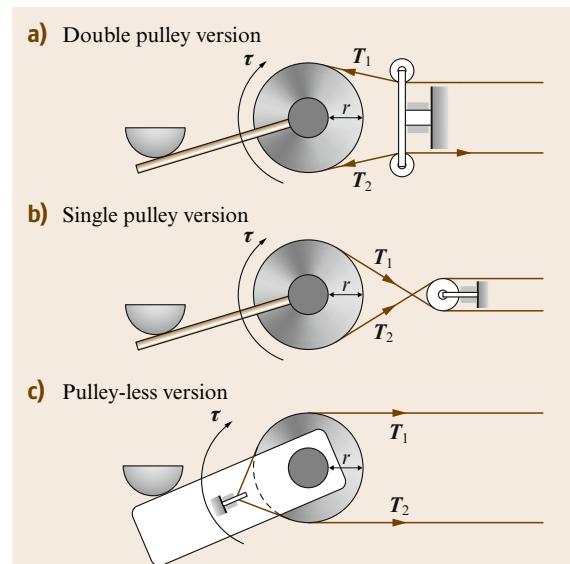

Fig. 15.8 A tension differential type (TDT) sensor [15.22]

we are completely released from the plastic deformation of the elastic plate due to pre-tension. Furthermore, the sensor is constructed with just a single body. There are a couple of variations of this type of torque sensor. When decreasing the pulley distance in Fig. 15.8a, the sensor eventually results in the single-pulley version with zero distance, as shown in Fig. 15.8b. The single-pulley version has been implemented into the Darmstadt hand [15.23] and the MEL hand [15.24]. Furthermore, if the sensor is built into the finger link connected by the concerned tendon, there is no relative motion between the sensor and the tendon. As a result, we can remove the pulley, as shown in Fig. 15.8c. This is called the pulley-less version and has been implemented in the Hiroshima hand. The tension-differential-type torque sensor will be a powerful tool for measuring a tendon drive joint.

Fingertip Tactile (or Force) Sensors

Most robot manipulation and assembly tasks would benefit from the utilization of tactile sensory information. When lifting an object, tactile sensing could detect the onset of slip in time for corrective action to be taken. In addition to the contact point between the fingertip and the object, several object properties, such as the friction coefficient of the object surfaces, surface texture, and weight can be determined by utilizing a fingertip tactile (or force) sensor. A six-axis force sensor allows us to detect contact point as well as the contact force between the finger and the environment if a single contact is assumed. For the finger model shown in Fig. 15.9 we have the following relationship between the sensor output and contact force

$$\mathbf{F}_s = \mathbf{f}, \quad (15.1)$$

$$\mathbf{M}_s = \mathbf{x}_c \times \mathbf{f}, \quad (15.2)$$

where $\mathbf{f} \in \mathbb{R}^3$, $\mathbf{F}_s \in \mathbb{R}^3$, $\mathbf{M}_s \in \mathbb{R}^3$, and $\mathbf{x}_c \in \mathbb{R}^3$ are the external force vector, the force vector measured by the six-axis force sensor, the moment vector measured

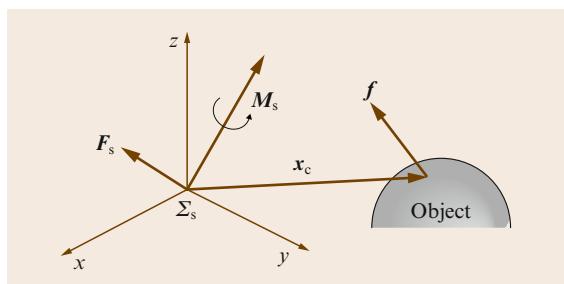

Fig. 15.9 Sensor coordinate system Σ_s

by the six-axis force sensor, and the position vector indicating the contact position, respectively. From the first equation, we can directly obtain the contact force. Putting \mathbf{F}_s into the second equation leads to $\mathbf{M}_s = \mathbf{x}_c \times \mathbf{F}_s$. \mathbf{x}_c is determined in such a way that $\mathbf{M}_s = \mathbf{x}_c \times \mathbf{F}_s$ may be satisfied. For a finger with a convex object, we always have two mathematical solutions, as shown in Fig. 15.10a, where the meaningful solution is the one satisfying $\mathbf{f}^t \mathbf{n} > 0$ (a finger can only push the object). However, for a finger with a concave object, we have at least four mathematical solutions, as shown in Fig. 15.10b, where two of those are physically possible. A finger with a six-axis force sensor located in the fingertip, Fig. 15.10c, can avoid multiple solutions. On the other hand, only forces applied to the fingertip can be detected, and if more links are in contact with the object it would be necessary to have a force/torque sensor placed in each of them.

This type of solution, i.e., a multiaxis sensor for measuring not only forces and torques but also the position of the contact point, is known in the literature as the *intrinsic tactile (IT)* principle [15.25]. In general, compared with the use of traditional tactile sensors (see below) this leads to a simplification in the design since it requires fewer wires and connections for the sensor.

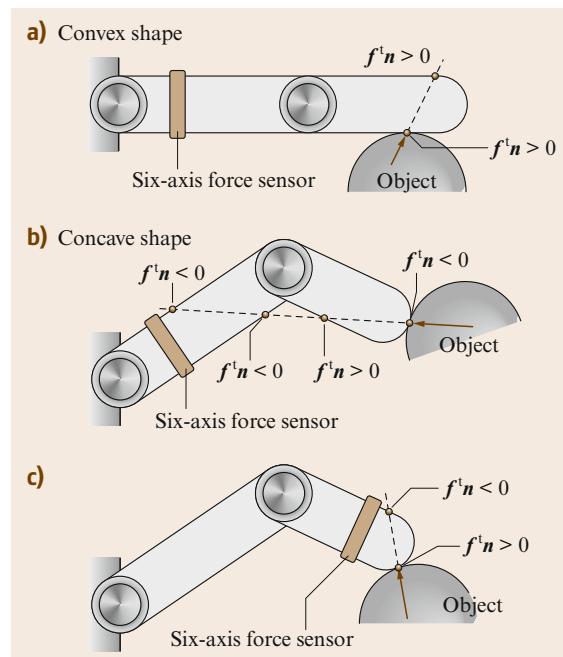

Fig. 15.10a–c Interpretation of solutions: (a) convex shape, (b) concave shape, and (c) six-axis force sensor

Tactile Sensors

Another important class of sensing devices consists of tactile sensors, which are used for several purposes, such as shape recognition, contact point determination, and pressure/force measurement. A number of tactile sensors have been proposed in the literature, with several different solutions concerning the realizable features: optical, piezoresistive, piezoelectric, and so on; see, e.g., [15.26, 27] for an overview on technologies and applications.

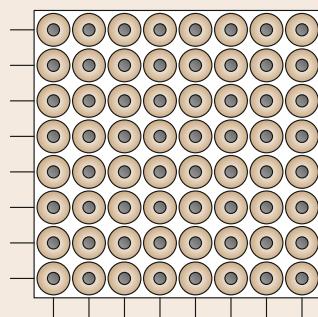

Tactile sensors have been introduced in robotics since the late 1970s. Nowadays, as with force sensors, tactile sensors are also commercially available devices. Probably, they represent the most commonly adopted sensorial class for industrial grippers, even though they are often used as advanced *on/off* devices to check whether a grasp or contact condition occurs.

Usually, they consist of a matrix (array) of sensing elements. Each sensing element is usually referred to as a *taxel* (from *tactile element*), and the whole set of information is called a *tactile image* (Fig. 15.11). The main goal of this class of sensors is to measure the pressure map over the sensing area.

In general, the types of information that may be obtained from a tactile sensor are:

- *contact*: this is the most simple information given by the sensor, concerning the presence or absence of a contact;
- *force*: each sensing element provides information related to the amount of locally applied force, which can be used in several ways for successive elaborations;
- *simple geometrical information*, i. e., the position of the contact area, the geometrical shape of the contact itself (planar, circular, and so on);
- *the main geometrical features of the object*: by proper elaborations of the data from the taxels, it is possible to deduce the type of object in contact with the sensor, for example, a sphere or a cylinder (data relative to the three-dimensional shape);
- *mechanical properties*, such as friction coefficient or roughness. Also thermal properties of the object may be measured by a tactile sensor;
- *slip condition*, i. e., the relative movement between the object and the sensor.

a) Scheme of a tactile sensor

b) Example of data from a tactile sensor

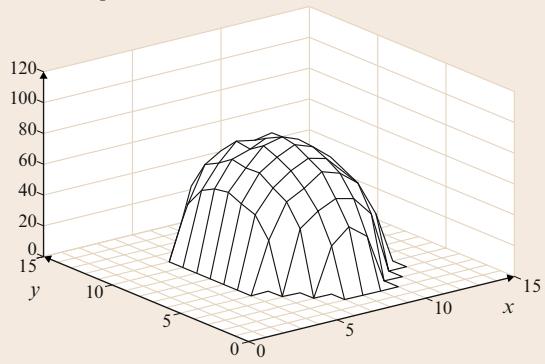

Fig. 15.11a,b A tactile sensor: (a) scheme and (b) example data

Several technologies have been adopted for the design of tactile sensors, ranging from piezoresistive to magnetic, to optical effects, and so on. Among the most common, one can mention:

- resistive and conductive effect
- electromagnetic effect
- capacitive effect
- piezoelectric effect
- optical effect
- mechanical methods

Each of these technologies has positive and negative aspects. Common drawbacks, however, are the size of these sensors, which are usually quite large in comparison with the available space, and the necessity of a large number of electrical connections.

15.4 Modeling and Control of a Robot Hand

The dynamic model of a robot hand with in-site actuation is very similar to the model of a traditional (industrial) robot, and the hand can be considered as a collection of robot manipulators. On the other hand, remote actuation introduces some peculiar features that have to be carefully considered. In particular, the problems linked to nonlinear phenomena (e.g., friction and backlash), the compliance of the transmission system, and the non-collocation of sensors and actuators are critical for the design of the control. Moreover, the use of single-acting actuators, such as tendon-based actuation systems, requires the adoption of proper control techniques that allow the imposition of the desired torque at each joint of the hand despite the coupling among them.

15.4.1 Dynamic Effects of Flexible Transmission Systems

The transmission system of robot hands with remote actuation is usually characterized by a high level of friction and nonnegligible dynamic effects which complicate the control problem. A simple representation considers a single axis motion with two inertial elements linked by an elastic transmission. This is the typical representation of elastic joints in which the former element represents the motor inertia, while the latter is related to the inertial properties of the actuated joint/link, see Fig. 15.12a. More complex models assume a dynamic model for the transmission system, i.e., the

classical representation of tendons based on the serial repetition of masses linked by springs/dampers, reported in Fig. 15.12b. These simple models are particularly useful to understand some drawbacks and limitations due to the fact that actuation system and actuated element are located in two different places and the motion is transmitted by a nonideal (that is, not purely static) element. If we consider the capability of the fingers' joint to apply a force on environment, the effects of the transmission system on the open-loop response of the system modeled as in Fig. 15.12a are a noticeable reduction of the bandwidth and an important phase delay between the input F_a (the force applied by the motor) and the output F_c (the force exchanged at the contact). As shown in Fig. 15.13, the open-loop transfer function

$$\frac{F_a}{F_c} = \frac{(b_c s + k_c)(b_t s + k_t)}{[j_m s^2 + (b_t + b_c)s + k_t + k_c](j_m s^2 + b_t s + k_t) - (b_t s + k_t)^2} \quad (15.3)$$

is characterized by four poles that, for increasing values of the transmission stiffness k_s , move from their initial locations (which depend on the values of physical parameters j_1 , j_m , etc., although for $k_s = 0$ at least one pole is in the origin of the Gauss plane) towards the poles of a system with an infinitely rigid transmission (for k_c tending to ∞ , two poles go to infinity) and a total inertia given by the contributions of both the

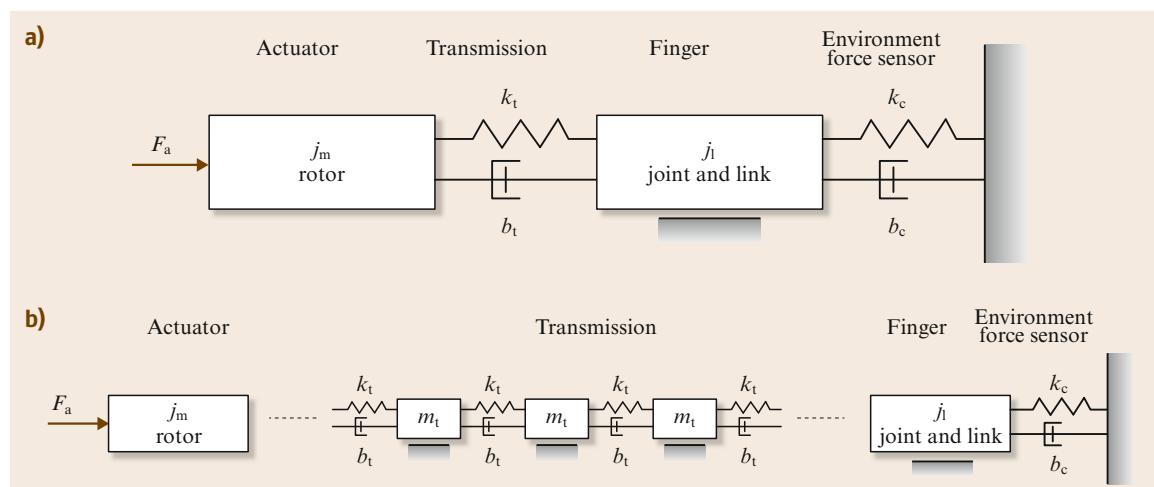

Fig. 15.12 (a) Model of a robot joint with transmission flexibility and (b) with tendon-based transmission

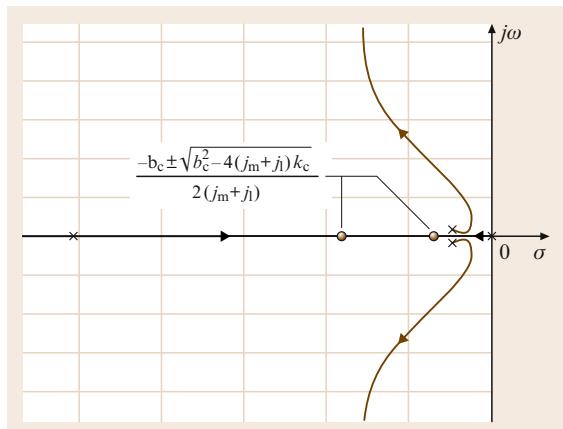

Fig. 15.13 Root contour of the transfer function (15.3) with variable k_t

motor and the link. In this case the transfer function is:

$$\frac{F_a}{F_c} = \frac{(b_c s + k_c)}{(j_l + j_m)s^2 + b_c s + k_c} \quad (15.4)$$

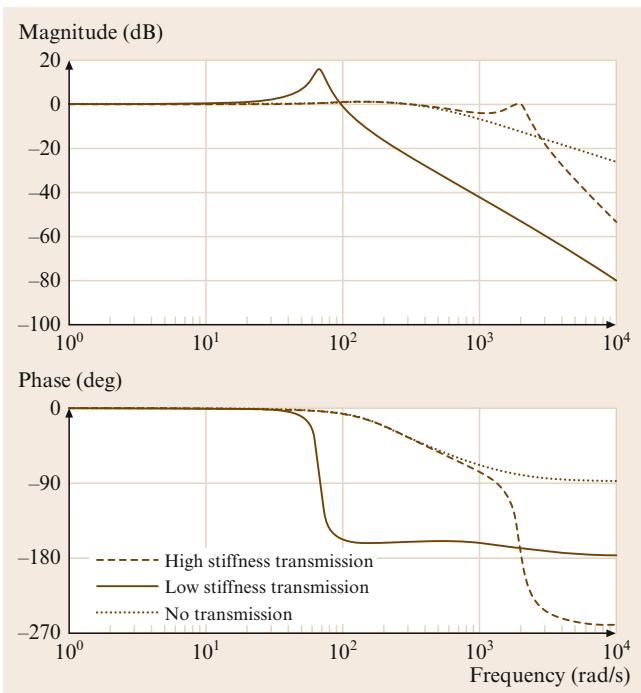

Fig. 15.14 Bode plots of the open-loop transfer function (15.3) for low stiffness values (continuous line), high stiffness value (dashed line) and with no transmission (dotted line)

As a consequence, the bandwidth of the system with flexible transmission, which for high values of k_s approximates those of (15.4), decreases when the compliance of the transmission is not negligible; see the Bode plots reported in Fig. 15.14. The bandwidth of a system with flexible transmission is strongly affected by the location of the speed reducer: when the reducer is placed at the joint the bandwidth is K_r times higher than the one achievable with the reduction applied directly on the motor [15.28] (see Fig. 15.15; K_r is the reduction ratio). Moreover, it is worth noticing that for low values of the stiffness k_t a sharp phase drop occurs at the frequency of the flexible mode. Therefore, there are some (relatively low) frequencies at which the force applied by the motor and the one measured with a sensor in the finger's joint are completely out of phase. These effects, which may cause the instability of the overall system under force control (or impedance control) are referred to as *non-collocation*. In general, when actuators and sensors are physically located at different points of a flexible structure (or a structure with flexible transmission), there will be unstable modes in the closed-loop system [15.29].

From the control viewpoint, the problem of mechanical transmission flexibility is further exacerbated by the nonlinear frictional phenomena that inevitably affect remote actuation and motion transmission. In fact, the linear viscous friction, represented in Fig. 15.12 by the damping coefficient b_t , is accompanied by stiction and Coulomb friction, both of which are discontinuous at zero velocity (see Fig. 15.16). These nonlinearities may cause limit cycles and input-dependent stability, and must be accurately taken into account in the design of the robot hand structure as well as of its control

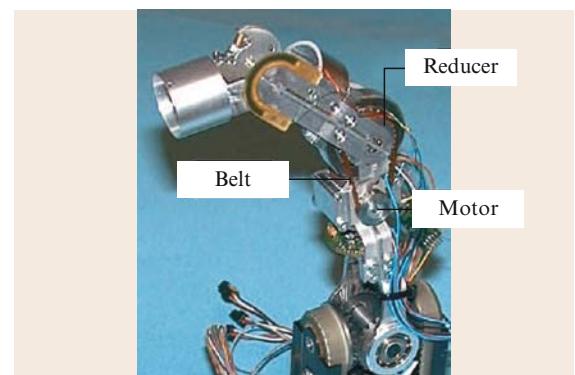

Fig. 15.15 Reducer location on the medial joint of the DLR hand II

architecture [15.30], for instance, in the design of the Utah/MIT dexterous hand (Fig. 15.17) in order to reduce static friction, the idea of using tendon sheaths was abandoned in favor of pulleys [15.3]. In order to find an optimal tradeoff between complexity and reliability of the mechanical arrangement and achieved friction level, a number of solutions that combine sheaths and pulleys for routing the tendon from actuators to fingers' joints have been adopted in the design of robot hands, e.g., the Stanford hand and the UB hand 3 reported in Fig. 15.18. The UB hand is characterized by an extremely simple structure, with the tendons completely routed within sheaths, but on the other hand the friction cannot be absolutely neglected and precise modeling of the interaction between the tendons and the tube is necessary for control purposes.

15.4.2 Transmission Model of Tendon-Outer-Tube System

This system can be modeled as shown in Fig. 15.19, where T_{in} , T_{out} , T_0 , ξ_{in} , ξ_{out} , R_i , x , and L are the tension at the input side, the tension at the output side, the initial pretension, the displacement at the input side, the displacement at the output side, the local radius of routing, the coordinate system along the wire, and the length of the tendon, respectively. The relationship between the tension at output and the input displacement is given by [15.31]

$$T_{\text{out}} - T_0 = K_t(\xi_{\text{in}}\phi_B), \quad (15.5)$$

where K_t and ϕ_B are the total stiffness and the equivalent backlash, respectively, given by

$$\frac{1}{K_t} = \frac{1}{K_e} + \frac{1}{K_s} + \frac{1}{K_{\text{ap}}}, \quad (15.6)$$

$$K_{\text{ap}} = K_w \frac{\lambda}{e^\lambda - 1}, \quad (15.7)$$

$$\phi_B = \frac{T_0 L}{E A} \cdot \frac{e^\lambda - \lambda - 1}{\lambda}, \quad (15.8)$$

$$\lambda = \sum |\beta_i| \mu \operatorname{sgn} \xi_{\text{in}}, \quad (15.9)$$

where K_e , K_s , K_w , K_{ap} , μ , E , A , and β_i are the stiffness of the environment, the stiffness of the force sensor, the apparent stiffness of the tendon, the friction coefficient, the Young's modulus, the cross-sectional area, and the bending angle of each segment of tendon, respectively. For example, $\sum |\beta_i| = 2\pi$ for the case given in Fig. 15.19. As can be seen from this example, the friction-related parameter λ increases dramatically when

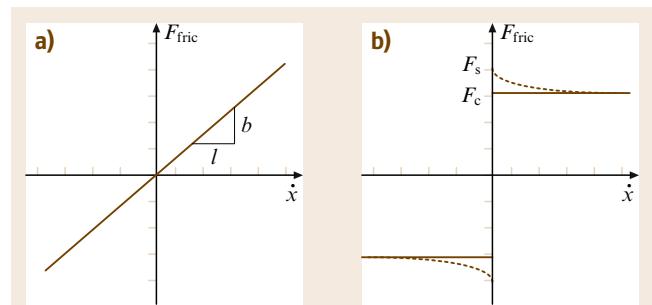

Fig. 15.16a,b Frictional phenomena: (a) viscous friction and (b) stiction and Coulomb friction

the tube is heavily bent. While we have the great advantage of choosing a free route for the power transmission, it results in a large nonlinearity for the transmission system. We should note that, while both the apparent stiffness of the tendon and the equivalent backlash vary with λ which is a function of the curvature of the route

Fig. 15.17 The Utah/MIT robotic hand

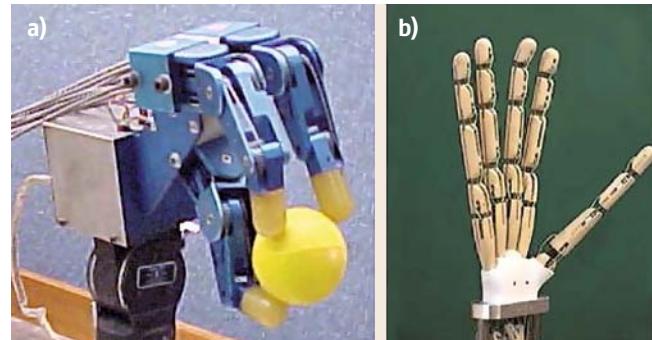

Fig. 15.18a,b Tendon-based robot hands: (a) Stanford/JPL hand and (b) UB hand 3

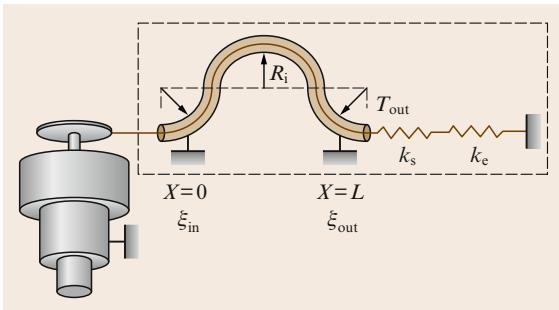

Fig. 15.19 Model of tendon-outer-tube transmission

as well as the friction coefficient, ϕ_B and K_{ap} result in $\phi_B = 0$ and $K_{ap} = K_w$ under $\mu = 0$. From the control viewpoint, such hysteresis is, of course, undesirable. To cope with these issues, each tendon should be designed to be as short as possible, so that we may keep high stiffness and small backlash in the transmission system.

15.4.3 Control Through Single-Acting Actuators

The use of single-acting actuators (i.e., standard motors with tendinous transmission), which are commonly assumed in the design of robot hands with remote actuation, requires the adoption of specific control techniques in order to guarantee the desired torques at the joints and to maintain at each time a positive tension on the tendons. To this purpose, the tendons are treated like inelastic frictionless elements and the problem is addressed in a way completely decoupled from the issue of device stability, discussed in previous sections.

A tendon, routed in the finger structure through sheaths or/and pulleys, can be modeled by means of an *extension function* $l_i(\theta)$ [15.32] that relates the joints' configuration with the tendon elongation. In the case of the tendon network represented in Fig. 15.2, the extension functions of the three tendons have the form:

$$l_i(\theta) = l_{0i} \pm R\theta_1 \pm R\theta_2,$$

where R is the radius of the pulleys and $\theta = [\theta_1 \ \theta_2]^T$ is the vector of the joint variables. Once the extension function has been determined, it is straightforward to derive the relationship between the tendons forces and the resulting joints torques. In fact, the relation between the joint speeds $\dot{\theta}$ and the tendon speeds \dot{l} can be deduced by simply differentiating the expression of extension functions

$$\dot{l} = \frac{\partial l}{\partial \theta}(\theta)\dot{\theta} = P(\theta)\dot{\theta}. \quad (15.10)$$

Because of the conservation of the power, from (15.10), one can deduce

$$\tau = P^\top(\theta)f, \quad (15.11)$$

where the τ are the torques exerted on the joints, and the f are the force applied by tendons. From (15.11) it results that the force transmitted by a tendon may affect (and, in general, will affect) more than one joint.

In order to guarantee the possibility of exerting joint torques in every direction under the constraint of pure tensile forces, for any $\tau \in \mathbb{R}^n$ there must exist a set of forces $f_i \in \mathbb{R}^m$ such that

$$\tau = P^\top(\theta)f \text{ and } f_i > 0, i = 1, \dots, m, \quad (15.12)$$

where n and m are, respectively, the number of joints and the number of tendons. In this case the tendon network is said *force closure*. If the condition expressed by (15.12) is verified, given a desired torque vector τ it is possible to compute the force that the actuators must provide to the tendons according to

$$f = P^\dagger(\theta)\tau + f_N, \quad (15.13)$$

where $P^\dagger = P(P^\top P)^{-1}$ is the pseudo-inverse of the coupling matrix P^\top and $f_N \in \mathcal{N}(P^\top)$ is a vector of *internal forces* that ensures that all tendon tensions are positive. In general, internal forces will be chosen as small as possible, so that the tendons are always taut but are not subject to excessive strains.

15.4.4 Control of a Robot Hand

The modeling and control aspects described in the previous sections, although very important and fundamental, can be considered as a sort of *low-level* problem in the control of a robot hand, in the sense that they are related to the specific physical properties of the device.

There are also other problems that must be faced and solved in order to operate in a profitable manner with a multifingered hand. These problems are solved by a proper design of the *high-level* control for the hand, which must take into account the interaction of the hand with the objects and more generally with the environment. In this context, general aspects that must be considered are: the control of forces/torques applied at the contact points, the necessity to model contact compliance/friction effects, the type of mobility both for the fingers and at the contact (rolling, sliding, etc.), a suitable planning algorithm for grasping and/or manipulating the objects, and so on.

These problems are illustrated in details in Chap. 26, Chap. 27, and Chap. 28.

15.5 Applications and Trends

In the industrial environment, simplicity and cost are the main guidelines for the design of end-effectors, and therefore simple devices, such as open/close grippers, are very common and widely used. This situation has led over the years to the development of a number of special-purpose devices, optimized for single specialized operations but not suitable for other tasks. At the moment, dexterous multifingered hands have not really been applied to any major application, mainly because of problems of reliability, complexity, cost.

On the other hand, more and more operations are currently envisaged for robots working in environments designed for, and utilized by, human operators. Entertainment, maintenance, space exploration, help to disable persons are just a few examples of the use of robotic systems in which interaction with tools and objects designed for human beings (or directly with them) is implied. In all these circumstances, the robot must be able to grasp and manipulate objects (different in dimension, shape, weight, etc.) similarly to humans, and therefore a robot hand, with a proper number of fingers and joints and also with an anthropomorphic appearance, seems to be the most adequate solution.

Fig. 15.20 The NASA/JPL Robonaut

At the moment, there are several projects aimed at the development of anthropomorphic robots. Among the most well known, one can mention the [NASA/JPL](#) Robonaut [15.18] (Fig. 15.20), the devices developed at the [DLR](#), and the several projects on humanoid robots currently under development.

15.6 Conclusions and Further Reading

The design of multifingered robot hands has attracted the interest of the research community since the early days of robotics, not only as a challenging technical problem itself but probably also because of anthropomorphic motivations and the intrinsic interest in better knowledge of the human body. In the last decades, as previously discussed, several important projects have been launched, and important examples of robot hands have been developed. Nevertheless, the current situation is that reliable, flexible, dexterous hands are still not available for real applications. For these motivations, it is also easy to foresee in the future a consistent research activity in this fascinating field, with developments at the technological (sensor, actuator, material, etc.) and methodological (control, planning, etc.) levels.

Important connections with other scientific fields, such as cognitive science, are also expected.

As this research is so wide, it is not simple to suggest to interested readers further readings, except for classic books such as [15.32–34]. In fact, depending on the specific research area, many publications are available, although often not organized as reference books, mainly as technical papers published in journals or presented at international conferences. Moreover, since hundreds of new papers are published every year covering the different aspects of this robotic field, it is really quite difficult, and also not fair, to give specific suggestions for further readings at this time. We can therefore only refer to the citations already provided in the chapter.

Legged Robots

Shuuji Kajita, Bernard Espiau

In this chapter, we introduce legged robots. After introducing the history of legged robot research in Sect. 16.1, we start to discuss hopping robots and analyze a simple passive walker as a typical cycling walking robot in Sect. 16.2; the Poincaré map is one of the most important tools to analyze its dynamics and stability. In Sect. 16.3, the dynamics and control of general biped robots are discussed. The key is the forward dynamics subject to the unilateral constraint between the feet and the ground. Its formal treatment leads to walking trajectory generation and various control methods. As a practical scheme to control biped robots, we discuss the zero-moment point (ZMP) in Sect. 16.4, including its definition, physical meaning, measurement, calculation, and usage. In Sect. 16.5, we move to multilegged robots. In this field, the most important subject is the relationship between gaits and stability. We also introduce the landmark robots in this field. In Sect. 16.6, we overview the divergence of the legged robots. We see leg-wheel hybrid robots, leg-arm hybrid robots, tethered walking robots, and wall-climbing robots. To compare these legged robots with different configurations, we use some useful performance indices such as the Froude number and the specific resistance, which are introduced in Sect. 16.7. We conclude the chapter and address future trends in Sect. 16.8.

The idea of designing and realizing artificial entities is almost as old as humanity. After some wonderful formal studies by Leonardo Da Vinci, the first notable artificial machines, called *automatons* were built, among others

by Jacquard, Jacquet-Droz, Vaucanson (including his famous duck) mainly in France around the 18th century. This was followed by a florilegium of realizations from 1850 to World War I. The area then experienced a long

eclipse, up to the early 1970s. It should be noticed that the revival was then driven by scientists, instead of the

brilliant engineers, artists or magicians of the previous centuries.

16.1 A Brief History

The pioneering works in the field of legged robots were achieved around 1970 by two famous researchers, Kato and Vukobratovic. Both works were characterized by the design of relevant experimental systems. In Japan, the first anthropomorphic robot, WABOT 1, was demonstrated in 1973 by I. Kato and his team at Waseda University. Using a very simple control scheme, it was able to realize a few slow steps in static equilibrium. This achievement was the starting point of a prolific generation of legged robots in Japan.

In parallel, M. Vukobratovic and his team were very involved in the problems generated by functional rehabilitation. At the Mihailo Puppin Institute, Belgrade, Yugoslavia, they designed the first active exoskeletons, and several other devices such as the *Belgrade's hand*, but the most well-known outcome remains their analysis of locomotion stability, which exhibited around 1972 the concept of zero-moment point (ZMP), widely used since that time [16.3]. This was the first attempt to formalize the need for dynamical stability of legged robots; the idea was to use the dynamic wrench in order to extend a classical criterion of static balance (the center of mass should project inside the convex hull of contact points). This important point will be detailed later in this Chapter.

In the next decade, the breakthroughs came from the United States. Following the early work of R. McGhee in the 1960s at USC (University of Southern California), then in the 1970s at OSU (Ohio State University), which resulted in the first computer-controlled walking machine, M. Raibert started to study dynamically stable running at CMU (Carnegie Mellon University). Then, he launched the Massachusetts Institute of Technology (MIT) LegLab, where a sequence of active hopping robots, with one, two or four legs were designed, with impressive results, among them a famous flip performed by a two-legged hopping machine. Simultaneously, R. McGhee and K. Waldron, after the building of some prototypes, achieved the design of the largest hexapod in the world, called the *adaptive suspension vehicle*, a quasi-industrial system able to walk on natural irregular terrain, which was driven by a human (Sect. 16.5.2).

A third key period for research in legged robots was the early 1990s. Indeed, the idea of studying

purely passive mechanical systems was pioneered by *McGeer* [16.4]. In this seminal paper, McGeer introduces the concept of natural cyclic behavior, for a class of very simple systems: a plane compass on an inclined plane. Stable walking results from the balance between increase of the energy due to the slope and loss at the impacts. However, what should be emphasized here is that McGeer popularized for roboticists the analysis of such systems in terms of orbital stability using Poincaré maps. Several researchers have followed the tracks open by McGeer, with many extensions (examples in Fig. 16.1): adding trunk, feet and knees [16.1], semipassive control, walking/running underactuated systems like the Rabbit robot [16.2], etc.

Finally, the end of the millennium was a period of intense technological activities. Industrial breakthroughs showed to the world that building true humanoids was now possible. In Japan, the first humanoid robot, P2, was exhibited by Honda in 1996, followed by several more. Presently, the most impressive technical achieve-

Fig. 16.1a,b Underactuated biped robots [16.1,2]

ments are still realized by industrial companies: ASIMO (Honda), QRIO (Sony), HRP (Kawada), being the major examples today, among others. In parallel, it should be noticed that the market for small humanoid robots, mainly aimed at entertainment, has grown steadily over the last decade.

While examining the history above and the present state of the art, it is clear that roboticists are now facing a challenge. Very nice technological achievements are available, especially biped robots. However, the ability of these systems to walk truly autonomously on uneven and various terrains in a robust way, i.e., in daily life, remains to be demonstrated. The goal of this chapter is therefore to provide some keys in modeling and recent

control advances, in order to be able to design adequate and efficient control schemes when needed. This will be based on two main classes of approaches: the use of so-called forward dynamics on one hand, and the use of the ZMP on the other hand. The Chapter is organized as follows: after a brief summary of the control principles used for hopping and passive robots, we will focus on the issues needed for the control of biped robots from a dynamic model scheme: modeling aspects, stability issues, trajectory generation, and control. Then we will present in depth the concept of ZMP and its use in a control scheme. Since the first parts are mainly concerned with biped robots, the chapter will end with a section dedicated to multilegged robots.

16.2 Analysis of Cyclic Walking

16.2.1 A Few Points About Hopping Robots

Cyclic legged robots are those that reach, either naturally or with the help from a control, a steady-state behavior characterized by a cycle in the phase plane. The underlying assumption is that there exists in some sense a more or less hidden set of optimal natural behaviors of the system. Within this class, hopping (or bouncing) robots are interesting since they are generally unstable, but capable of high performance in terms of velocities.

As mentioned, these robots have been widely studied in the MIT LegLab. It is not the goal of the Chapter to develop in depth the related design approaches and control techniques, and we refer the reader to the excel-

lent, although ancient, book by *Mark Raibert* [16.5] on the subject. Let us just give a flavor of Raibert's results, taken from this reference.

The basis of the work is in fact the planar one-leg hopping robot. Raibert proved that the control of such system could be split into three separate components: the first controls the altitude by providing a fixed thrust during each cycle; the second part controls the forward velocity of the whole system by assigning to the foot, at each step, a given distance from the hip when landing; and the last one controls the body attitude by servoing the hip during the stance phase. The related algorithms are quite simple and allow a real-time implementation. What is very interesting is that this simple approach applies almost straightforwardly to the case of the three-dimensional (3-D) one-legged hopping robot (Fig. 16.2b), and moreover this three-part control scheme can also be extended to biped (Fig. 16.2a) or quadruped robots by adding techniques of leg sequencing and using the concept of a virtual leg when pairs of legs operate in unison.

Indeed, this interesting piece of work was not really followed up, but was surely the inspiration for many researches on cyclic systems. Among these, purely passive walkers have largely been considered, and we will now provide some insight into this area.

16.2.2 Stability of Passive Walking

The aim of this section is to present some basic facts and concepts related to passive walking. Many more details may be found in the literature, for example

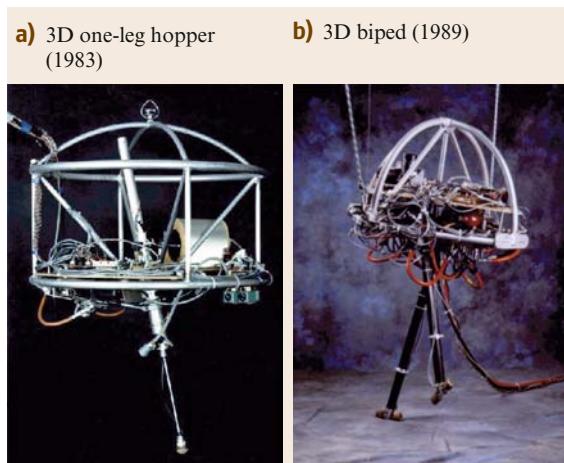

Fig. 16.2a,b Raibert's hopping robots [16.5]

in [16.1, 4, 6] among others. The issues considered here are mainly taken from [16.7]. We use the simplest possible model (Fig. 16.3), an unactuated symmetric planar compass descending a slope of angle ϕ . Masses are pinpoint, and telescopic massless legs are only a way of ensuring foot clearance. Several assumptions underlie the model. Among these, let us mention that the swing phase is assumed to be slipless, and that the double stance phase, during which the swing and support leg are exchanged, is instantaneous. The related impact is slipless and inelastic. We define (following the notation in Fig. 16.3):

$$\begin{cases} \mu = \frac{m_H}{m}; \beta = \frac{b}{a} \\ \mathbf{x} = [\mathbf{q}, \dot{\mathbf{q}}]^\top = [q_{ns}, q_s, \dot{q}_{ns}, \dot{q}_s]^\top. \end{cases} \quad (16.1)$$

The swing-stage equations of the robot, similar to those for a frictionless double pendulum, can be written in the form of Lagrangian dynamics

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \frac{1}{a}\tau_g(\mathbf{q}) = 0, \quad (16.2)$$

where

$$\mathbf{H}(\mathbf{q}) = \begin{pmatrix} \beta^2 & -(1+\beta)\beta \cos 2\alpha \\ -(1+\beta)\beta \cos 2\alpha & (1+\beta)^2(\mu+1)+1 \end{pmatrix},$$

$$\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) = \begin{pmatrix} 0 \\ -(1+\beta)\beta \dot{q}_{ns} \sin(q_s - q_{ns}) \\ (1+\beta)\beta \dot{q}_s \sin(q_s - q_{ns}) \\ 0 \end{pmatrix},$$

$$\tau_g(\mathbf{q}) = \begin{pmatrix} g\beta \sin q_{ns} \\ -[(\mu+1)(1+\beta)+1]g \sin q_s \end{pmatrix},$$

where 2α is the inter-leg hip angle.

The specificity of this system with respect to, for example, manipulation robots, is that we have to complete the continuous dynamics with equations describing the step transition. We will encounter this requirement of separate modeling in legged locomotion again when presenting the dynamics of bipedal walking (Sect. 16.3.2).

The pre- and the post-impact configurations of the robot can be related by $\mathbf{q}^+ = \mathbf{S}\mathbf{q}^-$, where \mathbf{S} is a 2×2 antisymmetric matrix with unit elements. The principle of conservation of angular momentum applied to the robot gives $\mathbf{Q}^-(\alpha)\dot{\mathbf{q}}^- = \mathbf{Q}^+(\alpha)\dot{\mathbf{q}}^+$, from

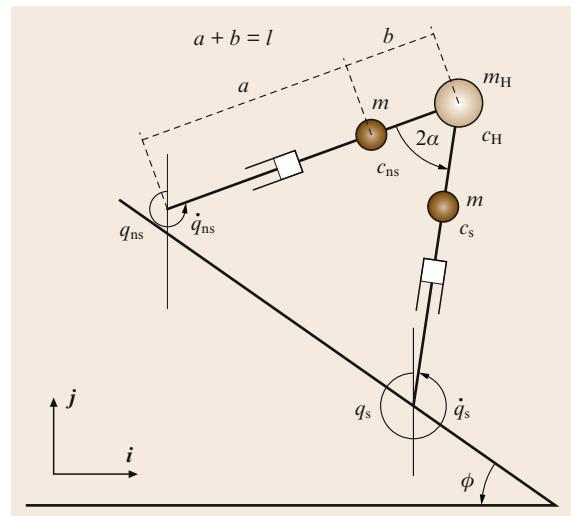

Fig. 16.3 Compass model

which we can obtain the joint velocity relationship $\dot{\mathbf{q}}^+ = [\mathbf{Q}^+(\alpha)]^{-1}\mathbf{Q}^-(\alpha)\dot{\mathbf{q}}^- = \mathbf{A}(\alpha)\dot{\mathbf{q}}^-$, where

$$\begin{aligned} \mathbf{Q}^-(\alpha) &= \begin{pmatrix} -\beta & -\beta + [\mu(1+\beta)^2 + 2(1+\beta)] \cos 2\alpha \\ 0 & -\beta \end{pmatrix}, \\ \mathbf{Q}^+(\alpha) &= \begin{pmatrix} \beta[\beta - (1+\beta) \cos 2\alpha] \\ \beta^2 \\ (1+\beta)[(1+\beta) - \beta \cos 2\alpha] \\ \dots + 1 + \mu(1+\beta)^2 \\ -\beta(1+\beta) \cos 2\alpha \end{pmatrix}. \end{aligned}$$

The complete state vector \mathbf{x} before and after impact can thus be written as

$$\mathbf{x}^+ = \mathbf{W}(\alpha)\mathbf{x}^- \quad (16.3)$$

$$\text{with matrix } \mathbf{W}(\alpha) = \begin{pmatrix} \mathbf{S} & 0 \\ 0 & \mathbf{A}(\alpha) \end{pmatrix}.$$

The periodic dynamic behavior of this system can be summarized in the phase portrait given in Fig. 16.4, where discontinuities result from impacts. The stability of this system can be analyzed in terms of *orbital stability*, a theoretical definition of which can be found in [16.7]. Intuitively, this means that, when the system deviates from its trajectory in the phase plane within a certain domain (the basin of attraction), its natural be-

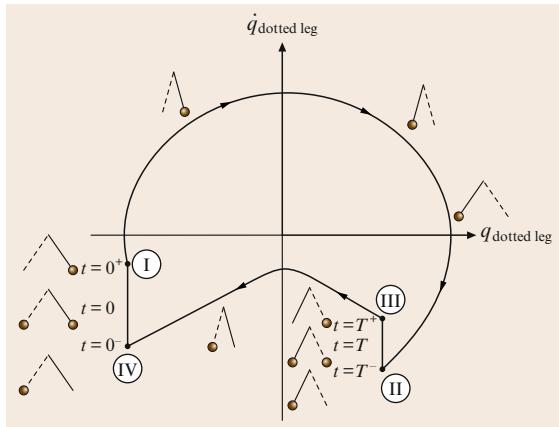

Fig. 16.4 Typical cycle

havior is to return to this phase-plane trajectory, called the limit cycle.

The concept of orbital stability is well suited to the analysis of cyclic systems such as steady-state walking. Thus, the robustness of the obtained gait can be assessed by measuring the size of the basin of attraction. However, for a general nonlinear system, the proof of the existence of a limit cycle, the analysis of its local orbital stability, and the procedure to compute the cycle and its basin of attraction are often difficult. For example, in the present case, the analysis would require the explicit integration of the dynamics during the swing phase. Nevertheless, it is possible to test the local stability of a limit cycle, once it has been found. One method to determine the stability of the robot gait is through the numerical computation of its Poincaré

map [16.4]. Limit cycles are fixed points of this map, which in the context of biped locomotion is called the *stride function* [16.4]. Essentially the procedure consists of injecting small perturbations to the robot states around the limit cycle and calculating the eigenvalues of the sensitivity matrix. For an orbitally stable cycle the eigenvalues lie within the unit circle. A natural choice of the Poincaré section corresponds to the state where the swing leg hits the ground. This introduces a natural discretization of the dynamics. For two successive touchdowns of the same leg, the states of the robot are related as:

$$\mathbf{x}_k = \mathbf{F}(\mathbf{x}_{k+1}). \quad (16.4)$$

The equilibrium is the solution of $\mathbf{x}^* = \mathbf{F}(\mathbf{x}^*)$. By taking a first-order expansion, we have

$$\mathbf{F}(\mathbf{x}^* + \Delta\mathbf{x}^*) \approx \mathbf{x}^* + (\nabla\mathbf{F})\Delta\mathbf{x}^*. \quad (16.5)$$

Therefore, $(\nabla\mathbf{F})\Delta\mathbf{x}^* \approx \mathbf{F}(\mathbf{x}^* + \Delta\mathbf{x}^*) - \mathbf{x}^*$, and a numerical procedure can be used to check whether the moduli of the eigenvalues of $(\nabla\mathbf{F})$ are strictly less than 1. One method is to apply successively smaller perturbations to every state and observe their first-return map, then to numerically solve the equation $(\nabla\mathbf{F})\boldsymbol{\tau} = \boldsymbol{\Psi}$, where the 4×4 diagonal matrix $\boldsymbol{\tau}$ collects the state variable perturbations and $\boldsymbol{\Psi}$ the measured variations in the first-return map. Note that this method is quite general and can be applied to other kind of mechanical systems that exhibit a periodic behavior.

It has been shown that passive walking robots can exhibit stable limit cycles. Often, for a given slope, ϕ , and for a particular range of slopes, the number of such stable behaviors is one. Interestingly, increasing ϕ may lead to the appearance of period doubling, evolving towards a chaotic behavior if ϕ is too large (Fig. 16.5).

In conclusion, it should be emphasized that this class of machines has inspired the design of efficient simple biped robots. Indeed, systems that exhibit natural passive gaits are *optimal* in some energetic sense. A limit cycle is analogous to the comfortable walking gait of humans, in which the consumption of metabolic energy per unit distance is minimal. An interesting idea is therefore to add to a passive system a minimum set of actuators in order to just compensate for the loss of energy when the system is not on a descending slope. Several laboratory realizations are based on this principle, but this idea has yet to be exploited for operational legged robots.

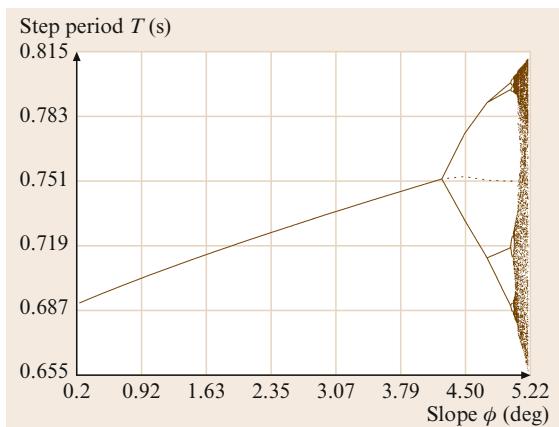

Fig. 16.5 Bifurcations and chaos

16.3 Control of Biped Robots Using Forward Dynamics

This section presents a view of the state of the art in modeling and control of biped robots in the framework of forward dynamics. Space does not allow to go deeply into the details of the equations or their derivation, which is why we only provide the reader with the essential issues and refer to more complete papers, such as [16.8, 9] and mainly the deep analysis of [16.10, 11].

16.3.1 Configuration Space

A biped robot is usually modeled as a rigid tree-form tridimensional articulated structure. Basically, the internal parameterization is q_1 , while that of the joint space is Q . If the robot is considered as having its foot (resp. feet) motionless during every phase of swing (resp. stance), then the model is that of a classical robot manipulator. If all joints are actuated, then the closure equations make the robot overactuated during the stance phase (with two feet on the ground). However, it is more correct and general to consider a walking robot as a free system in space, but subject to nonconstant unilateral contacts. The configuration space is therefore $\{Q\} \oplus R^3 \oplus SO(3)$, where the six-dimensional (6-D) displacement of a given body is parameterized by q_2 .

16.3.2 Dynamics

A basic modeling approach consists of splitting the dynamics equations into three parts: Lagrangian dynamics in the full space; constraints due to contact forces; and transition equations with impacts.

Continuous Dynamics and Contact Forces

Under the assumption that the robot structure is rigid, continuous dynamics can be expressed in the Lagrangian form

$$\mathbf{H}(q)\ddot{q} + \mathbf{C}(q, \dot{q})\dot{q} + \mathbf{G}(q) = \boldsymbol{\Gamma} + \boldsymbol{\Gamma}_{\text{ext}}, \quad (16.6)$$

where $q = (q_1, q_2) \in \mathcal{R}^n$ is defined in Sect. 16.3.1. $\boldsymbol{\Gamma} = [0, \tau]^T \in \mathcal{R}^n$ is the generalized efforts vector, including the joint actuation torques (generally bounded), $\tau \in \mathcal{R}^m$; \mathbf{H} is the inertia matrix, \mathbf{C} is the matrix of centrifugal, gyroscopic, and Coriolis effects, and τ_g is the generalized gravity force vector. The set (q, \dot{q}) constitutes the *state* of the robot.

The points of the robot in contact with the ground satisfy a closure equation of the form

$$\boldsymbol{\phi}(q) = \begin{pmatrix} \boldsymbol{\phi}_n(q) \\ \boldsymbol{\phi}_t(q) \end{pmatrix} = 0,$$

where $\boldsymbol{\Gamma}_{\text{ext}}$ are the torques generated by these ground contact, which can be expressed as

$$\boldsymbol{\Gamma}_{\text{ext}} = \mathbf{J}(q)^T \boldsymbol{\lambda}(q, \dot{q}),$$

where $\mathbf{J}(q) = \frac{\partial \boldsymbol{\phi}(q)^T}{\partial q}$ is the Jacobian matrix of the contact points of the robot, i.e., where the external forces are applied. $\boldsymbol{\lambda}(q, \dot{q})$ are Lagrange multipliers. We can split this expression into two parts

$$\boldsymbol{\Gamma}_{\text{ext}} = \mathbf{J}_n(q)^T \boldsymbol{\lambda}_n(q, \dot{q}) + \mathbf{J}_t(q)^T \boldsymbol{\lambda}_t(q, \dot{q}).$$

The subscripts ‘n’ and ‘t’ stand for normal and tangential to the ground components, respectively. The Lagrange multipliers $\boldsymbol{\lambda}_n$ and $\boldsymbol{\lambda}_t$ express the amplitudes of those efforts.

Now, there are two main ways of modeling the ground interaction. First, it is possible to consider a viscoelastic model, but this suffers from possible problems in the physical analysis and numerical integration. We will consider here the opposite case: that the contacts are rigid and result in a set of constraints, called unilateral, such as nonpenetration, to which should be added a friction model. The semipositive normal forces and accelerations of the contact points are therefore related by a complementarity condition [16.10, 12]

$$\boldsymbol{\lambda}_n^T(q, \dot{q}) \ddot{\boldsymbol{\phi}}_n(q) = 0, \boldsymbol{\lambda}_n(q, \dot{q}) \geq 0, \ddot{\boldsymbol{\phi}}_n(q) \geq 0.$$

Excluding the case where the system is slipping, tangential constraints can be written as

$$\ddot{\boldsymbol{\phi}}_t(q) = 0.$$

Finally, since the existence of friction limits the allowed tangential forces, a nonslip condition is satisfied as long as

$$\|\boldsymbol{\lambda}_t\| \leq \mu_0 \boldsymbol{\lambda}_n,$$

where μ_0 is the friction coefficient, which depends on the materials in contact.

Impacts

As stated in Sect. 16.2.2, if the impact is assumed to be inelastic and nonsliding, the velocity of the system jumps from \dot{q}^- to \dot{q}^+ according to the equations

$$\mathbf{H}(q)(\dot{q}^+ - \dot{q}^-) = \mathbf{J}_n(q)^T \boldsymbol{\Lambda}_n(q, \dot{q}) + \mathbf{J}_t(q)^T \boldsymbol{\Lambda}_t(q, \dot{q}),$$

where $\boldsymbol{\Lambda}(q, \dot{q}) = [\boldsymbol{\Lambda}_n(q, \dot{q}), \boldsymbol{\Lambda}_t(q, \dot{q})]^T$ is the vector of the impulse forces.

Under the assumption that contact points do not move after impact, we can write:

$$\dot{\phi}_n(q) = J_n(q)\dot{q}^+ = 0 \quad \text{and} \quad \dot{\phi}_t(q) = J_t(q)\dot{q}^+ = 0$$

Dynamic Balance

Basically, a biped robot is in equilibrium if it maintains a walk without falling. In the early times of robotics, the gaits were *statical*. This means that, when the velocities and accelerations are small, and assuming that contact points are motionless during each phase of the step, the balance condition reduces to the classical one: the projection of the robot's center of mass belongs to the convex hull of contact points. Therefore, a static walk can be defined as a continuous sequence of configurations ensuring the forward progression and maintaining the erected position of the system simultaneously such that at each instant the static equilibrium condition is satisfied. As we will see later, related control schemes are easy to design.

However, the true interesting issue is dynamic balance. Nicely addressed in the case of Raibert's hopping robots or for passive walkers through orbital stability as presented in Sect. 16.2.2, the questions of stability and balance deserve a deeper analysis in the case of other kinds of biped robots, such as the work described in [16.11].

For a biped robot, the *dynamical equilibrium* can be intuitively linked to the idea of a possible movement. Let us firstly return to the dynamics; splitting the equations in a way coherent with the two parts of the configuration space, the dynamics (16.6) can be rewritten as:

$$\begin{cases} H_1(q)\ddot{q} + C_1(q, \dot{q})\dot{q} = \tau + J_1(q)^\top \lambda - \tau_{g1}(q), \\ H_2(q)\ddot{q} + C_2(q, \dot{q})\dot{q} = 0 + J_2(q)^\top \lambda - \tau_{g2}(q), \end{cases} \quad (16.7)$$

where τ is the set of actuator torques.

It can be shown [16.11] that the left-hand side of the second equation of (16.7) is equivalent to the dynamic wrench of the system, while the right-hand side is equivalent to the wrench of contact and gravity forces. This equation is of the Newton–Euler form, where the Newton part can be expressed easily in terms on the acceleration of the center of mass of the robot. This shows a fundamental issue: the global displacement and orientation of the robot can only be realized through contact forces. Moreover, this motion is necessarily associated with a change of posture. More generally, the system can achieve a desired movement if and only if the total

wrench of gravity and contact forces is equal to the dynamic wrench of the robot. For a given control scheme, the question is then to check whether this property is satisfied by the robot under control.

In the case where all contact points are in the same plane, it can be shown that there exists a point in this plane around which the horizontal rotation momentum of gravity and dynamic forces vanishes. This point is known as the *zero-moment point* (ZMP), and is also the *center of pressure* (CoP). We will see in Sect. 16.4 how this concept allows the derivation of efficient control schemes.

Another way of setting the problem of the dynamic balance of a walking machine while also taking into account nonhorizontality and tangential forces is to state the problem as follows. A necessary condition for a walking system to realize a motion specified by a trajectory $q(t)$ on a given time interval is that there exists contact forces $\lambda(t)$ such that

$$\begin{cases} H_2(q)\ddot{q} + C_2(q, \dot{q})\dot{q} + \tau_{g2}(q) = J_2(q)^\top \lambda, \\ A(\lambda) \geq 0, \end{cases} \quad (16.8)$$

where the vector inequality $A(\lambda) \geq 0$ gathers all constraints on normal (unilaterality) and tangential (Coulomb friction) forces. Finally, the motion can definitively be achieved if the actuation forces are compatible with the dynamical requirements of the first equation of (16.7). As an illustration of this, we will propose in the next section a control method in relation to this approach.

16.3.3 Trajectory Generation

A frequently used approach for designing a full biped control scheme is to combine the a priori definition of desired trajectories to follow, a classical control allowing them to be tracked, and dedicated online adaption techniques to cope with model uncertainties, obstacles, and disturbances to prevent the robot from falling. Two main classes of methods can be used to compute the desired (also called *reference*) trajectories: they can either be obtained from capturing human motions, or be purely computer generated. In the latter case, the usual approach includes two steps: first, a set of output variables with adequate dimension is chosen. This is generally made from the three-dimensional (3-D) coordinates of a few selected points on the robot. Secondly, after parameterization (under the form of splines, for example) the desired trajectories of these variables are computed for every phase of the gait: stance, swing, left or right, etc.,

allowing one to take into account, for example, obstacles or stairs. They can be either all synchronized in time, or be functions of a single timed reference coordinate. The most interesting way of achieving this computation is to use an optimization algorithm based on the dynamics that takes into account various constraints. The trajectories either remain specified in the output space or are transformed in trajectories in the joint space, $\mathbf{q}_d(t)$. Finally, these trajectories are tracked by a controller, as explained later; an online walk stabilization mechanism is often added.

Another approach to be mentioned is the possibility to use bio-inspired techniques, such as the central pattern generator. The idea is to design self-oscillating systems (i.e., without inputs, although the shape of the output is tunable through some parameters) from which synchronized periodic motions of the joints can be derived. This approach is generally used for generating gaits for multilegged robots (quadrupeds, hexapods) or snake-like systems, but some works also address biped robots [16.13]. The most well-known nonlinear oscillator is the Van der Pol equation

$$\ddot{y} + a(1 - by^2)\dot{y} + c^2 y = 0, \quad (16.9)$$

from which many variations can be derived. Similar results can be obtained from a more biologically inspired point of view, through the design of neural oscillators [16.14]. In this case, sets of artificial neural networks with possible open-loop sinusoidal excitation are connected to generate plausible walking patterns. In some cases it is even possible to create a kind of feedback to cope with environmental variations or to improve stability [16.15].

16.3.4 Control

We present in this subsection three examples of control schemes only, without details. Indeed, many kinds of control schemes are reported in the literature and it is not possible in a single chapter to provide an exhaustive view. We therefore refer the reader to the best journals and conferences in this field for more information [16.16–23].

Simple Dynamic Control

For simplicity, let us only consider the case where the desired walking behavior is specified as a set of multidimensional reference joint trajectories, $\mathbf{q}_d(t)$, defined for every distinct walking phase. It is now necessary to design a control scheme allowing these trajectories to be tracked as accurately as possible in the ideal case. Basi-

cally, a proportional–integral–derivative (PID) loop on the tracking error is the core of such a control scheme. However, since the use of high gains in a PID controller is not always desirable, due both to the presence of noise and to the need for discretization, good tracking performance require the integration of mechanical modeling issues into the control. When the dynamics of the system are well known, it is often interesting to use them, in a so-called computed torque approach, in which the applied control torque is of the generic form

$$\boldsymbol{\Gamma} = \hat{\mathbf{H}}(\mathbf{q})(k_p(\mathbf{q} - \mathbf{q}_d) + k_v(\dot{\mathbf{q}} - \dot{\mathbf{q}}_d) + \ddot{\mathbf{q}}) \\ + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \hat{\mathbf{t}}_g(\mathbf{q}) + \hat{\mathbf{I}}_F, \quad (16.10)$$

where, in relation to the dynamics of (16.6), the hats mean that approximate models are used. $\hat{\mathbf{I}}_F$ covers friction aspects and the k_* are control gains. This form is given in the joint space, but can be also used in other diffeomorphic output spaces. Concerning the models, let us note that, at least, the compensation of gravity term $\hat{\mathbf{t}}_g(\mathbf{q})$ should be considered. Moreover, one of the most important source of errors is the effect of internal friction. As soon as an effective model of friction in joints, gears, and actuators, $\hat{\mathbf{I}}_F$, is available, it should be used, of course with care. In practice, if foot switches exist, phase transitions, leg synchronization, and reinitialization of the trajectories on their cycle can be triggered by the events generated by such sensors (see also Sect. 7.4).

This kind of control can be used at least for generating static walking. If the trajectories have been generated in a dynamical framework, for example, by taking into account a desired position of the ZMP, it can also be used in dynamic walk, possibly with the addition of a dedicated stabilization algorithm. Many variations of this scheme exist based, for example, the linearization of the dynamics, or the use of an inverted-pendulum model.

Nevertheless, although this kind of control can overcome some internal disturbances, it is neither sufficient to ensure the stability of walking in a robust enough way in real time, nor able to cope with environmental uncertainties. The basic requirement is now to find a way of controlling the ground contact forces in order to be sure that the support foot (or feet) remain motionless when it is specified and/or needed by the reference trajectory. This means that the control has to ensure that the inequality conditions (no sliding, no take-off), which involve the Lagrange multipliers as stated in Sect. 16.3.2, are verified at each time despite disturbances. Nevertheless, this capacity of reaction will be limited by the bounds that exist on the actuators.

An adequate way of addressing the question of online walk stabilization is to share the control in two parts [16.24, 25]: a first part, which is devoted to the tracking of the prescribed trajectory and involves a large subset of the joints and a second part, dedicated to the control of the ground forces through selected joints (the trunk, or more often, the ankles). It can effectively be shown that controlling ankle torques is a way of approximately control ground reaction forces through an adequate compliant model. Like the similar scheme called *hybrid control* in robot manipulators (see Sect. 7.4), the implementation can use the contact wrenches more or less directly, estimated from force/torque sensors integrated within the ankles or the soles of the feet.

A Variation: The Use of Parameterized Trajectories

A drawback of the classical tracking trajectory approach is that it is necessary to explicitly design as many trajectories as possible situations. Therefore, adaptation to disturbances requires a jump from one trajectory to another, for example, in order to stride over a small obstacle or when it is required to increase or lower the overall velocity by modifying the shape, duration, and length of the prescribed step. An interesting attempt to derive a systematic way of online adaption of the behavior of the system consists of adding degrees of freedom to the definition of the trajectories to be tracked by parameterizing them [16.26]. The principle of the method is described below.

Let us consider that, in fact, the reference trajectory depends on a set of time-varying twice-differentiable parameters p : $\mathbf{q}_d = \mathbf{q}_d[p(t)]$. Various characterizations of the trajectories may appear in p : step length, maximal height of the heel trajectory, time scaling, etc. These parameters are reflected, for example, in the coefficients of the splines that define the trajectories. They are set to a nominal value p^* corresponding to the desired motion. However, since they are supposed to evolve when needed, it is necessary to set their dynamics of return to p^* , through a linear second-order behavior $\ddot{p}_d = f(p, \dot{p}, p^*)$. Now, it can be shown that it is possible to gather the dynamics, including a PD control scheme like (16.10), the unilaterality of contacts, the requirements of nonsliding and no take-off, and the bounds on actuators, all described in Sect. 16.3.2 and summarized in (16.8), into a single vector inequality of the form

$$A(\mathbf{q}, \dot{\mathbf{q}}, p, \dot{p}, \ddot{p}) \leq 0. \quad (16.11)$$

The problem is now solved by finding at each time through an adequate optimization method (such as FSQP (feasible sequential quadratic programming), originally developed at ISR (Institute of Systems Research), University of Maryland) the parameter acceleration \ddot{p} that minimizes $\|\ddot{p}_d - \ddot{p}\|^2$ while ensuring that (16.11) is satisfied. This approach is, for example, able to compensate for disturbances such as external forces applied to the body, since they are reflected at the internal-state level, and are therefore accounted for through the respect of the inequality (16.11). It has been shown [16.26] that it is possible to increase the range of acceptable disturbances by a factor ten using this method, compared to nonadaptive approaches. Furthermore, the use of exteroceptive sensors such as distance, proximity, and vision is allowed as soon as they directly generate a modification of the parameters, for example, in order to climb a stair or avoid an obstacle.

Online Optimization

The ultimate way to adapt the motion of the robot in real time is to even avoid using any type of precomputed trajectories. This requires that both the desired motion and the related control can be computed online. In the most general case, one can even imagine that these two steps could be fused into a single approach. Besides, thanks to the exponential growth of available embedded computing power, it is now possible to envision the computation of accurate dynamical models and/or the use of complex optimization techniques in real time. This is why we propose to end this part of the chapter with the description of promising optimization-based methods that avoid the explicit synthesis of analytical trajectories.

Model Predictive Control (MPC). The idea is to start from well-known *model predictive control (MPC)* techniques based on the following principle. Let us assume that a dynamical model of the system that is good enough for synthesizing a control scheme is available. Then, the following operations are achieved at each sampling time:

1. measurement of the actual state
2. computation of the control that optimizes a given state-dependent cost function on a finite horizon, starting from the current discrete time
3. application of the control input at the first time index only
4. return to step 1

A main drawback of the standard approach is that the available theoretical results of stability are presently

limited to the linear case or to very particular classes of nonlinear systems. For example, the nonlinear model predictive control (NMPC) presents stability properties under certain assumptions. Moreover, it has some ability to handle constraints, which makes it well suited to the problem of walking pattern synthesis and control of a biped robot subject to unilateral constraints or disturbances due to an unstructured environment. A complete overview of theoretical and practical results concerning the MPC or the NMPC can be found in [16.27]. However, it can be seen from these papers that applying such algorithms is not straightforward when dealing with highly dynamical systems such as robots.

Trajectory-Free NMPC. Following the idea of the parameter adaptation method presented earlier based on the real-time minimization of a cost function through an SQP (sequential quadratic programming) method, an alternative approach consists of solving at every time point a constrained optimization problem with a moving horizon [16.28]. A set of constraints is imposed in order both to ensure the feasibility of walking and to satisfy the user's requirements. Defining these constraints is then the only way which is used to express all the issues involved in the motion of the robot.

As an example of such specifications, let us consider the swing phase in normal steady-state walking. The *inequality* constraints belong to two distinct subsets.

1. Intrinsic constraints related to safety issues:

- respecting physical limits: the admissible control torques belong to a given set, which may depend on the instantaneous joint velocities; the range of angular joint positions is bounded;
- ensuring stability: all along the swing phase, the normal contact forces at the support foot are

strictly greater than given positive values; the absolute values of the tangential forces are less than given thresholds that depend on the friction parameters.

2. The constraints associated with the gait specification:

- achieving forward progression: the horizontal velocity of the ankle of the swing leg belongs to a given positive interval; the horizontal position of the pelvis stays inside the position of the toes of the support foot and the horizontal position of the heel of the swinging foot;
- controlling the posture: the angle expressing the trunk bending is positive and bounded; the angle between the sole of the swing foot and the ground is fixed; the height of the pelvis is low-bounded;
- ensuring foot clearance: the altitude of the ankle is constrained to stay inside a given area (for example, specified by two polynomial functions of its horizontal position). These functions are a way of avoiding obstacles or climbing stairs.

All these constraints can be gathered in the single vector inequality $g(\cdot) \leq 0$. The *equality* constraints are mainly:

- the dynamics itself (16.6) instanced for the swing phase
- the initial conditions on the state: at time t_{k+1} , they are the final state at time t_k

Therefore the method consists of optimizing, from the inputs (control, state, contact forces, etc.), the anticipated future behavior of the system, subject to the constraints above, using an internal model over a finite sliding time horizon, which is the prediction horizon. Since the problem is finally termed open-loop constrained optimization, solved at each sampling time, the last step is to define an objective function to minimize. Usually, such a cost function includes a term linked to the final state over the prediction horizon and a quadratic expression reflecting some energetic considerations.

The solution of the optimization algorithm is a sequence of N_c control inputs over the prediction horizon N_p . Only the first input is applied to the system and the procedure starts again. It should be noted that the feedback effect, which should be included in any real-time control, appears through the use of *actual* current values of the state in the optimization. Furthermore, the adaptation of the motion in order to react to unexpected events can be performed by modifying online the set of equality and inequality constraints.

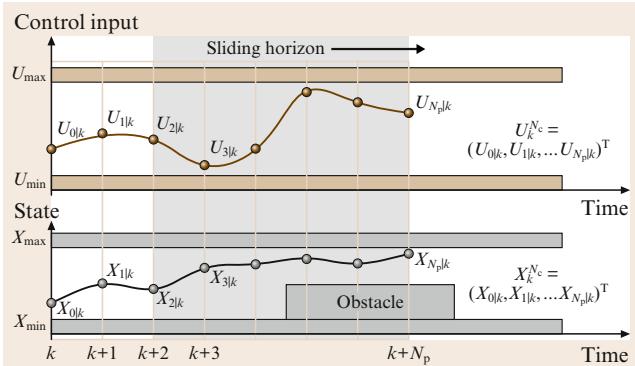

Fig. 16.6 NMPC principles

Let us consider Fig. 16.6, for example. Here, the state $X_{i|k}$ is the prediction of the heel altitude at time $k+i$, computed from the current time k . Then the detection of an obstacle leads to modification of the polynomial that is the lower limit of the trajectory of X . The prediction horizon finally allows one to anticipate the dynamical

behavior of the system, which ensures that the foot safely crosses over the obstacle.

This method is known as trajectory-free nonlinear model predictive control and is described in detail in [16.28]. An extension of the predictive control method to the case of ZMP-based control is presented in [16.29].

16.4 Biped Robots in the ZMP Scheme

The zero-moment point (ZMP) might be one of the most famous technical terms born in robotics community. Figure 16.7 shows two important figures in the scene of ZMP-based biped walking. Figure 16.7a is WL-10RD, developed by Takanishi and Kato. This is the first ZMP-based robot, which successfully realized dynamic biped walking in 1985 [16.30]. It is a 12-degree-of-freedom (DOF) biped, 1.43 m high and weighing 84.5 kg, and driven by hydraulic actuators.

Figure 16.7b is ASIMO, a 26-DOF humanoid robot developed by Honda Motor Co. in 2000 [16.31]. This is one of the most famous robots in public culture, and at the same time, its superior performance of biped locomotion (walking and running) is well acknowledged by specialists. According to the published papers and patents, ZMP takes an important role in the walking control of ASIMO.

In this section, we describe the basic definition, the calculation, and the usage of ZMP.

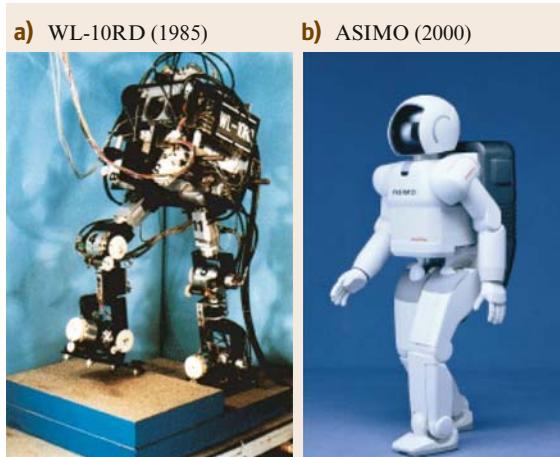

Fig. 16.7a,b Biped robots controlled in the ZMP scheme [16.30, 31]

16.4.1 Mechanisms

Figure 16.8 shows recently developed biped robots controlled by the ZMP scheme. Figure 16.8a is Johnnie, developed by Gienger et al. in 2001 [16.32]. It is a 1.80 m-high 17-DOF humanoid weighing 40 kg, driven by direct-current (DC) servo motors with harmonic drive gears and ball screws. Figure 16.8b is HRP-2L, which was developed by Kaneko et al. [16.33]. It is a 1.41 m-high 12-DOF biped weighing 58.2 kg, driven by DC servo motors with harmonic drive reduction gears. Figure 16.8c is WL-16R, developed by Takanishi et al. [16.34] as a walking chair that can carry a human weighing up to 94 kg. It is a 1.29 m-high 12-DOF biped weighing 55 kg with Stewart-platform-type legs driven by electric linear actuators. Figure 16.8d is HUBO, developed by Oh et al. [16.35]. It is a 1.25 m-high 41-DOF humanoid robot weighing 55 kg.

Although these robots have different leg mechanism and outlook, they share some common features:

1. there are at least six fully actuated joints for each leg,
2. the joints are position controlled,
3. the feet are equipped with force sensors, which are used to measure the ZMP.

As we will see in the following subsections, these are the fundamental requirements for ZMP-based walking robots.

16.4.2 Zero-Moment Point (ZMP)

The term *zero-moment point (ZMP)* was coined by Vukobratović and Stepanenko in 1972. They said [16.36]:

In Fig. 16.9 an example of force distribution across the foot is given. As the load has the same sign all over the surface, it can be reduced to the resultant force R, the point of attack of which will be

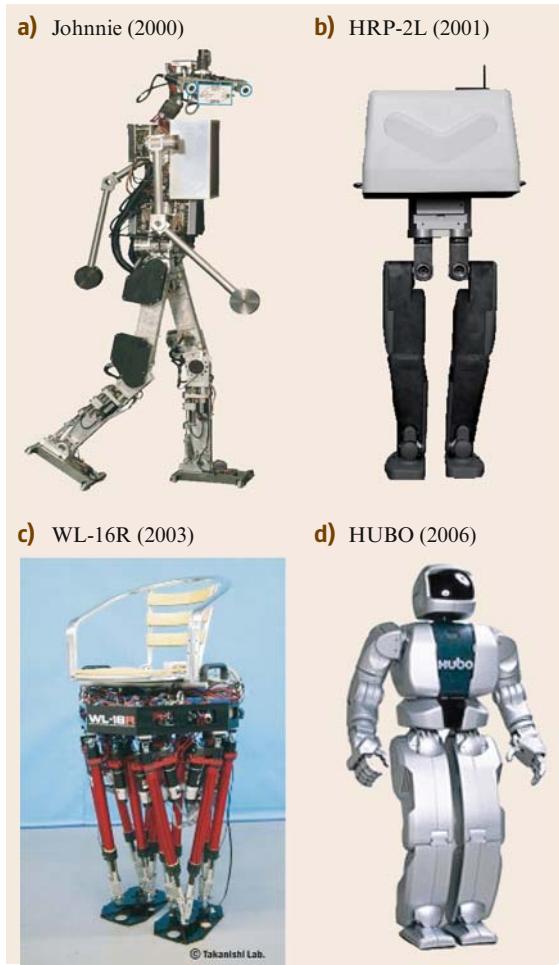

Fig. 16.8a-d Biped robots controlled in the **ZMP** scheme [16.32–35]

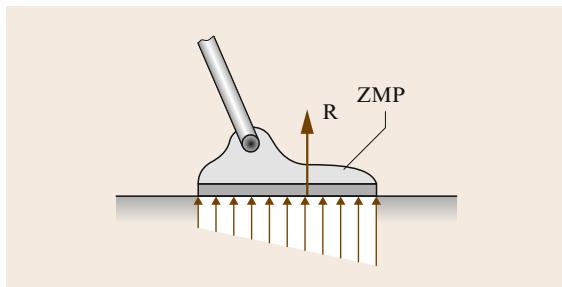

Fig. 16.9 Original definition of the zero-moment point (**ZMP**) [16.36]

in the boundaries of the foot. Let the point on the surface of the foot, where the resultant R passed,

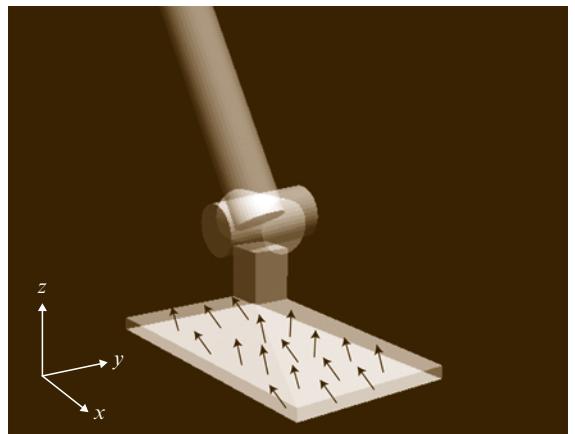

Fig. 16.10 Floor reaction force in three dimensions

be denoted as the zero-moment point, or **ZMP** in short.

We can see that the **ZMP** is defined as a center of pressure (CoP) of the floor reaction force.

For the further discussion, let us discuss detailed floor reaction force in three dimensions, as shown in Fig. 16.10.

Suppose that the floor reaction force is acting on a finite number of contact points $\mathbf{p}_i (i = 1, \dots, N)$ and that each force vector is of the form

$$\mathbf{f}_i := [f_{ix} \ f_{iy} \ f_{iz}]^\top ,$$

where f_{ix} , f_{iy} , and f_{iz} are the force components in the x , y , and z directions in the coordinate system fixed to the ground, respectively. The **ZMP** can be calculated as

$$\mathbf{p} := \frac{\sum_{i=1}^N \mathbf{p}_i f_{iz}}{\sum_{i=1}^N f_{iz}} . \quad (16.12)$$

It can also be written as

$$\mathbf{p} = \sum_{i=1}^N \alpha_i \mathbf{p}_i , \quad (16.13)$$

$$\alpha_i := f_{iz}/f_z , \quad (16.14)$$

$$f_z := \sum_{i=1}^N f_{iz} . \quad (16.15)$$

Since an ordinary walking robot cannot generate adhesive force on its soles,

$$f_{iz} \geq 0 \quad (i = 1, \dots, N) . \quad (16.16)$$

Then we can say,

$$\begin{cases} \alpha_j \geq 0 & (i = 1, \dots, N), \\ \sum_{i=1}^N \alpha_i = 1. \end{cases} \quad (16.17)$$

The points that satisfy (16.13) and (16.17) form the *support polygon*, the convex hull of the contacting point. Thus, we can conclude that the **ZMP** always exists in the support polygon. In other words, *the ZMP never leaves the support polygon* as the result of the unilateral constraint on the floor reaction force.

Now let us calculate the torque around the **ZMP**:

$$\tau = \sum_{i=1}^N (\mathbf{p}_i - \mathbf{p}) \times \mathbf{f}_i. \quad (16.18)$$

This equation can be rewritten in terms of vector components as

$$\tau_x = \sum_{i=1}^N (p_{iy} - p_y) f_{iz} - \sum_{i=1}^N (p_{iz} - p_z) f_{iy}, \quad (16.19)$$

$$\tau_y = \sum_{i=1}^N (p_{iz} - p_z) f_{ix} - \sum_{i=1}^N (p_{ix} - p_x) f_{iz}, \quad (16.20)$$

$$\tau_z = \sum_{i=1}^N (p_{ix} - p_x) f_{iy} - \sum_{i=1}^N (p_{iy} - p_y) f_{ix}, \quad (16.21)$$

where p_{ix} , p_{iy} , p_{iz} are the components of the position vector \mathbf{p}_i and p_x , p_y , and p_z are the components of the **ZMP**.

When the floor is horizontal, we have $p_{iz} = p_z$ for all i , thus, the second term of (16.19) and the first term of (16.20) become zero. Moreover, by substituting (16.12) into (16.19) and (16.20), we obtain

$$\tau_x = \tau_y = 0. \quad (16.22)$$

This is the reason why \mathbf{p} was named as *zero-moment* point. Nevertheless, one must note that the frictional force creates a nonzero vertical moment (16.21) in the general case.

$$\tau_z \neq 0. \quad (16.23)$$

16.4.3 Computed ZMP: ZMP Calculated from Robot Motion

With given robot dynamics and motion, we can calculate or predict the resulting **ZMP** by using Newton's law. To distinguish this from the original **ZMP** defined in the

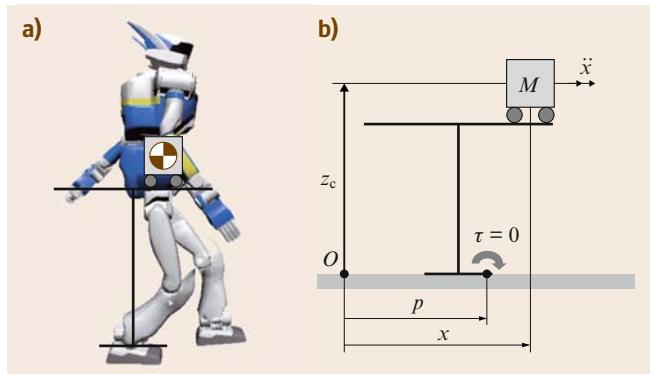

Fig. 16.11a, b Cart-table model [16.37]

former subsection, we will use the term *computed ZMP* as in the paper of Vukobratović et al. [16.3]

Simple Case

Let us start with an extremely simple mechanism. Figure 16.11a illustrates a walking robot and its simplified model, which consists of a running cart on a massless table. The cart has mass M and its position is (x, z_c) corresponds to the center of mass of the robot (Fig. 16.11b). Also, the table is assumed to have the same support polygon as the robot.

In this case, the torque τ around the point p is given by

$$\tau = -Mg(x - p) + M\ddot{x}z_c, \quad (16.24)$$

where g is the acceleration due to gravity. Using the zero-moment condition of $\tau = 0$, the computed **ZMP** of this cart-table model is obtained as

$$p = x - \frac{z_c}{g}\ddot{x}. \quad (16.25)$$

From this equation, we can observe two fundamental facts about the computed **ZMP**.

1. When the acceleration of the cart is zero, the **ZMP** corresponds to the projection of the CoM: $p = x$.
2. The computed **ZMP** is not bounded by the support polygon. In fact, we can easily determine x and \ddot{x} to give any specified value of p .

The second fact is explained in Fig. 16.12a. When the cart acceleration is too large, the computed **ZMP** goes outside of the support polygon. This happens since (16.25) does not consider the support polygon and the unilateral constraint (16.16). In other words, (16.25) assumes that the foot is glued to the floor. If the unilateral constraint is properly considered, we have the state of

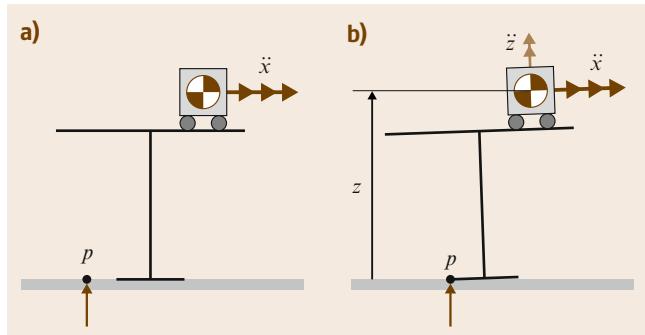

Fig. 16.12a,b Computed ZMP (a) fictitious case (b) correct result

Fig. 16.12b. Since the table is no longer upright, the computed ZMP must be calculated by

$$p = x - \frac{z}{g+z} \ddot{x}, \quad (16.26)$$

which gives the computed ZMP on the edge of support polygon.

In much of the literature, states like Fig. 16.12b are not explicitly discussed, but the computed ZMP is allowed to leave the support polygon under the implicit assumption of the glued foot on the floor. In this case, a computed ZMP outside of the support polygon implies that the robot might not maintain its feet in full contact with the ground and that the walking motion will not be performed as planned.

When the computed ZMP is inside the support polygon, it guarantees the full foot-ground contact under the unilateral constraint, while it tells us nothing about stability in the context of control theory.

Computed ZMP for Full 3-D Dynamics

We will show a method to calculate the computed ZMP of a robot that consists of N rigid-body links in three dimensions. As in the preceding treatment, we assume that the all kinematic information (the position of the CoM, link orientation, link velocity, etc.) have already been calculated by forward kinematics. In this subsection, the link postures and their angular velocities are represented in the ground-fixed coordinate system.

First we calculate the total mass M and the center of mass of the whole robot \mathbf{c} by

$$M = \sum_{j=1}^N m_j, \quad (16.27)$$

$$\mathbf{c} = \sum_{j=1}^N m_j \mathbf{c}_j / M, \quad (16.28)$$

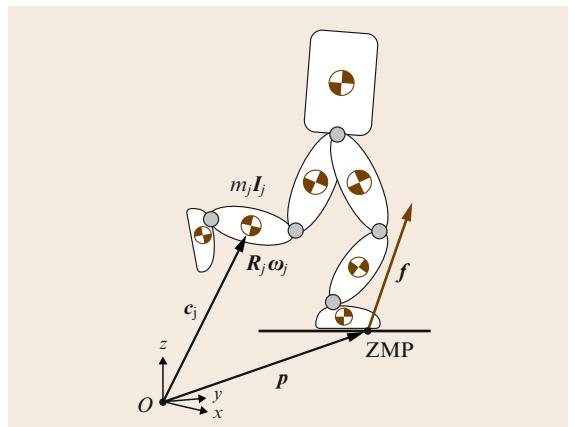

Fig. 16.13 Robot model and ZMP in three dimensions

where m_j and \mathbf{c}_j are the mass and the CoM of the j -th link, respectively.

The total linear momentum \mathcal{P} is given as

$$\mathcal{P} = \sum_{j=1}^N m_j \dot{\mathbf{c}}_j. \quad (16.29)$$

Then the total angular momentum \mathcal{L} with respect to the origin is

$$\mathcal{L} = \sum_{j=1}^N [\mathbf{c}_j \times (m_j \dot{\mathbf{c}}_j) + \mathbf{R}_j \mathbf{I}_j \mathbf{R}_j^\top \boldsymbol{\omega}_j], \quad (16.30)$$

where \mathbf{R}_j , \mathbf{I}_j , and $\boldsymbol{\omega}_j$ are the 3×3 rotation matrix, inertia tensor, and angular velocity of the j -th link, respectively. $\mathbf{R}_j \mathbf{I}_j \mathbf{R}_j^\top$ gives the inertia tensor in the ground-fixed frame.

Applied with the external force f and external moment τ , the change of linear and angular momenta are described by Newton and Euler's law:

$$f = \dot{\mathcal{P}} - Mg, \quad (16.31)$$

$$\tau = \dot{\mathcal{L}} - \mathbf{c} \times Mg, \quad (16.32)$$

where $\mathbf{g} := [00-g]^\top$ is the vector of acceleration due to gravity.

Suppose that the external force is acting on the ZMP located at \mathbf{p} .

$$\tau = \mathbf{p} \times f + \tau_{ZMP}, \quad (16.33)$$

where τ_{ZMP} is the moment at the ZMP, whose first and second components are zero.

Substituting (16.31) and (16.32) into (16.33) we obtain

$$\tau_{ZMP} = \dot{\mathcal{L}} - \mathbf{c} \times Mg + (\dot{\mathcal{P}} - Mg) \times \mathbf{p}. \quad (16.34)$$

The first and the second raws of this equation are

$$\tau_{ZMP,x} = \dot{\mathcal{L}}_x + Mg_y + \dot{\mathcal{P}}_y p_z - (\dot{\mathcal{P}}_z + Mg)p_y, \quad (16.35)$$

$$\tau_{ZMP,y} = \dot{\mathcal{L}}_y - Mg_x - \dot{\mathcal{P}}_x p_z + (\dot{\mathcal{P}}_z + Mg)p_x, \quad (16.36)$$

where we use the notations

$$\tau_{ZMP} := [\tau_{ZMP,x} \ \tau_{ZMP,y} \ \tau_{ZMP,z}]^\top,$$

$$\mathcal{P} := [\mathcal{P}_x \ \mathcal{P}_y \ \mathcal{P}_z]^\top,$$

$$\mathcal{L} := [\mathcal{L}_x \ \mathcal{L}_y \ \mathcal{L}_z]^\top,$$

$$c := [x \ y \ z]^\top.$$

The zero-moment point is calculated from (16.35) and (16.36) using $\tau_{ZMP,x} = \tau_{ZMP,y} = 0$

$$p_x = \frac{Mgx + p_z\dot{\mathcal{P}}_x - \dot{\mathcal{L}}_y}{Mg + \dot{\mathcal{P}}_z}, \quad (16.37)$$

$$p_y = \frac{Mgy + p_z\dot{\mathcal{P}}_y + \dot{\mathcal{L}}_x}{Mg + \dot{\mathcal{P}}_z}, \quad (16.38)$$

where p_z is the height of the floor.

When the robot remains stationary, we have the ZMP as the projection of the CoM:

$$p_x = x, \quad (16.39)$$

$$p_y = y. \quad (16.40)$$

Note that ZMP can also be calculated from the motion equation in Lagrangian form. See Sect. 16.3.2 for more details.

16.4.4 ZMP-Based Walking Pattern Generation

Prescribing Foot and ZMP Trajectories

In the original work, a model with a compensating mechanism was assumed to realize the prescribed ZMP pattern [16.36]. Figure 16.14a illustrates an example model, which uses predetermined leg trajectories while ZMP is controlled by using the compensating mass. This concept was realized by the WL-12 robot developed by Takanishi and Kato (Fig. 16.14b) [16.38].

In modern implementations, the body motion is used to realize prescribed ZMP trajectories, as shown in Fig. 16.15. Instead of the leg joint trajectories, the foot trajectories are prescribed. The leg motion is determined by inverse kinematics from the body and the feet trajectories.

Figure 16.16 shows an example ZMP trajectory for two forward steps. First, the time profile of the support

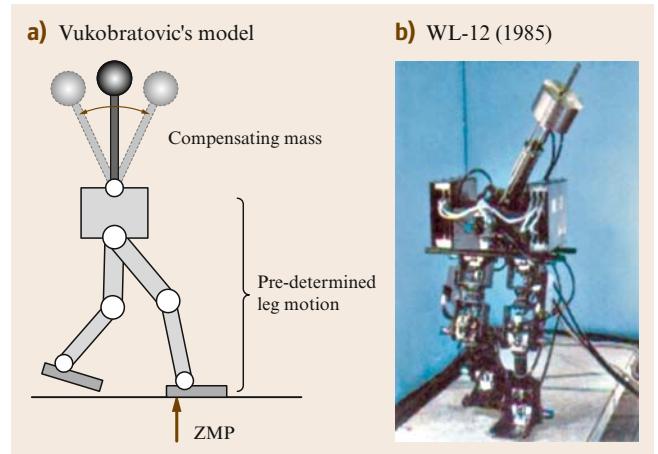

Fig. 16.14a, b Biped robots with compensating mass [16.38]

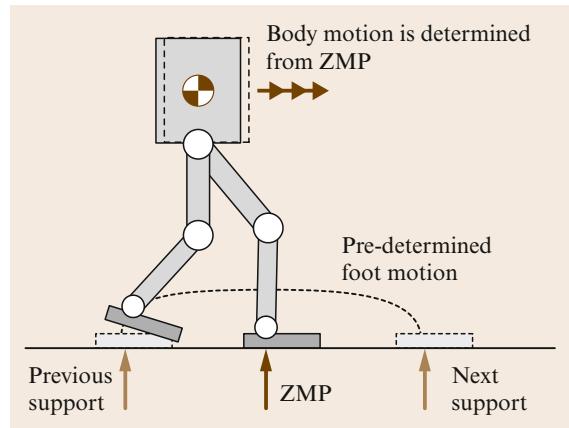

Fig. 16.15 Modern implementation of the ZMP scheme

polygon is determined from the foot trajectory as the gray band. Its width is determined from the foot geometry and the step length and changes at every touchdown (td) and lift-off (lo). Then the ZMP trajectory (bold line) is determined so that it runs within the support polygon. Note that we can design any ZMP trajectories as long as it remains inside of the support polygon with a certain stability margin.

Pattern Generation for the Desired ZMP

Let us define a function $ZMP(\cdot)$ that gives a calculated ZMP for the given robot motion.

$$\begin{pmatrix} p_x \\ p_y \end{pmatrix} = ZMP(q, \dot{q}, \ddot{q}), \quad (16.41)$$

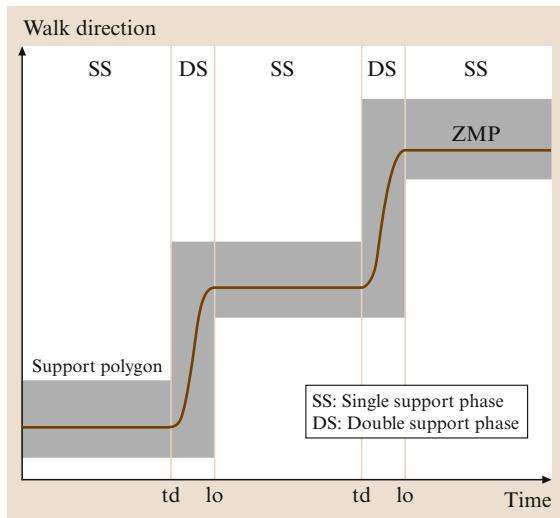

Fig. 16.16 Support polygon and prescribed ZMP trajectory.
td: touchdown; lo: lift-off

where \mathbf{q} , $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$ are the vectors of joint position, velocity, and acceleration, respectively. ZMP-based walking pattern generation is to determine the feasible $\mathbf{q}(t)$ that satisfies given desired ZMP $p_x^d(t)$, $p_y^d(t)$. It should be noted that:

1. As the premise of this method, the robot must be fully actuated and position controlled. Basically, underactuated or torque-controlled robots do not fit in this scheme.
2. When the dimension of \mathbf{q} is larger than three, extra constraints must be introduced to solve the redundancy. For example, constraints of constant body height and upright posture are frequently used.
3. Even under the proper constraints, (16.41) have infinite numbers of solutions because the initial condition $\mathbf{q}(0)$ is left free. This degree of freedom is used to avoid the divergence of the joint trajectories.
4. In practice, we do not need an exact control of ZMP: $p_x(t) = p_x^d(t)$, $p_y(t) = p_y^d(t)$. Nevertheless, it is preferred to minimize the sum of ZMP error during the walking motion.

Several practical methods have been proposed. Takanishi et al. proposed to solve this problem by using Fourier transformation [16.39]. By applying the fast Fourier transformation (FFT) to the ZMP reference, the ZMP equations can be solved in the frequency domain, then the inverse FFT returns the resulted CoM trajectory to the time domain. Kagami et al. proposed a method to

solve this problem in the discrete time domain [16.40]. They showed that the ZMP equation can be discretized as a trinomial expression, and that it can be solved efficiently by an algorithm of $O(N)$ for given reference data of size N .

Another practical method was described by Huang et al. [16.41]. Sugihara et al. proposed a method that can consider the multibody dynamics of a robot [16.42]. Nagasaka et al. proposed an efficient real-time method that is also applicable to running and jumping motion [16.43]. Harada et al. proposed another efficient real-time method that can be used when pushing an object during walking [16.44].

Pattern Generation Using Preview Controller

In this subsection, we will describe the method proposed by Kajita et al. [16.37]. Its stability and possible expansions are well discussed by Wieber [16.29].

For the simplicity, let us use the cart-table model of Fig. 16.11 again, but this time, we take the jerk of the cart as the system input u ,

$$\ddot{x} = u. \quad (16.42)$$

In this way, the ZMP equation (16.25) can be translated into a strictly proper dynamical system as

$$\begin{aligned} \frac{d}{dt} \begin{pmatrix} x \\ \dot{x} \\ \ddot{x} \end{pmatrix} &= \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} x \\ \dot{x} \\ \ddot{x} \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} u, \\ p &= \begin{pmatrix} 1 & 0 & -z_c/g \end{pmatrix} \begin{pmatrix} x \\ \dot{x} \\ \ddot{x} \end{pmatrix}. \end{aligned} \quad (16.43)$$

For this system, we can design a digital controller that lets the system output follow the reference input as

$$\begin{aligned} u(k) &= -G_i \sum_{i=0}^k e(i) - G_x \mathbf{x}(k), \\ e(i) &:= p(i) - p^d(i), \end{aligned} \quad (16.44)$$

where G_i is the gain for the ZMP tracking error, G_x is the state feedback gain, and $\mathbf{x} := [x \dot{x} \ddot{x}]^\top$. The value at the k -th sample time is indicated by appending (k) . The block diagram of the feedback system is shown in Fig. 16.17.

Although we can guarantee the stability of this system by LQ (linear quadratic) feedback gains, the controller of (16.44) cannot realize sufficient ZMP tracking due to the phase delay. To solve this problem, we must

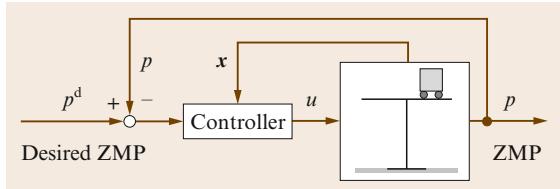

Fig. 16.17 ZMP tracking control

use the following controller:

$$u(k) = -G_i \sum_{i=0}^k e(i) - G_x x(k) - \sum_{j=1}^{N_L} G_p(j) p^d(k+j) \quad (16.45)$$

The third term is new and contains the **ZMP** reference up to N_L samples future. Since this controller uses future information, it is called a *preview controller* [16.45, 46]. The gain $G_p(j)$ is called the preview gain and Fig. 16.18 shows its profile towards the future. We can observe that the magnitude of the preview gain quickly diminishes, thus the **ZMP** reference in the far future can be neglected.

Figure 16.19 shows an example of a walking pattern generated by using a preview controller. The upper graph shows the sagittal motion along the x -axis and the lower graph shows the lateral motion along the y -axis. We can see that a smooth trajectory of the CoM (dashed line) is generated and that the resulting **ZMP** (bold line) follows the reference (thin line) with good accuracy.

16.4.5 ZMP-Based Walking Control

If we have an ideal mechanism on a perfect flat floor, we can expect that a robot walks just by a playback of prescribed joint trajectory. Since this is not the

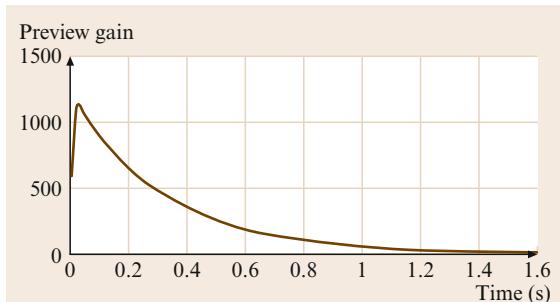

Fig. 16.18 Preview controller gain G_p (sample time $T = 5$ ms, $z_c = 0.814$ m, $Q_e = 1.0$, $Q_x = 0$, $R = 1.0 \times 10^{-6}$)

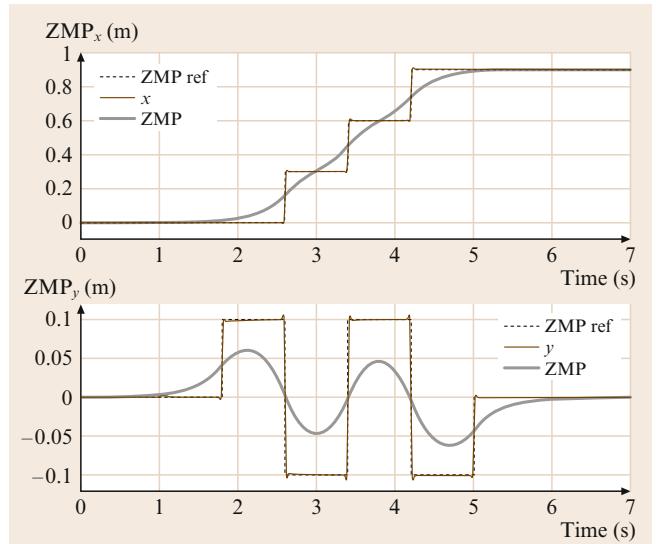

Fig. 16.19 Body trajectory obtained by preview control; previewing period $T N_L = 1.6$ s

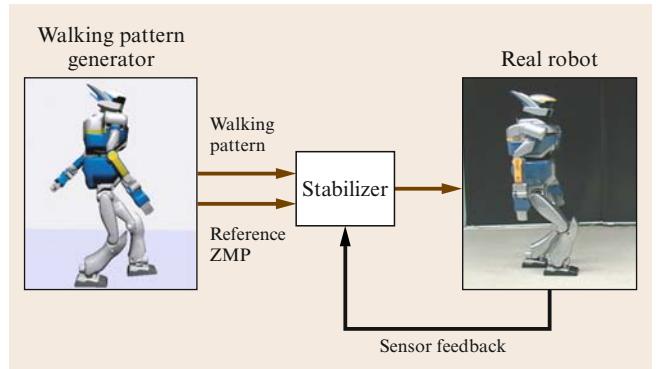

Fig. 16.20 Pattern generator and stabilizer

case in general, we need feedback control to modify the reference trajectory using sensor information, as shown in Fig. 16.20. Such stabilizers are discussed in [16.25, 47–50].

16.4.6 Expansion of the ZMP Concept

We can predict a robot fall when the CoM projection is observed outside of the support polygon. However, we cannot use the **ZMP** by this way, since the **ZMP** never leaves the support polygon of a real biped robot. When the **ZMP** is on the edge of the support polygon, all we can say is that *the robot can fall*, since it is merely a necessary condition of falling. As an alterna-

tive of **ZMP**, *Goswami* proposed a foot-rotating indicator (**FRI**) [16.51]. **FRI** is a **ZMP** calculated by omitting the acceleration of the supporting foot and is a measurable value of real robots that may leave the support polygon. When am **FRI** is outside of the support polygon, this indicates a support foot acceleration, which breaks a foot–floor contact.

Another problem is that the **ZMP** is defined only on the flat plane. *Sardain* and *Bessonnet* discussed a general

ZMP calculation including a double support phase on uneven terrain [16.52].

Saida et al. proposed a feasible solution of wrench (**FSW**) as a new criterion for a legged robot on uneven terrain [16.53].

Hirukawa et al. also proposed a universal stability criterion that can treat a general geometry of foot–ground contact and unidirectional force constraints [16.54].

16.5 Multilegged Robots

This section treats robots that have more than three legs.

16.5.1 Analysis of Static Gait

Compared with bipeds, multilegged robots have a wider choice of foot placing to maintain static balance. From this reason, many research works have concentrated on gait planning for statically stable walking rather than treating dynamic stability. In this subsection, we will introduce those important results by following *McGhee* [16.55] and *Song* and *Waldrone* [16.56].

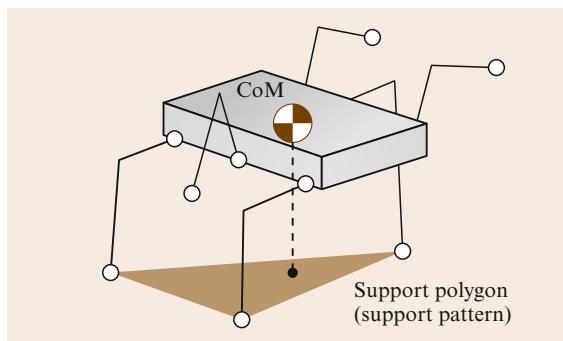

Fig. 16.21 Support polygon (support pattern) of a multilegged robot

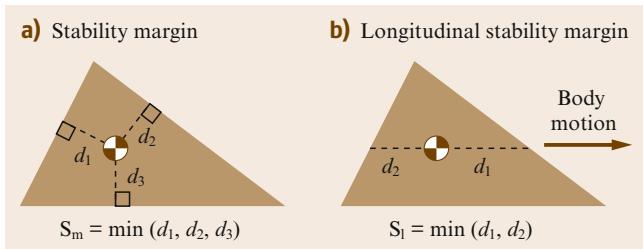

Fig. 16.22a,b Definition of stability margins

Stability Margins

In multilegged robot research, the term *support pattern* is frequently used for support polygon [16.55–57]. By neglecting the inertial effects caused by body and leg acceleration, we can guarantee that the robot maintains balance if the projection of the CoM falls inside the support pattern, as shown in Fig. 16.21.

For a given configuration of a walking robot, the *stability margin* S_m is defined as the minimum distance of the vertical projection of CoM to the boundaries of the support pattern in the horizontal plane, as illustrated in Fig. 16.22a. In addition, an alternative index was proposed to obtain the optimal gait analytically. That is the *longitudinal stability margin* S_l , which is defined as the minimum distance from the vertical projection of the CoM to the support pattern boundaries along the line parallel to the body motion.

Quadruped Creeping Gait and Crawl Gait

From the front to the rear of a $2n$ -legged robot or animal, let us index the left legs and the right legs by odd numbers $1, 3, \dots, 2n - 1$ and even numbers $2, 4, \dots, 2n$, respectively. Following this rule, the legs of a quadruped robot are numbered as in Fig. 16.23.

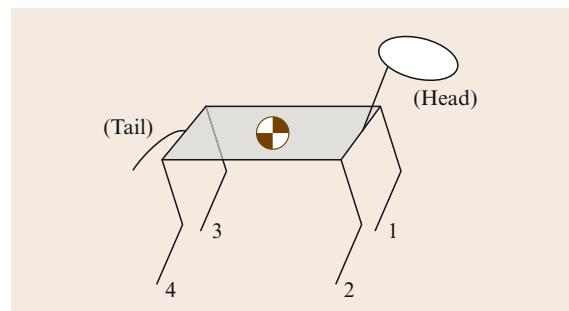

Fig. 16.23 Leg labeling of quadruped robot

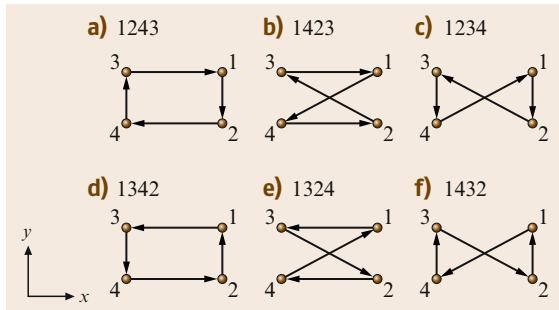

Fig. 16.24a–f Quadruped creeping gaits [16.57]

To walk keeping static stability, a quadruped robot must lift and place only one leg at each step. In general, such a pattern is called *creeping gait*. The possible creeping gaits of a quadruped robot can be expressed by a series of leg numbers to show the order of foot placing. Always choosing leg 1 as the first swing leg, we can distinguish $(4-1)! = 6$ different gaits, as shown in Fig. 16.24.

As we will see later, the 1423 creeping gait (Fig. 16.24b) gives the maximum stability for walking along the x -direction, and is called the *crawl gait*. Note that if the walking direction was $-x$, 1324 (Fig. 16.24e) gives the crawl gait. Likewise, 1234 (Fig. 16.24c) and 1432 (Fig. 16.24f) represent the crawl gait in the $-y$ and y directions, respectively.

On the other hand, the 1243 and 1342 creeping gaits (Fig. 16.24a, d) give medium stability and are suitable for turning.

Gait Diagram

Figure 16.25b is a *gait diagram* to describe the gait sequence of a multilegged robot. The horizontal axis indicates the time normalized by walk cycle time T . The line segment associated with each leg starts from the touchdown and ends at lift-off. Therefore, the length of the line segment indicates the period of the support phase. From this diagram, we can define the *duty factor* β_i and *phase* ϕ_i of leg i as

$$\beta_i = \frac{\text{support period of leg } i}{T}, \quad (16.46)$$

$$\phi_i = \frac{\text{touchdown time of leg } i}{T}. \quad (16.47)$$

The touchdown time of leg i is measured from the touchdown of leg 1; therefore, we have $\phi_1 = 0$ for any gait.

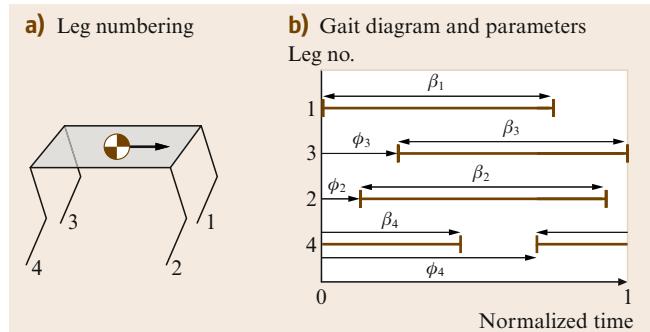

Fig. 16.25a,b Gait diagram and parameters

Wave Gait of Quadrupeds

There exists a special gait which gives maximum longitudinal stability margin for a quadruped robot [16.57]. It is called the *wave gait* defined as

$$\beta_i = \beta, \quad (i = 1, \dots, 4), \quad (16.48)$$

$$0.75 \leq \beta < 1, \quad (16.49)$$

$$\phi_2 = 0.5, \quad (16.50)$$

$$\phi_3 = \beta, \quad (16.51)$$

$$\phi_4 = \phi_3 - 0.5, \quad (16.52)$$

where β is the duty factor of the wave gait. Figure 16.26 shows the gait diagram of a wave gait of $\beta = 0.75$.

If we look at the order of foot placement in Fig. 16.26, it is a crawl gait (1423 creeping gait) shown in Fig. 16.24b. Therefore, a wave gait is the optimal crawl gait.

The most important feature of the wave gait is specified by (16.51). This means that leg 3 touchdowns at the moment of leg 1's lift-off, as indicated by the ellipse (broken line) in Fig. 16.26. Equation (16.49) gives the possible range of duty factor for a statically stable walking. In addition, a wave gait is characterized as *regular* and *symmetric*. A gait is regular when all legs have the same duty factor β , as specified by (16.48). A gait is

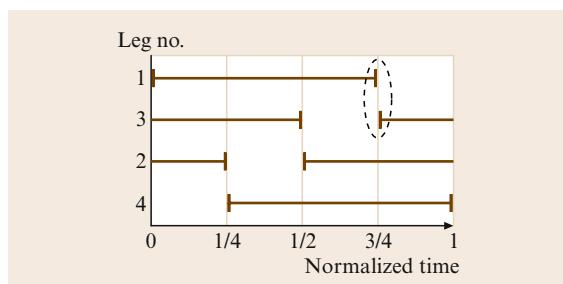

Fig. 16.26 Wave gait of a quadruped robot ($\beta = 0.75$)

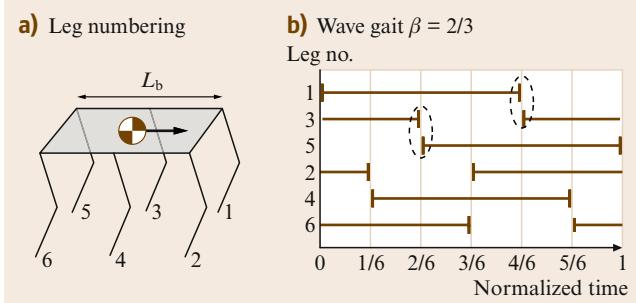

Fig. 16.27a,b Wave gait of a hexapod robot

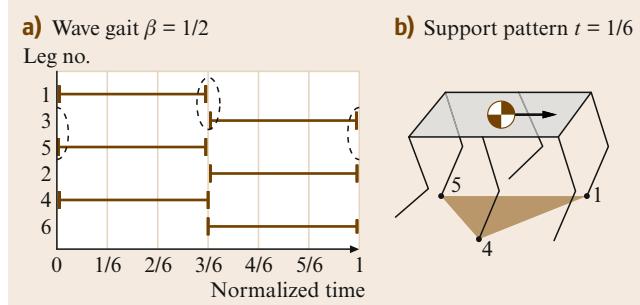

Fig. 16.28a,b Tripod gait of a hexapod robot

symmetric when the right and the left leg of each column has a phase difference of a half-cycle, 0.5 as specified by (16.50) and (16.52).

Wave Gait of $2n$ -Legged Robots

A wave gait of $2n$ -legged robots can be defined as a regular and symmetric gait with the following feature.

$$\phi_{2m+1} = F(m\beta), \quad (m = 1, \dots, n-1), \quad (16.53)$$

$$3/(2n) \leq \beta < 1, \quad (16.54)$$

where $F(x)$ gives the fractional part of a real number x . Equation (16.53) is a generalization of (16.51). An example wave gait for hexapod robot is shown in Fig. 16.27. The ellipses (broken line) show the condition (16.53).

Figure 16.28 shows a wave gait with $\beta = 1/2$, which is the most important for hexapod robots. From the constraint (16.54), this is the smallest duty factor for hexapods and thus results in the fastest walking speed. This gait is specially called a *tripod gait* since a robot is supported by the three legs 145 and 236 reciprocally (Fig. 16.28b).

It is known that *the longitudinal gait stability margin of a $2n$ -legged robot is maximized by wave gaits* [16.56]. Figure 16.29 shows the optimal wave-gait stability margin normalized by body length L_b (Fig. 16.27a) for

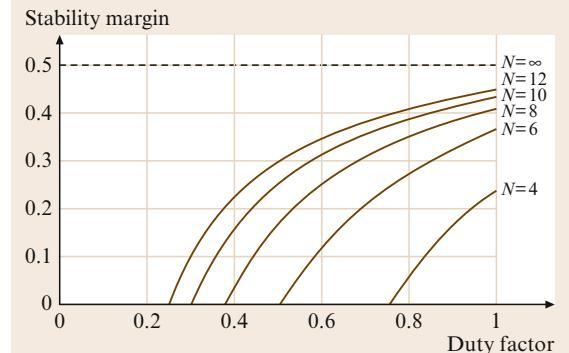

Fig. 16.29 Optimal wave-gait stability margin of N -legged locomotion systems [16.55]

Fig. 16.30 The adaptive suspension vehicle (1986) [16.58]

N -legged robots [16.55]. We can observe that by increasing the number of legs the stability and allowable range of duty factors are improved. The largest improvement is obtained from $N = 4$ to 6 and the gains gradually become small towards $N = \infty$. Since the cost of the hardware goes up in proportion to the number of the legs, this explains the rarity of developed robots with more than ten legs.

16.5.2 Practical Gait Design

Unlike the ideal analysis in previous section, real multi-legged robots are far more complex. In this subsection, we see more practical aspects of gait control by concentrating on a few state-of-the-art examples.

Hexapod: The Adaptive Suspension Vehicle

Figure 16.30 shows one of the most famous hexapods, the adaptive suspension vehicle (ASV) developed by Waldron and McGhee [16.56, 58]. The ASV is a hy-

Table 16.1 Specifications of the ASV [16.56]

| | Large-obstacle gait |
| | Precision footing gait |
| | Free gait |

draulically driven hexapod robot that can carry a person over rough terrain. Table 16.1 lists the design specifications and mobility of the ASV at experimentation in natural terrain.

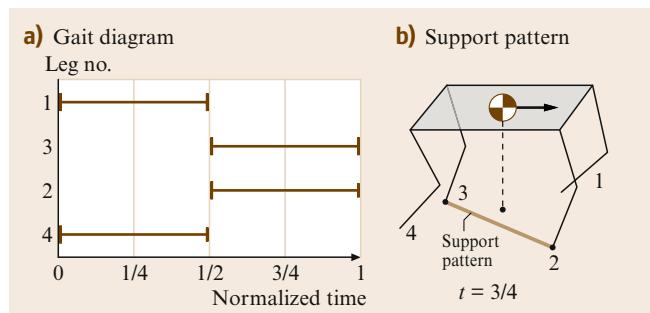

Table 16.2 shows the variety of gaits that was used to control the ASV. We can see that the wave gait appears at the top of list, however, it requires undesirable peak power consumption at certain moments. The *equal-phase gait* was designed to solve this problem. Another interesting gait is the *follow-the-leader* gait in which the middle foot is placed on the footprint made by the front foot, and the rear foot is placed in the footprint of the middle foot. By using this gait, the load on the human operator to specify foot placement when moving over difficult terrain can be drastically reduced. In this manner, each gait listed in Table 16.2 has some advantage depending on the ground adaptivity, power consumption or smoothness of body motion.

Quadruped: TITAN Series

Figure 16.31 shows quadruped robots developed by Hirose and his colleagues [16.59, 60]. TITAN III (Fig. 16.31a) has four legs, each 1.2 m long, and weighs

**Fig. 16.31a, b** The TITAN series [16.59, 60]**Fig. 16.32** Walking motion over a river [16.61]

80 kg. Each leg is driven by three DC motors, thus this is a 12-DOF walking robot. On flat ground, TITAN III uses a generalized crawl gait which allows the robot to move omnidirectionally (*crab-walk gait*). When the robot step into a rough terrain it uses *free gait*, which is a nonperiodic gait to search for safe footholds, avoiding obstacles and maintaining static stability. Figure 16.32 shows an example of free gait to walk over a river. Once the robot returns to flat ground, it is controlled to return the crab-walk gait, which is more efficient.

**Fig. 16.33a, b** Trot gait

TITAN IV (Fig. 16.31b) has a similar configuration to TITAN III, but weighs 160 kg. Since it has much powerful motors, an experiment of dynamic walk was conducted. For a given return speed of the swing leg U , the walking speed with duty factor β is

$$V = \frac{1-\beta}{\beta} U. \quad (16.55)$$

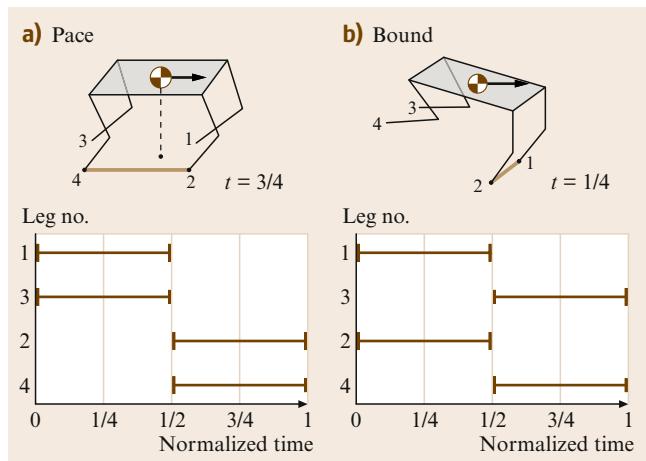

Fig. 16.34a,b Another dynamic gait of quadrupeds

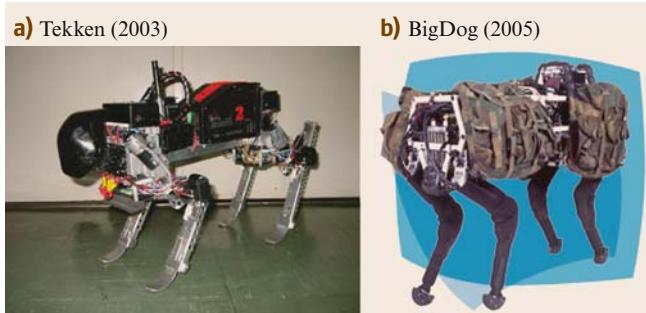

Fig. 16.35a,b Quadruped robots inspired by mammals [16.62, 63]

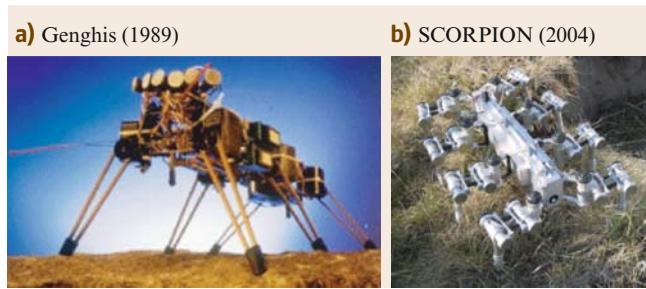

Fig. 16.36a,b Biologically inspired multilegged robots [16.64, 65]

For a statically stable wave gait, the smallest β is 0.75 (Sect. 16.5.1), thus $V = 0.33U$ is the maximum speed. However, by using a duty factor of $\beta = 0.5$, we can achieve $V = U$, three times faster than the maximum speed of static walk. Figure 16.33 shows such a gait. The gait diagram (Fig. 16.33) shows that the robot stands on two legs at all times, which is called the *trot gait*.

As illustrated in Fig. 16.33b, a trot gait is a dynamic walk where the **ZMP** should be controlled to be inside the support pattern (support polygon) while the projection of the CoM goes outside of it. Hirose et al. introduced the body swaying control to meet the **ZMP** condition and the *expanded trot gait* for a smooth transition from a static gait at slow speed to a dynamic gait at high speed [16.60]. Later, this technique was elaborated for TITAN VI, the successor to TITAN IV [16.66].

16.5.3 Dynamic Quadrupeds Inspired by Mammals

Nature exhibits a variety of implementations of legged locomotion and some of them are much more dynamic than in the analysis and synthesis discussed above. Figure 16.34 shows two dynamic gaits used by mammals [16.67]. Pace is used by camels and bound is used by running dogs, for example.

Raiert showed that trot, pace, and bound can be regarded as biped locomotion by pairing diagonal legs, front-rear legs, and lateral legs, respectively. Using this idea, he demonstrated a hydraulic running quadruped that can trot, pace, and bound [16.5]. Such gaits have also been realized by electrically powered quadrupeds using different control schemes [16.68, 69].

Figure 16.35a shows recently developed mammal-like quadruped robots. Tekken is an electric quadruped robot with a 20 cm body length and weight of 3.1 kg developed by Fukuoka and Kimura [16.62]. It can walk on irregular terrain by using a controller based on a central pattern generator (**CPG**) and reflex controls.

BigDog is an energy-autonomous hydraulic quadruped robot that is 1 m tall and 1 m long, and weighs 90 kg, developed by Buehler et al., (Fig. 16.35b). Each leg has one passive linear pneumatic compliance in the lower leg, and three active joints for knee, hip pitch, and roll [16.63]. In an outdoor environment, BigDog can walk up and down 35° inclines, can trot at speeds of up to 0.8 m/s, and can carry over 50 kg of payload.

16.5.4 Behavior-Based Multilegged Robots

Figure 16.36a shows a small hexapod robot Genghis (35 cm length and 1 kg weight) developed by Brooks [16.64]. Most importantly, the gait of Genghis was not explicitly controlled, but emerged from the carefully designed network named *subsumption architecture*. Genghis and other robots created by Brooks created a huge trend of *behavior-based*

robotics in robotics and artificial intelligence in the 1990s.

Figure 16.36b shows the eight-legged robot SCORPION (65 cm length and 11.5 kg weight) developed in collaboration between the University of Bremen and the National Aeronautics and Space Administration (NASA) [16.65]. The gait control of SCORPION is designed based on a behavior-based network and a central pattern generator.

16.6 Other Legged Robots

16.6.1 Leg–Wheel Hybrid Robots

Unlike animals or insects, a robot can be designed to have wheels that can rotate infinitely. By mixing the efficiency of wheels and the flexibility of legs, we can expect a robot of maximum terrain adaptability with minimum power consumption. Figure 16.37 shows examples of such design concept.

Figure 16.37a shows stair climbing by a biped leg–wheeled robot developed by Matsumoto et al. [16.70]. The robot is a planer biped with telescopic legs, but the tip of each leg is equipped with a powered wheel. During the single-leg support phase, the robot is controlled as a wheeled inverted pendulum. In addition, a controller was developed to realize a smooth transient between the single support and statically stable double support phases.

Figure 16.37b shows RollerWalker, developed by Hirose et al. [16.71, 76]. RollerWalker is a 12-DOF quadruped robot equipped with passive wheels on the tip of legs. It uses a roller-skating mode on a flat floor, while it can walk on an uneven terrain by retracting the passive wheels.

Figure 16.37c shows RHex developed by Buehler et al. [16.72]. Although it was originally inspired from the locomotion of cockroach, RHex has only six active DOF, that is, one actuator for each hip. Moreover, the legs can rotate full circle around the pitch axis. Using this unique design, RHex can walk and run over rugged, broken, and obstacle-ridden ground. Recently, it also demonstrated biped running with its rear legs [16.77].

Figure 16.37d shows Whegs II, another cockroach-inspired robot developed by Allen et al. [16.73]. This robot has only four active DOFs, one for propulsion, two for steering, and one for body flexion. Each leg is equipped with three spring-loaded spokes and is driven by the same actuator. Whegs II can realize

comparable mobility to RHex, while it uses fewer actuators.

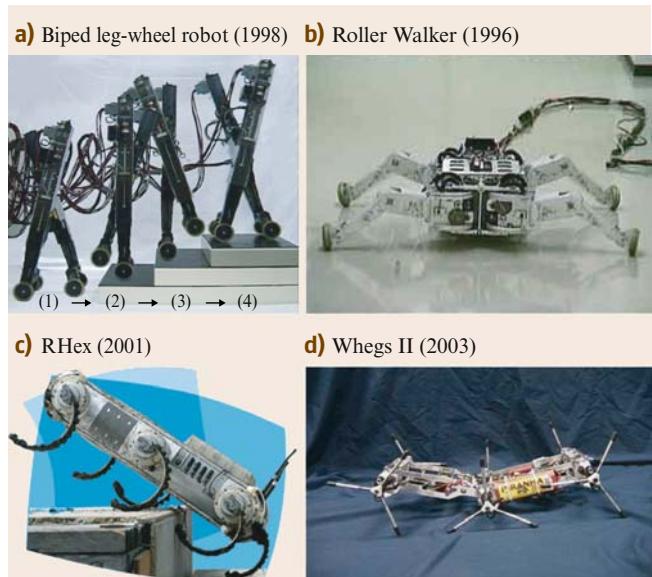

Fig. 16.37a–d Leg–wheel hybrid robots [16.70–73]

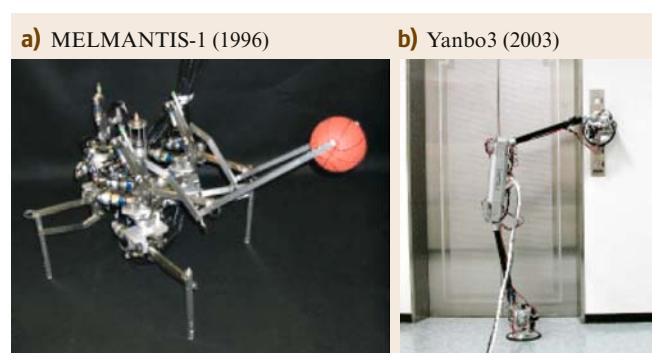

Fig. 16.38a,b Leg–arm hybrid robots [16.74, 75]

Fig. 16.39 Dante II (1994) [16.78]

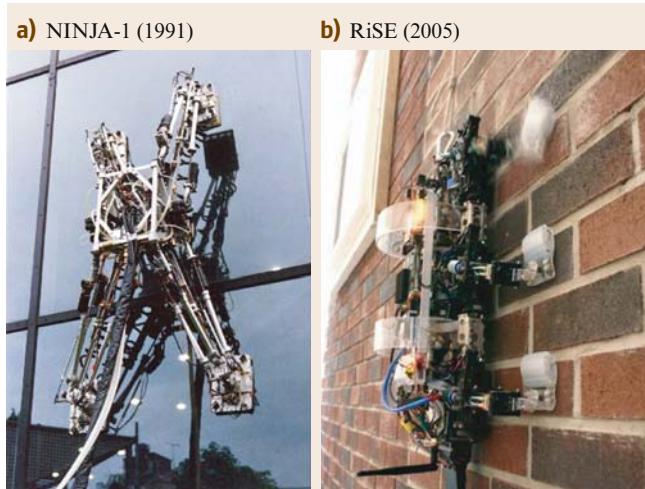

Fig. 16.40a,b Wall-climbing robots [16.79, 80]

16.6.2 Leg-Arm Hybrid Robots

Another design concept is the leg-arm hybrid robot. Since legs have inherently many degree of freedom, it is possible to use them as manipulators. In this way, we can minimize the total number of DOFs, complexity,

weight, and power consumption of the walking robot. MELMANTIS-1 (Fig. 16.38a) developed by *Koyachi* et al. is a hexapod walker with 22 DOFs that can transform its legs into manipulators [16.74]. The robot can manipulate an object using two legs while standing with four other legs, after traveling on six legs for maximum stability.

Yanbo3 is a biped walker with eight DOFs developed by the group of *Yoneda* and *Hirose* [16.75]. It is designed to have the minimum number of DOFs necessary for a biped robot as well as for a manipulator when it is in the single support phase. In Fig. 16.38b, the robot is pressing the elevator button using its foot.

16.6.3 Tethered Walking Robots

Figure 16.39 shows Dante II, an eight-legged tethered walking robot developed by the eCMU Field Robotics Center in 1994. It was used at an Alaskan volcano for scientific exploration. To descend down steep crater walls in a rappelling-like manner, the robot uses a tether cable anchored at the crater rim [16.78]. *Hirose* et al. also developed a tethered quadruped for construction work [16.81].

16.6.4 Wall-Climbing Robots

Wall-climbing robots are characterized by their foot mechanisms and leg configurations. The vital part is the foot mechanism to generate the pulling force, and the use of vacuum suction cups, electromagnets (for steel wall), adhesive materials, or miniature spine array have been proposed.

Figure 16.40a shows the wall-climbing quadruped NINJA-1 developed by *Hirose* et al. [16.79]. Each foot of NINJA-1 is equipped with a specially designed suction pad that can minimize its vacuum leakage. Another reliable wall-climbing robot with suction cups was developed by *Yano* et al. [16.82].

Figure 16.40b shows the wall-climbing hexapod RiSE developed by *Kim* et al. [16.80, 83]. Each foot of RiSE is equipped with arrays of miniature spines observed in some insects and spiders. The robot can reliably climb on a wide variety of outdoor surfaces including concrete, stucco, brick, and dressed sandstone.

16.7 Performance Indices

In this section, we introduce useful performance indices that can be used to evaluate legged robots of different configurations.

16.7.1 Expansion of the Stability Margin Concept

As we see in Sect. 16.5.1, the stability margin was originally proposed for a degree of stability of the static walking multilegged robots by McGhee and Frank [16.57]. For a dynamic walking robot, we can define a stability margin as the minimum distance of the ZMP to the boundaries of the support polygon, since the ZMP is the natural extension of a projected CoM on the ground. This fact was already mentioned in the original work on the ZMP [16.36], and has been used implicitly by many researchers. Explicit definition of this *ZMP stability margin* can be seen, for example, in Huang et al. [16.41].

For a legged robot on rough terrain, Messuri and Klein defined the *energy stability margin* as the minimum potential energy required to tumble the robot as,

$$S_E = \min_i(Mgh_i), \quad (16.56)$$

where h_i is the CG height variation during the tumble around the i -th segment of the support polygon and M is the total mass of the robot [16.85]. This concept is widely accepted, and there are some proposals for improvement [16.31, 86].

16.7.2 Duty Factor and Froude Number

Throughout this chapter, we have observed various walking robots that might fit best for certain environments and purposes. In some cases, however, we need to compare walking robots which have different masses,

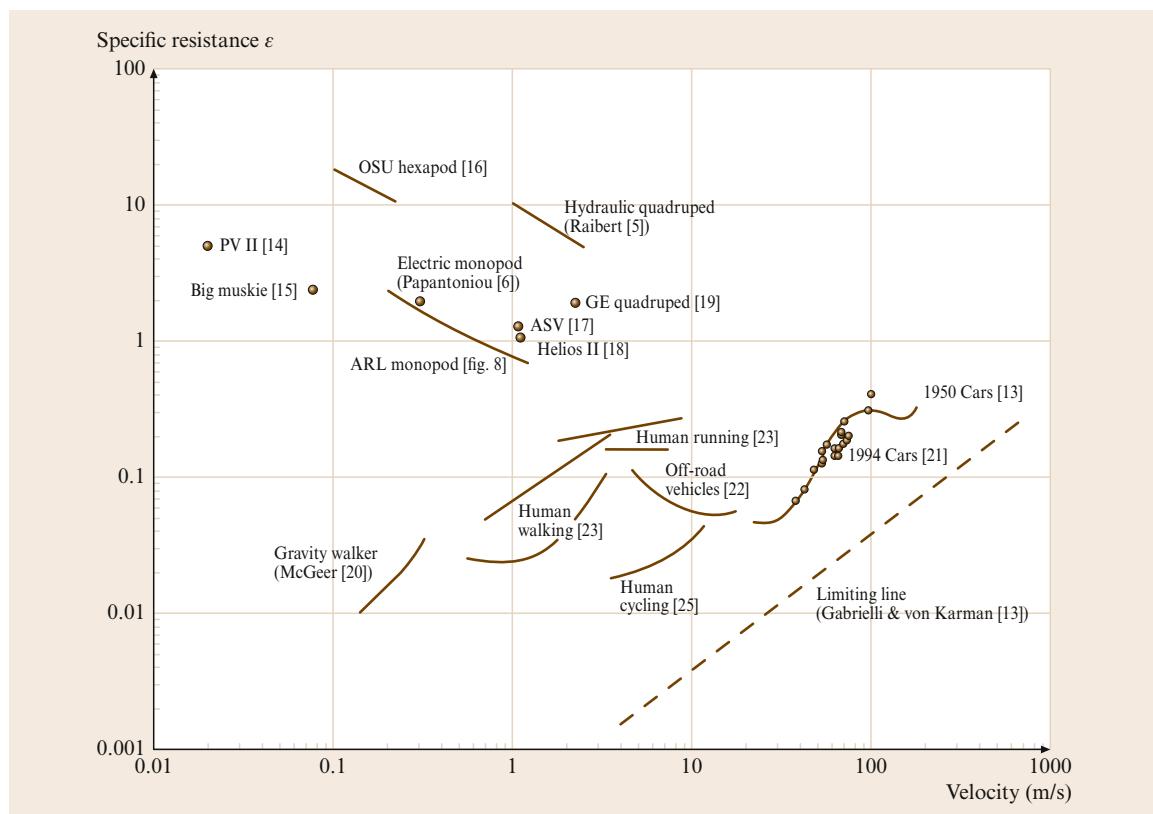

Fig. 16.41 The Gabrielli–von Karman diagram [16.84]

sizes, and numbers of legs by using a certain performance index. Such an index should be dimensionless like a Mach or Reynolds number in fluid mechanics.

One of the useful indices for walking machines was already shown, that is, the duty factor β defined as

$$\beta = \frac{(\text{support period})}{(\text{cycle time})}.$$

Duty factors can be used to make the distinction between walks and runs, since we have $\beta \geq 0.5$ for walking and $\beta < 0.5$ for running [16.67].

The Froude number is used in fluid mechanics to explain the behavior of surface waves. Since both of surface waves and legged locomotion are dynamic motion in gravity, Alexander used it to characterize animal locomotion [16.67, 87]. He calculated a Froude number by

$$F_{r_2} = \frac{V^2}{gh}, \quad (16.57)$$

where V is the walking or running speed, g is the acceleration due to gravity, and h is the height of hip joint from the ground. He showed that animals of different sizes use similar gaits when they travel with equal Froude numbers. In particular, most animals change their gait from walking to running at a speed equivalent to a Froude number of $F_{r_2} = 1$.

The Froude number is also defined as

$$F_{r_1} = \frac{V}{\sqrt{gh}}, \quad (16.58)$$

which is the square root of F_{r_2} and can be used as a dimensionless speed for animals or legged robots.

16.7.3 Specific Resistance

The *specific resistance* is another important dimensionless number that is used to evaluate the energy efficiency of a mobile robot.

Gabrielli and von Karman discussed the performance of various vehicles using the power consumption per unit distance. That is

$$\epsilon = \frac{E}{Mgd}, \quad (16.59)$$

where E is the total energy consumption for a travel of distance d , M is the total mass of the vehicle, and g is the acceleration due to gravity [16.88]. Note that when we push a box of mass M a distance d on a floor with friction coefficient μ , we consume the energy $M\mu gd$ and the specific resistance becomes $\epsilon = \mu$. Therefore, we can say that the specific resistance indicates how smooth the locomotion is.

In their original work, Gabrielli and von Karman plotted the specific resistance as a function of speed for various vehicles as Fig. 16.41. This is called the *Gabrielli-von Karman diagram* and it was used to compare various styles of locomotion by Umetani and Hirose [16.89]. Gregorio, Ahmadi and Buehler also showed the specific resistance of recent walking robots including their efficient hopping robot, ARL monopod [16.84].

16.8 Conclusions and Future Trends

In this chapter, we have discussed the following topics.

Sect. 16.1 A brief history: The history of legged robot research was introduced.

Sect. 16.2 Analysis of cycling walking: As the typical cycling walking robot, a simple passive walker was analyzed. The Poincaré map is one of the most important tools for this purpose.

Sect. 16.3 Control of biped robots using forward dynamics: The dynamics and control of biped robots were discussed. The treatment of the unilateral ground force is the key issue for bipeds, as well as other legged robots.

Sect. 16.4 Biped robots in the ZMP scheme: As a practical scheme to control biped robots, the zero-moment point (**ZMP**) was discussed.

Sect. 16.5 Multilegged robots: The relationship between gaits and stability was discussed. In addition, the landmark robots in this field were introduced.

Sect. 16.6 Other legged robots: We introduced leg-wheel hybrid, leg-arm hybrid, tethered walking, and wall-climbing robots. One might be impressed with the range of imagination displayed here, but these examples are still just the tip of the iceberg.

Sect. 16.7 *Performance indices*: The stability margin, Froude number, and the specific resistance were discussed. They are useful performance indices to compare legged robots in different configurations.

Over the last three decades, legged robots have become faster, more efficient, and more robust. This trend may continue in the future, aiming for ultimate mobility comparable to that of insects, mammals, and ourselves.

17. Wheeled Robots

Wheeled Robots

Guy Campion, Woojin Chung

The purpose of this chapter is to introduce, analyze, and compare the models of wheeled mobile robots (**WMR**) and to present several realizations and commonly encountered designs. The mobility of **WMR** is discussed on the basis of the kinematic constraints resulting from the pure rolling conditions at the contact points between the wheels and the ground. According to this discussion it is shown that, whatever the number and the types of the wheels, all **WMR** belong to only five generic classes. Different types of models are derived and compared: the posture model versus the configuration model, the kinematic model versus the dynamic model. The structural properties of these models are discussed and compared. These models as well as their properties constitute the background necessary for model-based control design. Practical robot structures are classified according to the number of wheels, and features are introduced focusing on commonly adopted designs. Omnidirectional robots and articulated robots realizations are described in more detail.

17.1 Overview

The purpose of this chapter is to provide a general description of wheeled mobile robots, to discuss their properties from the mobility point of view, to introduce several dynamical models necessary for the design of model-based control laws, and to describe the most commonly encountered realizations of such robots.

Throughout the chapter we make the assumption that the wheels satisfy the kinematic constraints relative to the pure rolling conditions at each contact wheel/ground, without sliding effects. This implies that we assume that the contact forces between the ground and the wheels magically take the right values allow-

ing the satisfaction of these conditions; this is an ideal model. In reality the contact forces appear as a consequence of local sliding, according to phenomenological contact force models. Using a singular perturbation approach it can be shown however that these sliding effects correspond to fast dynamics, i.e., to dynamical effects with characteristic times that are quite short with respect to the dynamics of the global motion of the robot, and can therefore be neglected, at least when using the ideal model for control design purpose [17.1] (Chap. 34).

The chapter is organized as follows. Section 17.2 is devoted to the characterization of the restriction of robot motion induced by these pure rolling conditions. We first describe the different types of wheels used in the construction of mobile robots and derive the corresponding kinematic constraints. This allows us to characterize the mobility of a robot equipped with several wheels of these different types, and we show that these robots can be classified into only five categories, corresponding to two mobility indices.

In Sect. 17.3, we present four types of generic state-space models allowing one to describe robot behavior within each of these five categories, and the relationships between these models. We introduce *kinematic* and *dynamic* models, whose inputs are, respectively, velocities and accelerations (or, equivalently input torques), as well as *posture* or *configuration* models, corresponding to a minimal description of the robot behavior, or to a full description, including the internal variables, respectively.

In Sect. 17.4, we present several structural properties of these models, from a control design point of view. We first discuss the questions of stabilizability, controllability, and nonholonomy of restricted mobility robots. We then discuss the problem of state feedback linearization, either input–output linearization by static state feedback, or full linearization by dynamic extension and dynamic state feedback.

In the last section we present several realizations of wheeled mobile robots, with several particular devices such as synchronous drive, Swedish wheels, and articulated robots.

17.2 Mobility of Wheeled Robots

In this section we describe a variety of wheels and wheel implementations in mobile robots. We discuss the restriction of robot mobility implied by the use of these wheels and deduce a classification of robot mobility allowing one to characterize robot mobility fully, whatever the number and type of the wheels.

17.2.1 Types of Wheels

In order to achieve robot locomotion, wheeled mobile robots are widely used in many applications. In general, wheeled robots consume less energy and move faster than other locomotion mechanisms (e.g., legged robots or tracked vehicles). From the viewpoint of control, less control effort is required, owing to their simple mechanisms and reduced stability problems. Although it is difficult to overcome rough terrain or uneven ground conditions, wheeled mobile robots are suitable for a large class of target environments in practical applications. When we think of a single-wheel design, there are two candidates: a standard wheel or a special wheel. A standard wheel can be understood as a conventional tire. Special wheels possess unique mechanical structures including rollers or spheres. Figure 17.1 shows the general

design of a standard wheel. Three conditions should be defined for a standard wheel design:

1. the determination of the two offsets d and b
2. a mechanical design that allows steering motion or not (i.e., to fix the wheel orientation or not)
3. the determination of steering and driving actuation (i.e., active or passive drive)

Condition 1 is the kinematic parameter design problem for a single standard wheel. The parameter d can be either 0 or some positive constant. Parameter b is the lateral offset of the wheel and is usually set to zero. In a special design, a nonzero b may be selected to obtain pure rolling contact between the wheel and ground without causing rotational slip at the contact point. However, this is rarely used and we mainly consider the case of zero lateral offset b .

Condition 2 is a design problem for whether the wheel orientation can be changed or not. If the steering axis is fixed, the wheel provides a velocity constraint on the driving direction. Condition 3 is the design problem of whether to actuate steering or driving motion by actuators or to drive steering or motion passively.

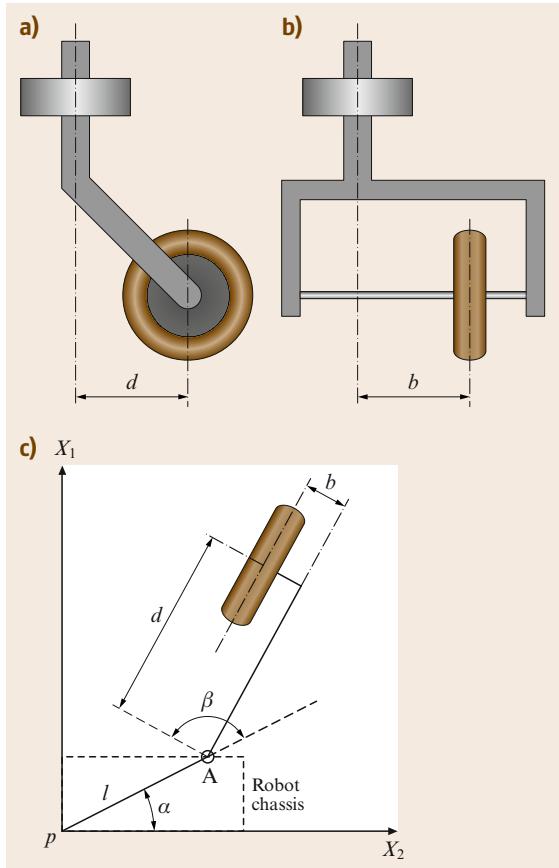

Fig. 17.1a–c The general design of a standard wheel. (a) side view (b) front view (c) top view

If steering motion is allowed, the offset d plays a significant role in the kinematic modeling. For a conventional caster wheel (i.e., an off-centered orientable wheel), there is a nonzero offset d . Point A in Fig. 17.1 indicates the location of the joint connecting the wheel module to the robot chassis. Two orthogonal linear velocity components at point A are obtained by a caster wheel, which result from the steering and driving motions of the wheel module. This implies that a passive caster wheel does not provide an additional velocity constraint on the robot's motion. If a caster wheel is equipped with two actuators that drive steering and driving motions independently, holonomic omnidirectional movement can be achieved because any desired velocity at point A can be generated by solving the inverse kinematics problem.

If the offset d is set to zero, the allowable velocity direction at point A is limited to the wheel orientation.

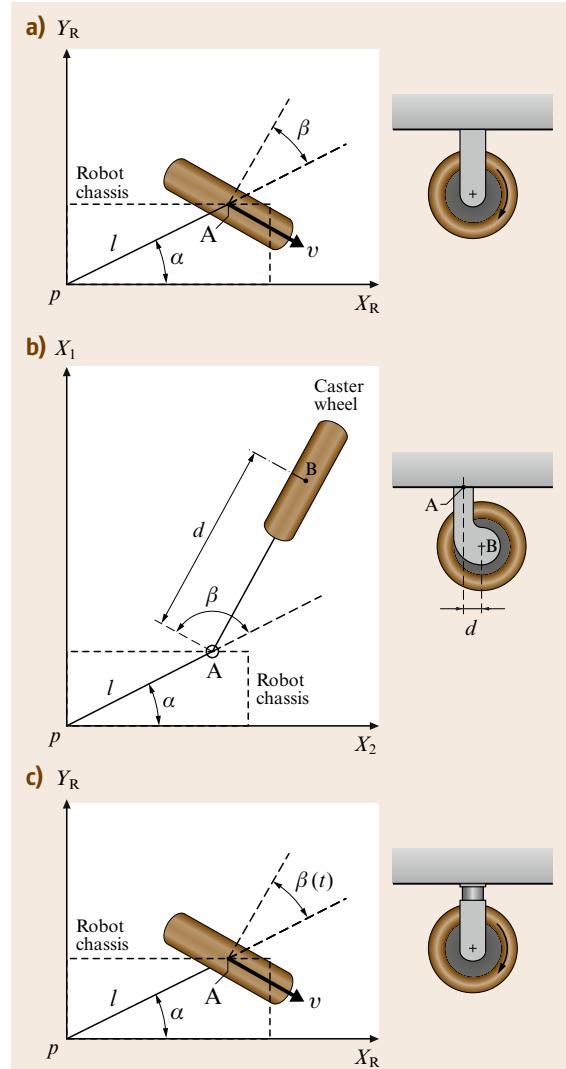

Fig. 17.2a–c Structures of standard wheels. (a) Passive fixed wheel. (b) Passive or active, off-centered orientable wheel. (c) Active orientable wheel without offsets

In such a case, the steering motion should not be passive because the wheel orientation cannot be changed passively. However, the driving velocity can be determined passively by actuation of other wheels. Wheel orientation should be actively steered to the desired velocity direction due to the nonholonomic velocity constraint. This implies that the wheel orientation should be aligned before movement.

In summary, four types of standard wheels are commonly used. The first is a passively driven wheel with

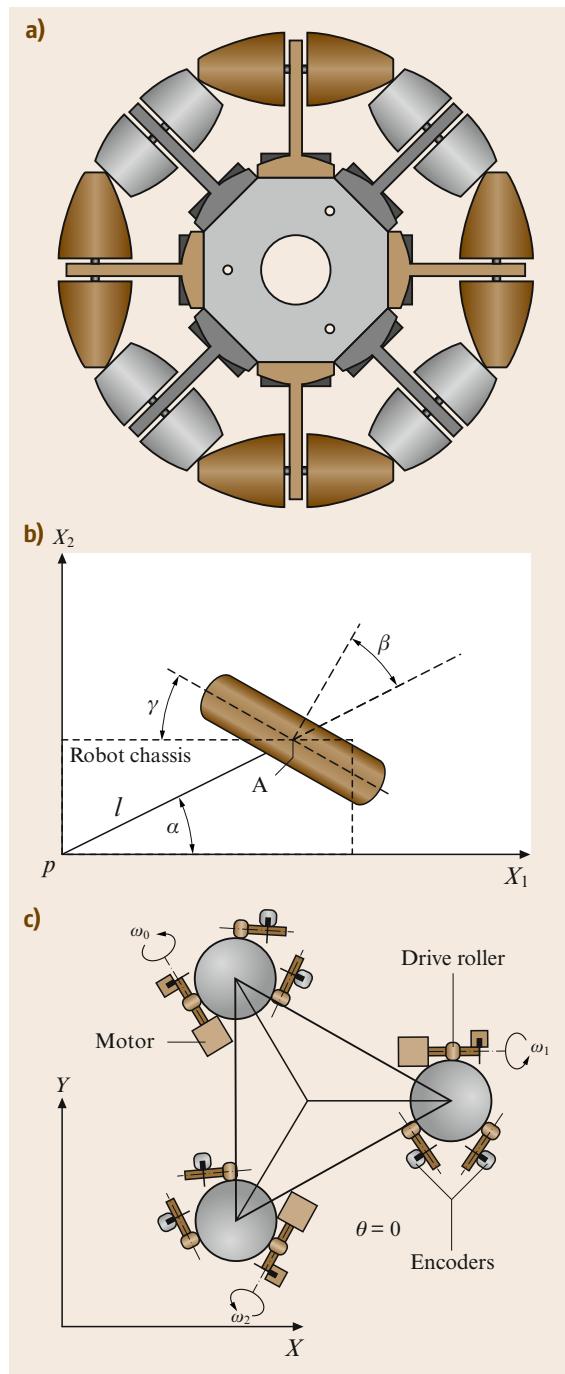

Fig. 17.3 (a) Swedish wheel. (b) Attachment of a Swedish wheel and (c) spherical wheel [17.2] ▶

trolled by actuators. The fourth is an active orientable wheel with zero offset d , where steering and driving motions are driven by actuators. The structures of each wheel type are shown in Fig. 17.2. The kinematics and constraints of those wheels will be explained in detail in Sect. 17.2.2.

Although standard wheels are advantageous because of their simple structure and good reliability, the nonholonomic velocity constraint (i.e., no side-slip condition) limits robot motion. On the other hand, special wheels can be employed in order to obtain omnidirectional motion of a mobile robot (omnimobile robot), i.e., to ensure three degrees of freedom for plane motion. We consider two typical designs of special wheels: the Swedish wheel and the spherical wheel. Figure 17.3a shows the Swedish wheel. Small passive free rollers are located along the outer rim of the wheel. Free rollers are employed in order to eliminate the nonholonomic velocity constraint. Passive rollers are free to rotate around the axis of rotation, which results in lateral motion of the wheel. As a result, a driving velocity should be controlled, while the lateral velocity is passively determined by the actuation of the other wheels.

A spherical wheel is shown in Fig. 17.3c. The rotation of the sphere is constrained by rollers that make rolling contact with the sphere. The rollers can be divided into driving and supporting rollers. The sphere is driven by actuation of the driving rollers, whereas the rolling contacts provide nonholonomic constraints, and the resultant motion of the sphere module becomes holonomic. This implies that the robot can be moved with any desired linear/angular velocities at any time. By using the spherical wheel, a holonomic omnidirectional mobile robot can be developed and the robot achieves smooth and continuous contact between the sphere and the ground. However, the design of the sphere-supporting mechanism is difficult and the payload must be quite low due to the point contact. Another drawback is that the surface of the sphere can be polluted when traveling over dirty ground and it is difficult to overcome irregular ground conditions. These drawbacks limit the practical application of the spherical wheel. An example of the use of spherical wheels can be found in [17.2] and [17.3]. The spherical structure can also be applied to special robotic transmissions; examples include the nonholonomic manipulator in [17.4] and the passive haptic system in [17.5].

17.2.2 Kinematic Constraints

We assume, as a first step, that the mobile robot under study is made up of a rigid cart equipped with non-deformable wheels, and that it is moving on a horizontal plane. The position of the robot on the plane is described, with respect to an arbitrary inertial frame, by the *posture* vector $\xi = (x \ y \ \theta)^T$, where x and y are the coordinates of a reference point P of the robot cart, while θ describes the orientation of a mobile frame attached to the robot, with respect to the inertial frame (Fig. 17.4).

We assume that, during motion, the plane of each wheel remains vertical and the wheel rotates around its horizontal axle, whose orientation with respect to the cart can be fixed or varying. We distinguish between two basic classes of idealized wheels, namely conventional and the Swedish wheels. In each case, it is assumed that the contact between the wheel and the ground is reduced to a single point. The kinematic constraints result from the fact that the velocity of the material point of the wheel in contact with the ground is equal to zero.

For a conventional wheel, the kinematic constraints imply that the velocity of the center of the wheel is parallel to the wheel plane (*nonslip condition*) and is proportional to the wheel rotation velocity (*pure rolling condition*). For each wheel the kinematic constraints therefore result in two independent conditions. For a Swedish wheel, due to the relative rotation of the rollers with respect to the wheel, only one of the velocity components of the wheel contact point is zero. The direction of this zero component is fixed with respect to the wheel plane and depends on the wheel construction.

For such wheels the kinematic constraints result in only one condition.

Conventional Wheels

We now derive the general form of the kinematic constraints for a conventional wheel.

As shown in Fig. 17.2, there are several variations of the conventional wheel design. First, we focus on the off-centered orientable wheel in Fig. 17.2b. The center of the wheel, B , is connected to the cart by a rigid rod from A (a fixed point on the cart) to B , aligned with the wheel plane. The rod, whose length is denoted by d , can rotate around a fixed vertical axle at point A . The position of A is specified by two constant polar coordinates, l and α , with respect to the reference point P . The rotation of the rod with respect to the cart is represented by the angle β . The radius of the wheel is denoted by r , and its angle of rotation around its horizontal axle is denoted φ . The description therefore involves four constant parameters: α, l, r , and d , and two variables: $\varphi(t)$ and $\beta(t)$.

With these notations the kinematic constraints are derived as follows.

We make the derivation explicit for the general situation corresponding to a caster wheel (Fig. 17.2b). For fixed or steering wheels one just has to consider either the case $d = 0$ and constant β (fixed wheels), or $d = 0$ and variable β (steering wheels).

First we evaluate the velocity of the center of the wheel, which results from the following vector expression $\frac{d}{dt}OB = \frac{d}{dt}OP + \frac{d}{dt}PA + \frac{d}{dt}AB$. The two components of this vector in the robot frame are expressed as: $\dot{x} \cos \theta + \dot{y} \sin \theta - l\dot{\theta} \sin \alpha + (\dot{\theta} + \dot{\beta})d \cos(\alpha + \beta)$ and $-\dot{x} \sin \theta + \dot{y} \cos \theta - l\dot{\theta} \cos \alpha + (\dot{\theta} + \dot{\beta})d \sin(\alpha + \beta)$.

The projections of this vector onto the direction of the wheel plane, i.e., onto the vector $(\cos(\alpha + \beta - \pi/2), \sin(\alpha + \beta - \pi/2))$ and the vector of the wheel axle $(\cos(\alpha + \beta), \sin(\alpha + \beta))$, are $r\dot{\varphi}$ and 0, respectively, corresponding to the pure rolling and nonslip conditions.

After some manipulations, these conditions can be rewritten in the following compact form.

Pure rolling condition:

$$(-\sin(\alpha + \beta) \ \cos(\alpha + \beta) \ l \cos \beta) \mathbf{R}(\theta) \dot{\xi} + r\dot{\varphi} = 0, \quad (17.1)$$

Nonslip condition:

$$(-\cos(\alpha + \beta) \ \sin(\alpha + \beta) \ d + l \sin \beta) \mathbf{R}(\theta) \dot{\xi} + d\dot{\beta} = 0. \quad (17.2)$$

In these expressions $\mathbf{R}(\theta)$ is the orthogonal rotation matrix expressing the orientation of the robot with

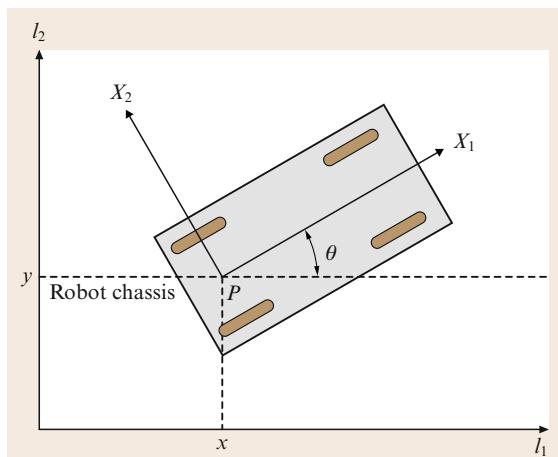

Fig. 17.4 The posture definition of a mobile robot on a plane

respect to the inertial frame, i.e.,

$$\mathbf{R}(\theta) = \begin{pmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (17.3)$$

As said before, these general expressions can be simplified for the different types of conventional wheels.

For *fixed wheels*, the center of the wheel is fixed with respect to the cart and the wheel orientation is constant. This corresponds to a constant value of β and $d = 0$ (Fig. 17.2a). The nonslip equation (17.2) then reduces to

$$(\cos(\alpha + \beta) \ \sin(\alpha + \beta) \ l \sin \beta) \mathbf{R}(\theta) \dot{\xi} = 0. \quad (17.4)$$

For *steering wheels*, the center of the wheel is also fixed with respect to the cart (i.e., $d = 0$), with β time-varying, so the nonslip equation takes the form (17.2). This structure was already introduced in Fig. 17.2c.

The situation described by (17.1) and (17.2), with a nonzero-length rod AB and time-varying orientation angle β corresponds to *caster wheels*.

Swedish Wheels

The position of a Swedish wheel with respect to the cart is described, as for a fixed wheels, by three constant parameters: α , β , and l . An additional parameter is required to characterize the direction, with respect to the wheel plane, of the zero component of the velocity at the contact point of the wheel. This parameter is γ , which is the angle between the axle of the rollers and the wheel plane (Fig. 17.3b).

The kinematic constraints now impose only one condition:

$$(-\sin(\alpha + \beta + \gamma) \ \cos(\alpha + \beta + \gamma) \ l \cos(\beta + \gamma)) \times \mathbf{R}(\theta) \dot{\xi} + r \cos \gamma \dot{\varphi} = 0. \quad (17.5)$$

17.2.3 Robot Configuration Variables

We now consider a wheeled robot equipped with N wheels of the above described types. We use the following subscripts to identify quantities related to these four types: ‘f’ for fixed wheels, ‘s’ for steering wheels, ‘c’ for caster wheels, and ‘sw’ for Swedish wheels. The numbers of wheels of each type are denoted by N_f , N_s , N_c , and N_{sw} , with $N = N_f + N_s + N_c + N_{sw}$.

The configuration of the robot is fully described by the following generalized coordinate vector.

- *posture coordinates*: the posture vector $\xi(t) = (x(t) \ y(t) \ \theta(t))^T$;

- *orientation coordinates*: the $N_s + N_c$ orientation angles of the steering and caster wheels, i.e., $\beta(t) = (\beta_s(t) \ \beta_c(t))^T$;
- *rotation coordinates*: the N rotation angles of the wheels, i.e., $\varphi(t) = (\varphi_f(t) \ \varphi_s(t) \ \varphi_c(t) \ \varphi_{sw}(t))^T$

This whole set of coordinates is termed the set of configuration coordinates. The total number of configuration coordinates is $N_f + 2N_s + 2N_c + N_{sw} + 3$.

17.2.4 Restriction on Robot Mobility

The *pure rolling conditions* for fixed, steering, and caster wheels, as well as the constraints relative to the Swedish wheels, can be written in the following compact form

$$\mathbf{J}_1(\beta_s, \beta_c) \mathbf{R}(\theta) \dot{\xi} + \mathbf{J}_2 \dot{\varphi} = 0, \quad (17.6)$$

with

$$\mathbf{J}_1(\beta_s, \beta_c) = \begin{pmatrix} \mathbf{J}_{1f} \\ \mathbf{J}_{1s}(\beta_s) \\ \mathbf{J}_{1c}(\beta_c) \\ \mathbf{J}_{1sw} \end{pmatrix}.$$

In this expression \mathbf{J}_{1f} , $\mathbf{J}_{1s}(\beta_s)$, $\mathbf{J}_{1c}(\beta_c)$, and \mathbf{J}_{1sw} are, respectively, $(N_f \times 3)$, $(N_s \times 3)$, $(N_c \times 3)$, and $(N_{sw} \times 3)$ matrices, whose forms derive directly from the kinematic constraints, while \mathbf{J}_2 is a constant $(N \times N)$ diagonal matrix whose entries are the radii of the wheels, except for the radii of the Swedish wheels which are multiplied by $\cos \gamma$.

The value $\gamma = \frac{\pi}{2}$ would correspond to the direction of the zero component of the velocity being orthogonal to the plane of the Swedish wheel. Such a wheel would be subject to a constraint identical to the nonslip condition for a conventional wheel, hence losing the benefit of implementing a Swedish wheel. This implies that $\gamma \neq \frac{\pi}{2}$ and that \mathbf{J}_2 is a nonsingular matrix.

The *nonslip conditions* for caster wheels can be summarized as

$$\mathbf{C}_{1c}(\beta_c) \mathbf{R}(\theta) \dot{\xi} + \mathbf{C}_{2c} \dot{\beta}_c = 0, \quad (17.7)$$

where $\mathbf{C}_{1c}(\beta_c)$ is a $(N_c \times 3)$ matrix, whose entries derive from the nonslip constraints (17.2), while \mathbf{C}_{2c} is a constant diagonal nonsingular matrix, whose entries are equal to d .

The last constraints relate to the *nonslip conditions for fixed and steering wheels*. They can be summarized as

$$\mathbf{C}_1^*(\beta_s) \mathbf{R}(\theta) \dot{\xi} = 0, \quad (17.8)$$

where

$$\mathbf{C}_1^*(\beta_s) = \begin{pmatrix} \mathbf{C}_{1f} \\ \mathbf{C}_{1s}(\beta_s) \end{pmatrix},$$

where \mathbf{C}_{1f} and $\mathbf{C}_{1s}(\beta_s)$ are, respectively, $N_f \times 3$ and $N_s \times 3$ matrices.

It is important to point out that the restrictions on robot mobility result only from the conditions (17.8) involving the fixed and the steering wheels. These conditions imply that the vector $\mathbf{R}(\theta)\dot{\xi}$ belongs to $N[\mathbf{C}_1^*(\beta_s)]$, the null space of the matrix $\mathbf{C}_1^*(\beta_s)$. For any $\mathbf{R}(\theta)\dot{\xi}$ satisfying this condition, there exists a vector $\dot{\phi}$ and a vector $\dot{\beta}_c$ satisfying, respectively, conditions (17.6) and (17.7), because J_2 and C_{2c} are nonsingular matrices.

Obviously $\text{rank}[\mathbf{C}_1^*(\beta_s)] \leq 3$. If it is equal to 3 then $\mathbf{R}(\theta)\dot{\xi} = 0$, which means that any motion in the plane is impossible. More generally, restrictions on robot mobility are related to the rank of $\mathbf{C}_1^*(\beta_s)$, as will be discussed in detail below.

It is worth noticing that condition (17.8) has a direct geometrical interpretation. At each time instant the motion of the robot can be viewed as an instantaneous rotation about the instantaneous center of rotation (**ICR**), whose position with respect to the cart can be time varying. At each instant the velocity of any point of the cart is orthogonal to the straight line joining this point and the **ICR**. This is true, in particular, for the centers of the fixed and steering wheels, which are fixed points of the cart. On the other hand, the nonslip condition implies that the velocity of the wheel center is aligned with the wheel plane. These two facts imply that the horizontal rotation axles of the fixed and steering wheels intersect at the **ICR** (Fig. 17.5). This is equivalent to the condition that $\text{rank}[\mathbf{C}_1^*(\beta_s)] \leq 3$.

17.2.5 Characterization of Robot Mobility

As said before the mobility of the robot is directly related to the rank of $\mathbf{C}_1^*(\beta_s)$, which depends on the design of the robot. We define the degree of mobility δ_m as

$$\delta_m = 3 - \text{rank}[\mathbf{C}_1^*(\beta_s)]. \quad (17.9)$$

Let us first examine the case $\text{rank}(\mathbf{C}_{1f}) = 2$, which implies that the robot has at least two fixed wheels. If there are more than two fixed wheels, their axles intersect at the **ICR**, whose position with respect to the cart is then fixed in such a way that the only possible motion is a rotation of the cart about this fixed **ICR**. Obviously, from the user's point of view, such a design is not acceptable. We therefore assume that $\text{rank}(\mathbf{C}_{1f}) \leq 1$.

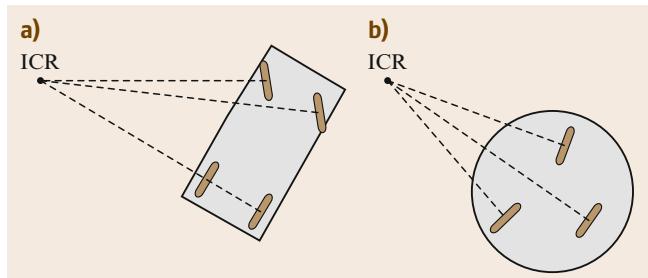

Fig. 17.5a,b The instantaneous center of rotation. (a) A car-like robot; (b) a three-steering-wheels robot

Moreover, we assume that $\text{rank}[\mathbf{C}_1^*(\beta_s)] = \text{rank}(\mathbf{C}_{1f}) + \text{rank}[\mathbf{C}_{1s}(\beta_s)] \leq 2$.

These two assumptions are equivalent to the following set of conditions.

1. If the robot has more than one fixed wheel, they are all on a single common axle.
2. The centers of the steering wheels do not belong to this common axle of the fixed wheels.
3. The number $\text{rank}[\mathbf{C}_1^*(\beta_s)]$ is equal to the number of steering wheels that can be oriented independently in order to steer the robot.

We call this number the *degree of steerability*:

$$\delta_s = \text{rank}[\mathbf{C}_{1s}(\beta_s)]. \quad (17.10)$$

If a robot is equipped with more than δ_s steering wheels, the motion of the extra wheels must be coordinated in order to guarantee the existence of the **ICR** at each instant.

We conclude that, for wheeled mobile robot of practical interest, the two defined indices, δ_m and δ_s , satisfy the following conditions.

1. The degree of mobility satisfies $1 \leq \delta_m \leq 3$. The upper bound is obvious, while the lower bound means that we consider only cases where motion is possible.
2. The degree of steerability satisfies $0 \leq \delta_s \leq 2$. The upper bound can be reached only for robots without fixed wheels, while the lower bound corresponds to robots without steering wheels.
3. The following is satisfied: $2 \leq \delta_m + \delta_s \leq 3$.

The case $\delta_m + \delta_s = 1$ is not acceptable because it corresponds to the rotation of the robot about a fixed **ICR**. The cases $\delta_m \geq 2$ and $\delta_s = 2$ are excluded because, according to the above assumptions, $\delta_s = 2$ implies $\delta_s = 1$. These conditions imply that only five structures are of practical interest, corresponding to the five pairs (δ_m, δ_s) satisfying the above inequalities, according to

the following array.

$$\begin{array}{cccccc} \delta_m & 3 & 2 & 2 & 1 & 1 \\ \delta_s & 0 & 0 & 1 & 1 & 2 \end{array}$$

Below, each type of structure will be designated by using a denomination of the form type (δ_m, δ_s) robot.

17.2.6 The Five Classes of Wheeled Mobile Robots

We now briefly describe the five classes of wheeled robot structures, pointing out the mobility restriction inherent to each class. Details and examples can be found in Sect. 17.5 and in [17.6].

Type (3,0) Robots

These robots have no fixed and no steering wheels and are equipped only with Swedish or caster wheels. Such robots are called *omnimobile*, because they have full mobility in the plane, which means that they are able to move in any direction without any reorientation.

Type (2,0) Robots

These robots have no steering wheels, but either one or several fixed wheels with a common axle. Mobility is restricted in the sense that, at a given posture $\xi(t)$, the velocity $\dot{\xi}(t)$ is constrained to belong to a two-dimensional distribution spanned by the vector fields $R^\top(\theta)s_1$ and $R^\top(\theta)s_2$, where s_1 and s_2 are two constant vectors spanning $N(C_{1f})$. A typical example of such a robot is the wheelchair.

Type (2,1) Robots

These robots have no fixed wheels and at least one steering wheel. If there is more than one steering wheel, their orientations must be coordinated in such a way that $\text{rank}[C_{1s}(\beta_s)] = \delta_s = 1$. The velocity $\dot{\xi}(t)$ is constrained to belong to a two-dimensional distribution spanned by the vector fields $R^\top(\theta)s_1(\beta_s)$ and $R^\top(\theta)s_2(\beta_s)$, where $s_1(\beta_s)$ and $s_2(\beta_s)$ are two vectors spanning $N(C_{1s}(\beta_s))$.

Type (1,1) Robots

These robots have one or several fixed wheels on a single common axle, and also one or several steering wheels, with the conditions that their centers are not located on the common axle of the fixed wheels, and that their orientations are coordinated. The velocity $\dot{\xi}(t)$ is constrained to belong to a one-dimensional distribution parameterized by the orientation angle of one arbitrarily chosen steering wheel. Mobile robots built on the model of a conventional car (often called *car-like* robots) belong to this class.

Type (1,2) Robots

These robots have no fixed wheels, but at least two steering wheels. If there are more than two steering wheels, then their orientation must be coordinated in order to satisfy the condition $\text{rank}[C_{1s}(\beta_s)] = \delta_s = 2$. The velocity $\dot{\xi}(t)$ is constrained to belong to a one-dimensional distribution parameterized by the orientation angles of two arbitrarily chosen steering wheels.

17.3 State-Space Models of Wheeled Mobile Robots

In this section, the mobility analysis discussed in the previous section is reformulated into a state-space form that will be useful for subsequent developments. We introduce four different kinds of state-space representation that are of interest for understanding the behavior of wheeled robots, and for control design purpose.

- The *posture kinematic model*, which is the simplest state-space model able to give a global description of the robot, from the users viewpoint.
- The *configuration kinematic model* allows one to describe the kinematic behavior of the whole robot, including all the configuration variables.
- The *configuration dynamic model* is the most general state-space model. It gives a complete description of

the dynamics including the forces provided by the actuators. In particular, it allows to one address the issue of actuator configuration and to define a criterion to check whether the motorization is sufficient to exploit the kinematic mobility fully.

- The *posture dynamic model*, which is feedback equivalent to the configuration dynamic model, constitutes a dynamical counterpart to the posture kinematic model.

17.3.1 Posture Kinematic Models

We have shown that, whatever the type of robot, the velocity vector $\dot{\xi}(t)$ is restricted to belong to a distribution

Δ_c defined as

$$\dot{\xi} \in \Delta_c = \text{span}\{\text{col}[\mathbf{R}^\top(\theta)\Sigma(\beta_s)]\},$$

where the columns of the matrix $\Sigma(\beta_s)$ constitute a basis of $N[\mathbf{C}_1^*(\beta_s)]$. This is equivalent to the following statement: for all t , there exists a vector η such that

$$\dot{\xi} = \mathbf{R}^\top(\theta)\Sigma(\beta_s)\eta, \quad (17.11)$$

The dimension of the distribution Δ_c , and hence of the vector $\eta(t)$, is equal to the degree of mobility δ_m of the robot. Obviously, in the case where the robot has no steering wheels, the matrix Σ is constant, and the expression (17.11) reduces to

$$\dot{\xi} = \mathbf{R}^\top(\theta)\Sigma\eta. \quad (17.12)$$

In the opposite case ($\delta_s \geq 1$), the matrix Σ explicitly depends on the orientation angles β_s , and the expression (17.11) can be augmented as follows:

$$\dot{\xi} = \mathbf{R}^\top(\theta)\Sigma(\beta_s)\eta, \quad (17.13)$$

$$\dot{\beta}_s = \varsigma. \quad (17.14)$$

The representation (17.12) (or (17.13) and (17.14)) can be viewed as a state-space representation of the model, reflecting the mobility restriction induced by the constraints; it is termed the *posture kinematic model*.

The state vector is constituted by the three posture coordinates $\dot{\xi}(t)$ and, possibly, by δ_s orientation coordinates $\dot{\beta}_s$. The vectors η and $\dot{\xi}$, of dimension δ_m and δ_s , respectively, are homogeneous to velocities and can be interpreted as control inputs entering the model linearly.

Nevertheless, this interpretation should be treated with some care, since the true physical inputs are the torques provided by the embarked actuators. The kinematic posture model is in fact only a subsystem of the general dynamic model that will be presented in Sect. 17.3.3.

This posture kinematic model allows us to discuss further the maneuverability of wheeled robots. The degree of mobility δ_m is equal to the number of degrees of freedom that can be *directly* manipulated from the inputs $\eta(t)$, without reorientation of the steering wheels. Intuitively, it corresponds to how many degrees of freedom the robot could have instantaneously from its current position, without steering any of its wheels. This number δ_m is not equal to the overall number of degrees of freedom of the robot that can be manipulated from the inputs $\eta(t)$ and $\varsigma(t)$, which is equal to the sum $\delta_M = \delta_m + \delta_s$ and which we could call degree of maneuverability. It includes the δ_s degrees of freedom that are accessible from

the inputs $\varsigma(t)$. However, the action of $\varsigma(t)$ on the posture coordinates $\dot{\xi}(t)$ is indirect, since it is achieved only through the coordinates β_s , which are related to the inputs $\varsigma(t)$ by an integral action, reflecting the fact that the modification of the orientation of a steering wheel cannot be achieved instantaneously. The maneuverability of a wheeled robot depends not only on δ_M , but also on the way these δ_M degrees of freedom are partitioned into δ_m and δ_s . Therefore, two indices are needed to characterize the maneuverability. Obviously the ideal situation is that of omnimobile robots where $\delta_M = \delta_m = 3$.

In order to avoid useless notational complications, we will assume from now on that the degree of steerability is equal to the number of steering wheels, i.e., $N_s = \delta_s$. This is a restriction from a robot design viewpoint. However, for the mathematical analysis of the behavior of mobile robots, there is no loss of generality in this assumption, although it considerably simplifies the technical derivation. Indeed, for robots with an excess of steering wheels, it is always possible to reduce the condition (17.8) to a minimal subset of exactly δ_s independent constraints that correspond to the δ_s wheels that have been selected as the master steering wheels and to ignore the other slave wheels in the analysis.

17.3.2 Configuration Kinematic Models

In order to discuss the restriction of mobility, we have considered only a subset of the conditions induced by the kinematic constraints, namely the nonslip conditions for the fixed and steering wheels (17.8). The remaining constraints are now used to derive the equations of evolution of the rotation velocities $\dot{\varphi}$ and of the orientation velocities of the caster wheels $\dot{\beta}_c$. From (17.6) and (17.7) it follows immediately that

$$\dot{\beta}_c = -\mathbf{C}_{2c}^{-1}\mathbf{C}_{1c}(\beta_c)\mathbf{R}(\theta)\dot{\xi}, \quad (17.15)$$

$$\dot{\varphi} = -\mathbf{J}_2^{-1}\mathbf{J}_1(\beta_s, \beta_c)\mathbf{R}(\theta)\dot{\xi}. \quad (17.16)$$

By combining these equations with the posture kinematic model (17.13), the state equations for β_c and φ become

$$\dot{\beta}_c = -\mathbf{D}(\beta_c)\Sigma(\beta_s)\eta, \quad (17.17)$$

$$\dot{\varphi} = -\mathbf{E}(\beta_s, \beta_c)\Sigma(\beta_s)\eta, \quad (17.18)$$

where

$$\mathbf{D}(\beta_c) = -\mathbf{C}_{2c}^{-1}\mathbf{C}_{1c}(\beta_c) \quad \text{and}$$

$$\mathbf{E}(\beta_s, \beta_c) = -\mathbf{J}_2^{-1}\mathbf{J}_1(\beta_s, \beta_c).$$

Defining q as the vector of configuration coordinates, i.e.,

$$q = \begin{pmatrix} \xi \\ \beta_s \\ \beta_c \\ \varphi \end{pmatrix},$$

the evolution of the configuration coordinates can be described by the following compact form, called the *configuration kinematic model*

$$\dot{q} = S(q)u, \quad (17.19)$$

where

$$S(q) = \begin{pmatrix} R^\top(\theta)\Sigma(\beta_s) & 0 \\ 0 & I \\ D(\beta_c)\Sigma(\beta_s) & 0 \\ E(\beta_s, \beta_c)\Sigma(\beta_s) & 0 \end{pmatrix},$$

and $u = \begin{pmatrix} \eta \\ \varsigma \end{pmatrix}$. (17.20)

The vector q is the vector of generalized coordinates allowing one to fully describe the position and the configuration of the mobile robot.

The constraints (17.6), (17.7), and (17.8) can be summarized under the following compact form

$$J(q)\dot{q} = 0, \quad (17.21)$$

where the matrix $J(q)$ is the Jacobian of the constraints, i.e.,

$$J(q) = \begin{pmatrix} J_1(\beta_s, \beta_c)R(\theta) & 0 & 0 & J_2 \\ C_{1c}(\beta_c)R(\theta) & 0 & C_{2c} & 0 \\ C_1^*(\beta_s)R(\theta) & 0 & 0 & 0 \end{pmatrix}. \quad (17.22)$$

The two matrices $S(q)$ and $J(q)$ satisfy the relation

$$S(q)J(q) = 0. \quad (17.23)$$

17.3.3 Configuration Dynamic Models

We now derive the dynamic configuration model which constitutes, from a mechanical viewpoint, the full system description, allowing one to relate the control inputs provided by the embarked actuators to the evolution of the generalized coordinates q . This model is derived using the Lagrange formalism.

We assume that the robot is equipped with actuators that can force either the orientation of the steering and

caster wheels, or the orientation of all the wheels. The torques provided by the actuators are denoted τ_φ for the rotation of the wheels, τ_c for the orientation of the caster wheels, and τ_s for the orientation of the steering wheels.

Using the Lagrange formalism, we obtain the following compact equations:

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{q}} \right) - \frac{\partial T}{\partial q} = \tau + J^\top(q)\lambda. \quad (17.24)$$

In this equation

1. $T(q, \dot{q})$ the kinetic energy of the robot can be expressed as a quadratic form $T(q, \dot{q}) = \frac{1}{2}\dot{q}^\top M(\beta_c)\dot{q}$, where $M(\beta_c)$ is a symmetric positive-definite matrix.
2. τ is the vector of the generalized forces associated with the torques provided by the actuators

$$\tau = \begin{pmatrix} 0 \\ \tau_s \\ \tau_c \\ \tau_\varphi \end{pmatrix},$$

3. the term $J^\top(q)\lambda$ is the vector of generalized forces associated with the kinematic constraints. The vector λ is the vector of the Lagrange multipliers associated with the constraints.

With the above expression for the kinetic energy (17.19) can be rewritten as

$$M(\beta_c)\ddot{q} + f(q, \dot{q}) = \tau + J^\top(q)\lambda. \quad (17.25)$$

(See Sect. 2.3 on the dynamics of rigid-body systems.)

The Lagrange multipliers are eliminated by left multiplying (17.25) by $S(q)$ and using (17.23). Moreover, \dot{q} and \ddot{q} can be eliminated using (17.19).

It follows that

$$\begin{aligned} & [S^\top(q)M(\beta_c)S(q)]\dot{u} \\ & + [S^\top(q)M(\beta_c)\dot{S}(q)u + S^\top(q)f(q, S(q)u)] \\ & = S^\top(q)\tau \end{aligned} \quad (17.26)$$

or, more compactly

$$H(q)\dot{u} + F(q, u) = S^\top(q)\tau. \quad (17.27)$$

This equation, together with the equation of the configuration kinematic model (17.19) constitutes the configuration dynamic model of the robot.

In this general formulation (17.27) τ represents all the torques that can potentially be applied for the orientation and rotation of the wheels. In practice, however, only

a limited number of actuators are used, which means that many components of this vector are identically zero. Our purpose now is to characterize the actuator configurations exploiting the maneuverability that can be expected from the posture kinematic model.

First, it is clear that all the steering wheels must be provided with an actuator for their orientation, otherwise these wheels would just play the role of fixed wheels.

Moreover, in order to ensure full robot mobility, N_m additional actuators (with $N_m \geq \delta_m$) must be implemented for either the rotation of some wheels or the orientation of some caster wheels. The vector of the torques developed by these additional actuators is denoted by τ_m , and we can write

$$\begin{pmatrix} \tau_c \\ \tau_\varphi \end{pmatrix} = P\tau_m, \quad (17.28)$$

where P is an $((N_c + N) \times N_m)$ elementary matrix that selects the components of τ_c and φ_c that appear explicitly in τ_m and may therefore be used as control inputs. With this notation, the dynamic equation (17.27) can be rewritten as

$$\begin{aligned} H(q)\dot{u} + F(q, u) &= \begin{pmatrix} I & 0 \\ 0 & B(\beta_s, \beta_c)P \end{pmatrix} \begin{pmatrix} \tau_s \\ \tau_m \end{pmatrix} \\ &= \Gamma(\beta_s, \beta_c) \begin{pmatrix} \tau_s \\ \tau_m \end{pmatrix}, \end{aligned} \quad (17.29)$$

where $B(\beta_s, \beta_c) = \Sigma^\top(\beta_c)(D^\top(\beta_c)E^\top(\beta_s, \beta_c))$

It must be pointed out that the evolution of the variable u can be assigned provided P (and equivalently the actuator implementation) is such that the matrix $B(\beta_s, \beta_c)P$ has full rank for all (β_s, β_c) . We assume in the sequel that this condition is satisfied, ensuring therefore full exploitation of the potential maneuverability of the robot.

17.3.4 Posture Dynamic Models

It follows from the above assumption that the configuration dynamic model is feedback equivalent (by smooth static time-invariant state feedback) to the following system:

$$\dot{q} = S(q)u, \quad (17.30)$$

$$\dot{u} = v, \quad (17.31)$$

where v represents a set of $(\delta_s + \delta_m)$ auxiliary independent control inputs.

This state feedback is given by

$$\begin{pmatrix} \tau_s \\ \tau_m \end{pmatrix} = \Gamma^+(\beta_s, \beta_c)[H(q)v - F(q, u)], \quad (17.32)$$

where Γ^+ denotes an arbitrary left inverse of Γ .

(See Sect. 6.6 on computer torque control.)

We emphasize that a further simplification is of interest from an operational viewpoint. In the context of trajectory planning or feedback control design, it is clear that the user is essentially concerned with controlling the posture of the robot (namely the posture coordinate $\xi(t)$) by using the control input v . This implies that we can deliberately ignore the coordinates β_c and φ and restrict our attention to the following posture dynamic model:

$$\dot{z} = B(z)u, \quad (17.33)$$

$$\dot{u} = v, \quad (17.34)$$

where

$$\begin{aligned} z &= \begin{pmatrix} \xi \\ \beta_s \end{pmatrix}, u = \begin{pmatrix} \eta \\ \varsigma \end{pmatrix} \text{ and} \\ B(z) &= \begin{pmatrix} R^\top(\theta)\Sigma(\beta_s) & 0 \\ 0 & I \end{pmatrix}. \end{aligned}$$

The first equation is nothing but the kinematic posture model equation (17.12), or (17.13, 17.14). The difference with this kinematic model is the presence of integrators on the input variables (17.34), so that the variables u are now part of the state vector. This leads to the appearance of a drift term in the dynamic model.

The posture dynamic model fully describes the system dynamics between the control input v and the posture ξ . The coordinates β_c and φ have apparently disappeared but it is important to note that they are in fact hidden in the feedback (17.32).

17.3.5 Articulated Robots

Up to now we have considered only simple mobile robots, i.e., robots made up of only one cart. In this section we extend this analysis to articulated robots, i.e., robots formed by a master cart with several trailers. A typical example is the well-known truck and trailers system.

Each of the trailers can be equipped of wheels of the types described in Sect. 17.2.2, actuated or not. The number of possible structures becomes almost infinite. This is why we restrict our analysis to passive trailers (no onboard actuators) equipped only with fixed wheels.

We consider a master cart that can be described by any of the five discussed types. The first trailer is connected to the cart, i.e., a material point of the trailer is fixed to a material point of the master cart. The relative position of the trailer with respect to the cart is described by a posture angle θ_1 . This trailer is equipped with one or several fixed wheels. If there is more than one wheel, then they have the same geometric axle. To this first trailer is connected a second trailer, of the same type, whose relative position with respect to the first is characterized by the angle θ_2 , and so on, for a sequence of N_t trailers.

The posture vector allowing one to describe this augmented system is now extended to a $3 + N_t$ generalized posture vector: $\xi^* = \begin{pmatrix} \xi \\ \theta^* \end{pmatrix}$, where ξ is the posture vector of the master cart while θ^* is the vector of the relative angles of the successive trailers. We also denote by ξ_i^* the posture of a partial system, from the master cart up to the i -th trailer, i.e.,

$$\xi_i^* = \left(\xi^\top \ \theta_1 \ \dots \ \theta_i \right)^\top.$$

The kinematic constraints relative to the fixed wheel j of trailer i ($1 \leq i \leq N_t$) can be expressed as in Sect. 17.2.2 using the following notations:

- The reference point is the connection point between trailer $(i-1)$ and trailer i .
- We define the posture of trailer i , ξ_i , by the vector made up by the coordinates of this reference point and the absolute orientation of the trailer, which is equal to $(\theta + \theta_1 + \dots + \theta_i)$.
- The position of the wheel with respect to this reference point is described by its polar coordinates α_{ij} and l_{ij} . The orientation of the wheel is given by the constant angle β_{ij} .
- The rotation angle of the wheel is denoted by φ_{ij} .

The *pure rolling condition* is then given by

$$(-\sin(\alpha_{ij} + \beta_{ij}) \cos(\alpha_{ij} + \beta_{ij}) l_{ij} \cos \beta_{ij} \mathbf{R}(\theta + \theta_1 + \dots + \theta_i) \dot{\xi}_i + r \dot{\varphi}_{ij}) = 0, \quad (17.35)$$

while the *nonslip* condition becomes

$$\cos(\alpha_{ij} + \beta_{ij}) \sin(\alpha_{ij} + \beta_{ij}) l_{ij} \sin \beta_{ij} \mathbf{R}(\theta + \theta_1 + \dots + \theta_i) \dot{\xi}_i = 0. \quad (17.36)$$

The posture vector of trailer i , ξ_i , can be expressed as a function of ξ and of the orientation angles of the preceding trailers, i.e.,

$$\xi_i = \mathbf{g}_i(\xi_{i-1}^*).$$

This implies that

$$\begin{aligned} \dot{\xi}_i &= \frac{\partial \mathbf{g}_i}{\partial \xi} \dot{\xi} + \sum_{k=1}^{i-1} \frac{\partial \mathbf{g}_i}{\partial \theta_k} \dot{\theta}_k \\ &= \mathbf{G}_i(\xi_{i-1}^*) \dot{\xi}_{i-1}^* \quad i = 1, \dots, N_t. \end{aligned} \quad (17.37)$$

Using this expression in the nonslip condition (17.36) for the N_t trailers, and using the nonslip condition for the master cart, we obtain the following set of equations reflecting the restriction of motion for all parts of the system:

$$\mathbf{J}^*(\beta_s, \theta, \theta_1, \dots, \theta_{N_t}) \dot{\xi}^* = 0. \quad (17.38)$$

Following the same lines as in Sect. 17.3.1, we derive the *posture kinematic model* of the articulated robot:

$$\dot{\xi}^* = \mathbf{S}^*(\beta_s, \theta, \theta_1, \dots, \theta_{N_t}) \eta, \quad (17.39)$$

$$\dot{\beta}_s = \varsigma. \quad (17.40)$$

The matrices \mathbf{J}^* and \mathbf{S}^* satisfy the relation

$$\mathbf{J}^*(\beta_s, \theta, \theta_1, \dots, \theta_{N_t}) \mathbf{S}^*(\beta_s, \theta, \theta_1, \dots, \theta_{N_t}) = 0. \quad (17.41)$$

Equation (17.37) provides the evolution of the relative angles of each trailer. It must be noticed that the time derivative of each of these angles depends on the input variables relative to the master cart (i.e., η and ς), on β_s , if the master cart is equipped with steering wheels, and on the relative angles of the preceding trailers only. This last property is due to the recursive structure of \mathbf{J}^* and \mathbf{S}^* .

Obviously it is possible to derive the three other models of the articulated robot, in a similar way as for the simple robot, as explained in Sects. 17.3.2, 17.3.3, and 17.3.4.

For the *configuration kinematic model* we consider the generalized vector constituted from all the variables, including the rotation angles of the wheels of the trailers. This model is derived as an extension of the posture model taking into account the pure rolling constraints (17.35). It has the form (17.19), with an appropriate definition of q . The *configuration dynamic model* is derived from the Lagrange equations of the system. It has the form (17.27), while the *posture dynamic model*, obtained via static state feedback, is again related to the posture kinematic, as for the simple robot (17.33) and (17.34).

17.4 Structural Properties of Wheeled Robots Models

Our purpose in this section is to discuss the structural properties of the above models of wheeled robots from a control design viewpoint. Since, in most situations, the user is only interested in the posture of the robot, and not in the *internal* variables (such as the wheel orientation angles), the most interesting models are the posture models (kinematic or dynamic). This is why the discussion on structural properties will be mainly based on the posture models.

17.4.1 Irreducibility, Controllability, and Nonholonomy

1. We first address the question of the reducibility of the *kinematic posture* state-space model (17.33). A state model is reducible if there exists a change of coordinates such that some of the new coordinates are identically zero along the motion system. For a nonlinear dynamical system without drift like (17.13, 14) reducibility is related to the dimension of the involutive closure $\bar{\Delta}$ of the following distribution Δ , expressed in local coordinates as

$$\Delta(z) = \text{span} [\text{col}B(z)] .$$

A well-known consequence of the Frobenius theorem is that the system is reducible only if $\dim(\bar{\Delta}) \leq \dim(\Delta) - 1$.

The following property can be checked for the *posture kinematic models* of wheeled robots.

For the posture kinematic model (17.33) $\dot{z} = B(z)u$,

- the input matrix $B(z)$ has full rank, i.e., $\text{rank}[B(z)] = \delta_m + \delta_s \forall z$,
- the involutive distribution $\bar{\Delta}(z)$ has constant maximal dimension, i.e., $\dim[\bar{\Delta}(z)] = 3 + \delta_s$.

As a consequence, the posture kinematic model of a wheeled robot is *irreducible*. This is a coordinate-free property.

This property has another consequence related to the controllability of the posture kinematic model. For a nonlinear dynamical model without drift of the form (17.13, 14), the strong accessibility algebra coincides with the involutive distribution $\bar{\Delta}(z)$, which has constant maximal dimension. It follows that the strong accessibility rank condition is satisfied and, therefore, the system is strongly accessible from any configuration. For such a driftless system this implies *controllability*. Practically, this means that a mobile robot can always be driven from any initial

posture ξ_0 to any final one ξ_f , in a finite time, by manipulating the velocity control inputs $u = (\eta^\top \varsigma^\top)^\top$. Finally, the difference between the dimensions of the two distributions $\Delta(z)$ and $\bar{\Delta}(z)$, i.e.,

$$\begin{aligned} \dim[\bar{\Delta}(s)] - \dim[\Delta(s)] &= (3 + \delta_s) - (\delta_m + \delta_s) \\ &= 3 - \delta_m , \end{aligned}$$

is related to the nonholonomy of the posture kinematic model.

If this difference is nonzero (i.e., if $\delta_m \leq 2$) the posture kinematic model is said to be *nonholonomic*. If $\delta_m = 3$, which is the case only for omnimobile robots, the kinematic posture model is *holonomic*.

2. The *configuration kinematic model* (17.23) is obtained from the posture model by adding the evolution of the internal variables $\beta_c(t)$ and $\varphi(t)$, and takes the same form $\dot{q} = S(q)u$.

In order to analyze reducibility and controllability issues we now have to consider the following two distributions: $\Delta_1(q) = \text{span}[\text{col}(S(q))]$, and its involutive closure $\bar{\Delta}_1(q)$.

It follows immediately that

$$\begin{aligned} \delta_m + N_s &= \dim[\Delta_1(q)] \leq \dim[\bar{\Delta}_1(q)] \leq \dim(q) \\ &= 3 + N + N_c + N_s . \end{aligned}$$

We define the *degree of nonholonomy* of the configuration kinematic model as

$$M = \dim[\bar{\Delta}_1(q)] - (\delta_m + \delta_s) .$$

This number represents the number of velocity constraints that are not integrable and therefore cannot be eliminated from the configuration evolution description, whatever the choice of the generalized coordinates. It must be pointed out that this number depends on the particular structure of the robot, and thus it has not necessarily the same value for two robots belonging to the same class.

On the other hand, for a particular choice of generalized coordinates, the number of coordinates that can be eliminated by integration of the constraints is equal to the difference between $\dim(q)$ and $\dim(\Delta_1(q))$.

It can be checked that the *configuration kinematic model* of all types of wheeled robots (including omnimobile robots) is *nonholonomic* (i.e., the degree of nonholonomy is not equal to zero), but is *reducible*.

Moreover, it does not satisfy the strong accessibility rank condition.

This property does not contradict the irreducibility of the posture kinematic model. The reducibility of the configuration model means that there exists at least one smooth function of $\mathbf{q}(t)$, involving explicitly at least one of the variables $\beta_c(t)$ and $\varphi(t)$, that is constant along the trajectories of the system compatible with the full set of kinematic constraints (17.21).

3. We have seen in Sects. 17.3.3 and 17.3.4 that the dynamic models ((17.30, 31), for the configuration model, or (17.33, 34) for the posture model) are related to the corresponding kinematic models, with the difference that the variables are part of the state vector. This implies the existence of a drift term and the fact that the input vector fields are constant. The dynamic models inherit the structural properties of the corresponding dynamic model. In particular, the posture dynamic model is irreducible and small-time locally controllable.

17.4.2 Stabilizability

Obviously, any arbitrary configuration $(\bar{\xi}^\top \bar{\beta}_s^\top)^\top$ may constitute an equilibrium point for the posture kinematic model. Equilibrium means that the robot is at rest somewhere, with a given constant posture $\bar{\xi}$ and a given constant orientation $\bar{\beta}_s$ of the steering wheels, and zero velocities, i. e., $\bar{u} = 0$.

Let us now consider the question of the existence of a feedback control $u(z)$ able to stabilize a mobile robot at a particular \bar{z} .

For *holonomic robots* (i. e., omnimobile robots, for which z reduces to ξ) the question is trivial, because $\dot{\xi}$ can be assigned arbitrarily from the input u . For instance the state-feedback control $u(z) = \mathbf{B}^{-1}(z)\mathbf{A}(z - \bar{z})$, ensures the following closed-loop dynamics

$$\dot{\xi} = A(\xi - \bar{\xi}),$$

and therefore, for any arbitrary Hurwitz matrix A , the exponential stability of the equilibrium \bar{z} .

For restricted mobility robots (*nonholonomic robots*) the situation is less favorable. Indeed the so-called Brockett necessary condition for the existence of smooth time-invariant stabilizing feedback is not satisfied, since the map $(z, u) \rightarrow B(z)u$ is not onto on a neighborhood of the equilibrium \bar{z} (Sect. 34.4.4).

We conclude that for restricted mobility robots the (*nonholonomic*) *posture kinematic* model is not stabilizable by a continuous static time-invariant state feedback.

Nevertheless such a model can be stabilized using smooth time-varying state feedback or noncontinuous feedback.

This property is inherited by the corresponding *dynamic configuration model*, which is also not stabilizable by continuous static time-invariant state feedback.

17.4.3 Static State-Feedback Linearizability

In this section we analyze the existence of state feedback achieving full or partial linearization of the posture models given by (17.33) for the kinematic model, or (17.33, 34) for the dynamic model.

A first result is the following. The largest subsystem of the posture kinematic model (17.33) linearizable by a smooth static feedback has dimension $(\delta_m + \delta_s)$. The largest linearizable subsystem of the dynamic model (17.33, 34) has dimension $2(\delta_m + \delta_s)$.

It can be checked that the largest linearizable subsystem of the kinematic posture model is obtained by selecting $(\delta_m + \delta_s)$ adequate linearizing output functions depending on z . A vector of $(3 - \delta_m)$ components remains nonlinearized. Similarly the largest linearizable subsystem of the posture dynamic model has dimension $2(\delta_m + \delta_s)$, with exactly the same linearizing output functions.

For omnimobile robots (i. e., robots with holonomic posture models), $\delta_m = 3$ and $\delta_s = 0$. The above property implies that the posture models are fully linearizable by static state feedback. In contrast, restricted mobility robots posture models are only partially linearizable.

17.4.4 Dynamic State-Feedback Linearizability – Differential Flatness

The purpose of this section is to show that posture models of wheeled robots can be fully linearized by dynamic state feedback. Obviously we only consider restricted mobility robots, because omnidirectional robots are fully linearizable by static state feedback, as discussed in the previous section.

Consider a nonlinear dynamical system given in general state-space form, affine in the inputs

$$\dot{z} = f(z) + \sum_{i=1}^m g_i(z)u_i, \quad (17.42)$$

where the state $z \in R^n$, the input $u \in R^m$, and the vector fields f and g_i are smooth.

When the system is not completely linearizable by diffeomorphism and static state feedback (as for

restricted mobility robots), full linearization can nevertheless possibly be achieved by considering more general dynamic feedback laws of the form

$$\begin{aligned} \mathbf{u} &= \alpha(z, \chi, w), \\ \dot{\chi} &= \mathbf{a}(z, \chi, w), \end{aligned} \quad (17.43)$$

where w is an auxiliary control input. Such a dynamic feedback is obtained through the choice of m suitable linearizing output functions

$$y_i = h_i(z), \quad i = 1, \dots, m. \quad (17.44)$$

We apply the so-called *dynamic extension algorithm* to system (17.42)–(17.44). The idea of this algorithm is to delay some *combinations of inputs* simultaneously affecting several outputs, via the addition of integrators, in order to enable other inputs to act in the meanwhile and therefore hopefully to extend an extended decoupled system of the form

$$y_k^{(r_k)} = w_k, \quad k = 1, \dots, m, \quad (17.45)$$

where $y_k^{(i)}$ denotes the i -th derivative of y_k with respect to time, r_k is the relative degree of y_k , and w_k denote the new auxiliary inputs. In order to get a *full* linearization, we shall have for the n_e -dimensional extended system

$$\sum_{i=1}^m r_i = n_e, \quad (17.46)$$

17.5 Wheeled Robot Structures

There are many design alternatives for wheeled mobile robots. Design problems of a single-body mobile robot include the selection of wheel types, the placement of wheels, and the determination of the kinematic parameters. Design objectives should be specified according to the target environments and tasks, as well as the initial and operational costs of a robot. In this section, robot structures are classified according to the number of wheels, and then features will be introduced focusing on commonly adopted designs.

17.5.1 Robots with One Wheel

A robot with a single wheel is basically unstable without dynamic control in order to maintain its balance of a body. A typical example is a unicycle. As a variation of a unicycle, a robot with a rugby-ball-shaped wheel

where n_e is the dimension of the extended state vector $\mathbf{z}_e = (z^\top \chi^\top)^\top$. If the condition (17.46) is satisfied, then

$$\mathbf{s} = \Psi(\mathbf{z}_e) = (y_1 \dots y_1^{(r_1-1)} \dots y_m \dots y_m^{(r_m-1)})^\top$$

is a local diffeomorphism.

A system that can be shown to be linearizable by using the dynamic extension algorithm is an example of a so-called *differentially flat system*. The linearizing outputs $y_i = h_i(z)$ are also called flat outputs. Conversely, differential flatness refers by definition to a system that can be linearized by dynamic state feedback. Roughly speaking, for a flat system, the state and the inputs can be expressed as algebraic functions of the flat outputs and their successive time derivatives.

These two related properties of linearizability by dynamic state feedback and differential flatness will be of interest for control design and path planning problems.

The fact that the posture kinematic and dynamic models of restricted mobility robots are differentially flat systems result directly from the following two properties.

1. Any controllable driftless system with m inputs and at most $m + 2$ states is a differentially flat system.
2. If a nonlinear system $\dot{z} = f(z, u)$ is differentially flat, then the augmented system $\dot{z} = f(z, u), \dot{u} = v$ is also a differentially flat system and is therefore generically fully linearizable by dynamic state feedback.

can be used in order to improve stability in the lateral direction, as studied in [17.7].

A spherical robot can also be considered as a single-wheel robot. A balancing mechanism such as a spinning wheel is employed to achieve dynamic stability. This approach has advantages including high maneuverability and low rolling resistance. However, single-wheel robots are rarely used in practical applications, because additional balancing mechanisms are required, control is difficult, and pose estimation by pure dead reckoning is not available. An example of a spherical robot can be found in [17.8].

17.5.2 Robots with Two Wheels

In general, there are two types of two-wheel robots, as shown in Fig. 17.6. Figure 17.6a shows a bicycle-

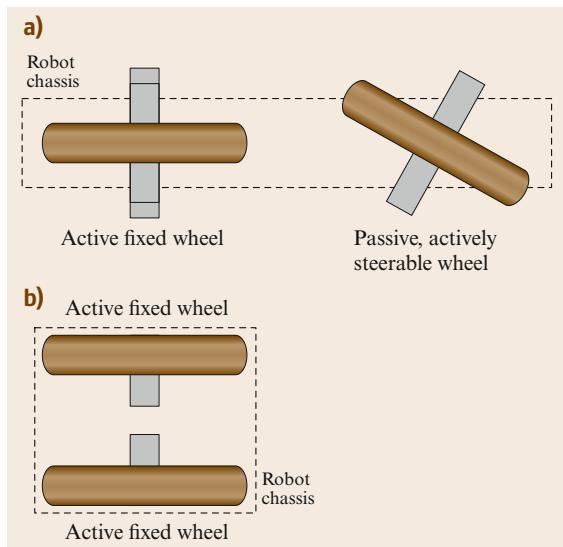

Fig. 17.6 (a) Bicycle-type robot, **(b)** inverted-pendulum-type robot

type robot. It is common to steer a front wheel and to drive a rear wheel. Since the dynamic stability of a bicycle-type robot increases with its speed, a balancing mechanism is not necessarily required. The advantage of this approach is that the robot width can be reduced. However, a bicycle type is rarely used because it cannot maintain its pose when the robot stands still. Fig. 17.6b shows an inverted-pendulum-type robot. It is a two-wheel differential drive robot.

It is possible to achieve static stability by accurately placing the center of gravity on the wheel axle. However, it is common to apply dynamic balancing control, which is similar to the conventional control problem for an inverted pendulum. The size of a robot can be reduced by using two-wheel robots, when compared with robots with more than three wheels. A typical application of a pendulum-type robot is to design a structure as a four-wheel robot, consisting of two pendulum robots connected. Then, the robot can climb stairs by lifting its front wheels while the robot reaches the stair. A major disadvantage is that control effort is always required for dynamic balancing. Examples of inverted-pendulum-type robots can be found in [17.9] and [17.10].

17.5.3 Robots with Three Wheels

Since a robot with three wheels is statically stable and has a simple structure, it is one of the most widely used

structures for wheeled robots. There are a large number of designs according to the choice of individual wheel types. Every wheel introduced in Sect. 17.2.1 can be used to construct three-wheel robots. In this section, five popular design examples are described: (1) two-wheel differential drive, (2) synchronous drive, (3) an omnimobile robot with Swedish wheels, (4) an omnimobile robot with active caster wheels, and (5) an omnidirectional robot with steerable wheels.

Two-Wheel Differential-Drive Robot

A two-wheel differential-drive robot is one of the most popular designs and is composed of two active fixed wheels and one passive caster wheel. The robot can be classified as a type (2,0) robot in the nomenclature of Sect. 17.2.6. It is possible to extend the robot to a four-wheel robot by adding passive caster wheels. The major advantages of the robot can be summarized as follows:

- A simple mechanical structure, a simple kinematic model, and low fabrication cost.
- A zero turning radius is available. For a cylindrical robot, the obstacle-free space can easily be computed by expanding obstacle boundaries by the robot radius r .
- Systematic errors are easy to calibrate.

On the other hand, its drawbacks are:

- difficulty of moving irregular surfaces. When the robot goes over uneven surfaces, its orientation might change abruptly if one of the active wheels loses contact with the ground;
- only bidirectional movement is available.

Synchronous-Drive Robot

A synchronous-drive robot can be built by using centered or off-centered orientable wheels. The steering and driving motions of each wheel are mechanically coupled by chains or belts, and the motions are actuated synchronously, so the wheel orientations are always identical. The kinematic model of a synchronous drive robot is equivalent to that of the unicycle, a type (1,1) robot. Therefore, omnidirectional motion, i. e., motion in any direction, can be achieved by steering the wheel orientations to the desired velocity direction. However, the orientation of the robot chassis cannot be changed. Sometimes a turret is employed to change the body orientation. The most significant advantage of the synchronous-drive robot is that omnidirectional movement can be achieved by using only two actuators. Since the mechanical structure guarantees synchronous steer-

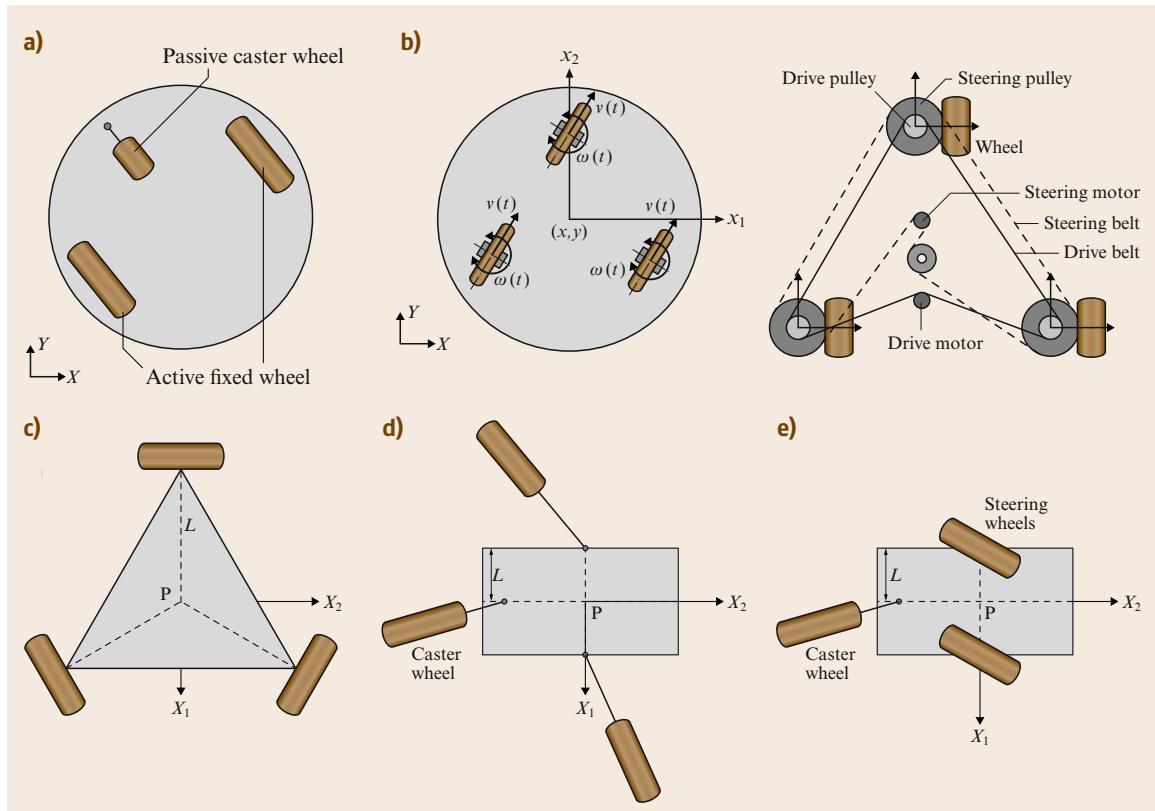

Fig. 17.7 (a) Two-wheel differential drive, (b) synchronous drive, (c) omnimobile robot with Swedish wheels, (d) omnimobile robot with active caster wheels, (e) omnidirectional robot with active steerable wheels

ing and driving motions, less control effort is required for motion control. Other advantages include that odometry information is relatively accurate and driving forces are evenly distributed among all the wheels. The drawbacks of this approach can be summarized as

- complicated mechanical structure
- if backlash or loose coupling is present in the chain transmission, velocity differences between wheels may occur
- in order to achieve omnidirectional movement, the wheel orientations should be aligned to the desired velocity direction before movement, due to the non-holonomic velocity constraints.

Omnimobile Robot with Swedish Wheels

The omnimobile robot with Swedish wheels corresponds to type (3,0) in the nomenclature of Sect. 17.2.6. At least three Swedish wheels are required to build a holonomic omnidirectional robot. A major advan-

tage of using the Swedish wheel is that omnidirectional mobile robots can be easily constructed. At least three Swedish wheels are required to build a holonomic omnidirectional robot. Since omnidirectional robots can be built without using active steering of wheel modules, the mechanical structures of actuating parts can have simple structures. However, the mechanical design of a wheel becomes slightly complicated. One drawback of the Swedish wheel is that there is a vertical vibration because of discontinuous contacts during motion. In order to solve this problem, a variety of mechanical designs have been proposed; examples can be found in [17.11] and [17.12]. Another drawback is its relatively low durability when compared to conventional tires. An example of a robot using Swedish wheels can be found in [17.13].

Omnimobile Robot with Active Caster Wheels

A holonomic omnidirectional robot can be constructed by using at least two active caster wheels, and the robot

also belongs to type (3,0). The robot can be controlled to generate arbitrary linear and angular velocities regardless of the wheel orientations. Since the robot uses conventional tires, the disadvantages of Swedish wheels, for example, vertical vibrations or durability problems, can be solved. An example can be found in [17.14]. The disadvantages of this robot can be summarized as follows:

- Since the location of the ground contact point (i. e., footprint) changes with respect to the robot chassis, instability can take place when the distance between the wheels is too short.
- If the robot switches its movement to the reverse direction, an abrupt change of wheel orientations may take place. This is called the shopping-cart effect, which may result in instantaneous high steering velocities.
- If a driving motor is directly attached to the wheel, wires to the motor will be wound due to steering motions. In order to avoid this, a gear train should be employed to transmit the input angular velocity from the driving motor, which is attached to the robot chassis. In this case, the mechanical structure becomes quite complicated.
- If a robot is equipped with more than two active caster wheel modules, more than four actuators are used. Since the minimum number of actuator to achieve holonomic omnidirectional motion is three, this is an overactuated system. Therefore, actuators should be accurately controlled in a synchronous way.

Omnidirectional Robot with Steerable Wheels

Centered orientable wheels are also employed to build omnidirectional robots; at least two modules are required. A significant difference between the active caster wheel and the centered orientable wheel is that the wheel orientation should always be aligned with the desired direction of velocity direction, as computed by inverse kinematics. This fact implies that this robot is non-holonomic and omnidirectional: it is a type (1,2) robot. The control problem is addressed in [17.15]. The mechanical drawbacks are similar to those of using active caster wheels (i. e., many actuators and complicated mechanical structures). Since the driving motor is directly attached to the driving axis in many cases, allowable steering angles are limited in order to prevent wiring problems.

There are a lot of design candidates for three-wheel robots, other than the five designs described above.

They can be classified and analyzed according to the scheme presented in Sect. 17.1. The above designs can be extended to four-wheel robots to improve stability. Additional wheels can be passive wheels without adding additional kinematic constraints. Active wheels can also be added and should be controlled by solving the inverse kinematics problem. Four-wheeled robots require suspension to maintain contact with the ground to prevent wheels from floating on irregular surfaces.

17.5.4 Four Robots with Four Wheels

Among the various four-wheel robots, we focus on the car-like structure. The front two wheels should be synchronously steered to keep the same instantaneous center of rotation. Therefore, this solution is kinematically equivalent to a single orientable wheel and the robot can be classified as a type (1,1) robot. A major advantage of a car-like robot is that it is stable during high-speed motion. However, it requires a slightly complicated steering mechanism. If the rear wheels are actuated, a differential gear is required to obtain pure rolling of the rear wheels during the turning motion. If the steering angle of the front wheel cannot reach 90°, the turning radius becomes nonzero. Therefore, parking motion control in a cluttered environment becomes difficult.

17.5.5 Special Applications of Wheeled Robots

Articulated Robots

As explained in Sect. 17.3.5, a robot can be extended to an articulated robot, which is composed of a robot and trailers. A typical example is the luggage-transferring trailer system at airports. By exploiting trailers, a mobile robot obtains various practical advantages. For example, modular and reconfigurable robots can change their configuration according to service tasks. A common design is the car with multiple passive trailers that was presented in Sect. 17.3.5, which is the simplest design of an articulated robot. From the viewpoint of control, some significant issues have been made clear, including a proof of controllability and the development of open- and closed-loop controllers using canonical forms such as the chained form. The design issues for trailer systems are the selection of wheel types and decisions regarding the link parameters. In practical applications, it is advantageous if trailers can move along the path of the towing robot. Passive trailers can follow the path of a towing robot within a small error by using a special

design of passive steering mechanism for trailers; see, for example, [17.16].

On the other hand, active trailers can be used. There are two types of active trailers. A first approach is to actuate wheels of trailers. The connecting joints are passive, and two-wheel differential-drive robots can be used as active trailers. By using this type of active trailers, accurate path-following control can be achieved. The second approach is to actuate connecting joints. The wheels of the trailer are passively driven. By appropriate actuation of the connecting joints, the robot can move without wheel actuation, by snake-like motions. As an alternative design, we can use an active prismatic joint to connect trailers, in order to lift the neighboring trailer. By allowing vertical motion, a trailer system can climb stairs and traverse rough terrain. Examples of active trailers can be found in [17.17].

Hybrid Robots

A fundamental difficulty of using wheels is that they can only be used on flat surfaces. To overcome this problem, wheels are often attached to a special link mechanism. Each wheel is equipped with independent actuators and a linkage mechanism enables the robot to adapt its configuration to irregular ground conditions. A typical design can be found in [17.18] and can be understood as a hybrid robot that is a combination of a legged robot and a wheeled robot. Another hybrid example is a robot equipped with both tracks and wheels. Wheels and tracks have complementary advantages and disadvantages. Wheeled robots are energy efficient, however, tracked robots can traverse rough terrain. Therefore,

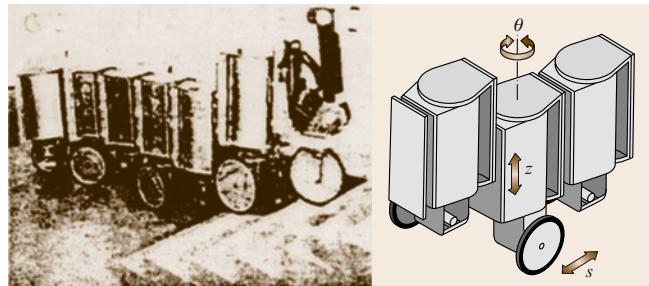

Fig. 17.8 An active trailer system [17.17]

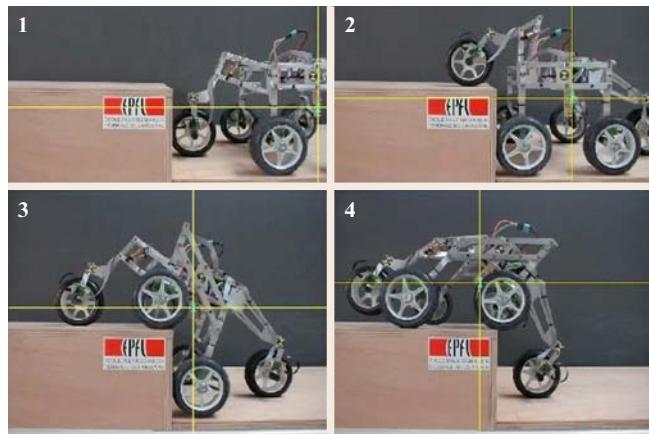

Fig. 17.9 A mobile robot for rough terrain [17.18]

a hybrid robot can selectively choose its driving mechanism according to environmental conditions, although fabrication cost increases.

17.6 Conclusions

The number of possible wheeled mobile robots realizations is almost infinite, depending on the number, type, implementation, geometric characteristics, and motorization of the wheels. This chapter describes several such realizations. Notwithstanding this variety it is possible to classify WMRs into only five generic categories. The (kinematic and dynamic) posture models have exactly the same structure within each of these classes. This fact is crucial for a model-based control design approach, such as that presented in Chap. 34.

The discussion of mobility and the derivation of the models are based on assumptions concerning the contact between the ground and the wheels: it is assumed

that pure rolling and nonslip conditions are satisfied for each wheel. These conditions lead to the kinematic constraints that constitute the basis of the analysis, and particularly of the properties related to the nonholonomy of these models. All model-based control designs therefore also rely on the same assumptions. These assumption are an idealization of the physical reality: these kinematic constraints are not satisfied exactly, and the contact effects are characterized by local slipping effects that are related through phenomenological laws to the contact forces. A question then arises immediately: what is the level of confidence in these models? Using a singular perturbation approach it has been shown that sliding effects can be considered as fast dynamics, with charac-

teristic times that are short compared to the dynamics of the global motion of the WMR and can be neglected, at

least for analysis and control design purposes (see, for instance, [17.1]).

Micro/Nanorobots

Bradley J. Nelson, Lixin Dong, Fumihiro Arai

The field of microrobotics covers the robotic manipulation of objects with dimensions in the millimeter to micron range as well as the design and fabrication of autonomous robotic agents that fall within this size range. Nanorobotics is defined in the same way only for dimensions smaller than a micron. With the ability to position and orient objects with micron- and nanometer-scale dimensions, manipulation at each of these scales is a promising way to enable the assembly of micro- and nanosystems, including micro- and nanorobots.

This chapter overviews the state of the art of both micro- and nanorobotics, outlines scaling effects, actuation, and sensing and fabrication at these scales, and focuses on micro- and nanorobotic manipulation systems and their application in microassembly, biotechnology, and the construction and characterization of micro and nanoelectromechanical systems (**MEMS/NEMS**). Material science, biotechnology, and micro- and nanoelectronics will also benefit from advances in these areas of robotics.

18.1 Overview of Micro- and Nanorobotics

Progress in robotics over recent years has dramatically extended our ability to explore, perceive, understand, and manipulate the world on a variety of scales extending from the edges of the solar system, to the bottom of the sea, down to individual atoms (Fig. 18.1). At the lower end of this scale, technology has been

moving toward greater control of the structure of matter, suggesting the feasibility of achieving thorough control of the molecular structure of matter atom by atom, as Richard Feynman first proposed in 1959 in his prophetic article on miniaturization [18.1]:

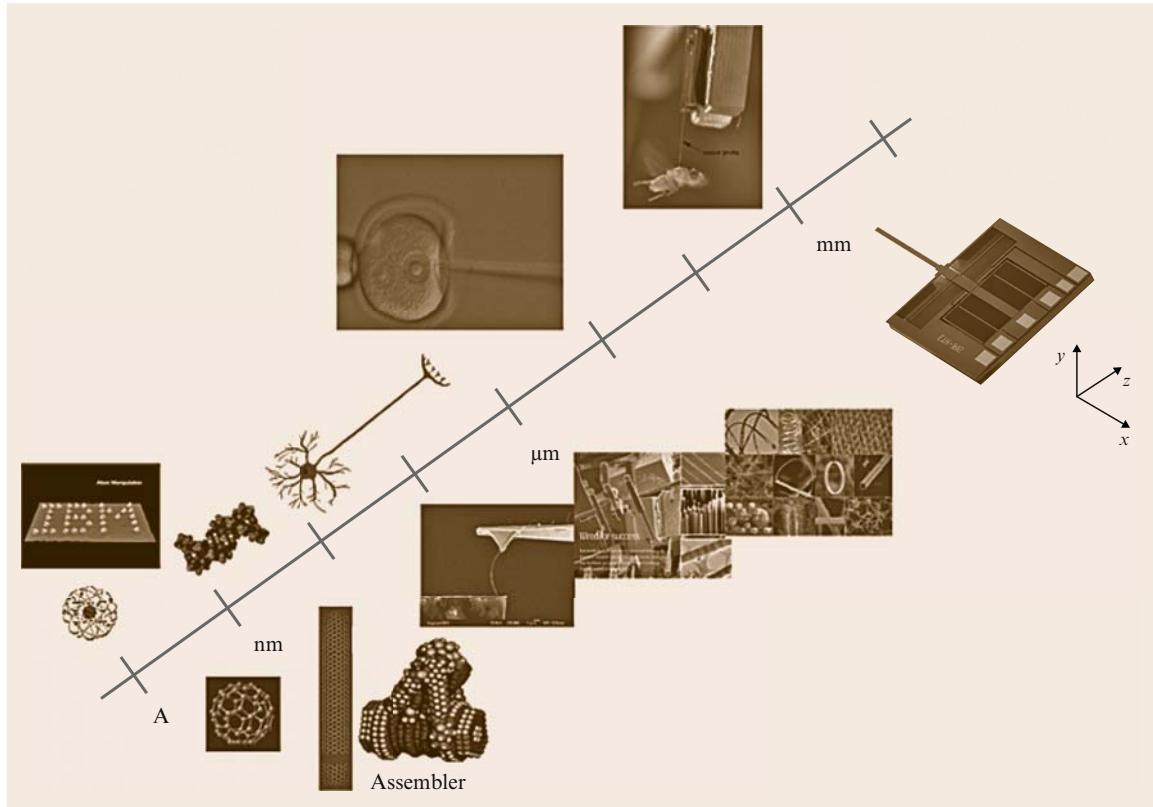

Fig. 18.1 Robotic exploration at micro- and nanometer scales

What I want to talk about is the problem of manipulating and controlling things on a small scale . . . I am not afraid to consider the final question as to whether, ultimately – in the great future – we can arrange the atoms the way we want: the very atoms, all the way down!

He asserted that

At the atomic level, we have new kinds of forces and new kinds of possibilities, new kinds of effects. The problems of manufacture and reproduction of materials will be quite different. The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom.

This technology is now labeled *nanotechnology*.

The *great future* of Feynman began to be realized in the 1980s. Some of the capabilities he dreamed of have been demonstrated, while others are being actively pursued. Feynman foresaw the possibility of

employing a microrobotic manipulator (*a master–slave system*) for bottom-up manufacturing (manipulation, assembly, etc.) of minute machines; one such device he described as “swallowing the surgeon”, which he attributed to his friend Albert R. Hibbs. He also imagined we could “build a billion tiny factories, models of each other, which are manufacturing simultaneously, drilling holes, stamping parts, and so on.” Micro- and nanorobotics research has progressed from these seemingly *far-out* concepts of the 1960s and 1970s to reality when microelectromechanical systems (**MEMS**) began to emerge in the late 1980s. These building blocks took the form of surface-micromachined micromotors and microgrippers made of polysilicon fabricated on a silicon chip [18.2]. In the late 1980s and early 1990s, more concrete suggestions on how one could realize **MEMS**-based microrobotic devices using such micromotors as well as potential applications were published [18.3, 4]. Today, a variety of micro-robotic devices are enabling new applications in various fields.

In industry, interesting areas for microrobotics include assembly [18.5, 6], characterization, inspection and maintenance [18.7, 8], microoptics (positioning of microoptical chips, microlenses and prisms) [18.9], and microfactories [18.10]. Many of these applications require automated handling and assembly of small parts with accuracy in the submicron range.

Other important fields include biology (manipulation, capturing, sorting and combining cells [18.11]) and medical technology [18.12, 13]. In surgery, the use of steerable catheters and endoscopes is very attractive and the development of increasingly small microrobotic devices is rapidly progressing. Wireless untethered microrobots that will explore and repair our bodies (“swallowing the surgeon”) appear to be simply a matter of time. In fact, endoscopy using wireless capsules (camera pills) are already on the market and allow for endoscopic imaging of the entire gastrointestinal tract [18.14], something currently not possible using standard scopes. Magnetic steering or crawling-type motions serve as promising ways for such devices to locomote in a controlled fashion [18.15]. Doctors could steer pill-mounted cameras and other actuators to areas of interest for visual investigation and biopsies beyond the range of current endoscopes.

Nanorobotics represents the next stage in miniaturization for maneuvering nanoscale objects. Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size, i.e., nanorobots, and large robots capable of manipulating objects that have nanometer dimensions with nanometer resolution, i.e., nanorobotic manipulators. The field of nanorobotics brings together several disciplines, including nanofabrication processes used for producing nanoscale robots, nanoactuators, nanosensors, and physical modeling at nanoscales. Nanorobotic manipulation technologies, including the assembly of nanometer-sized parts, the manipulation of biological cells or molecules, and the types of robots used to perform these types of tasks also form a component of nanorobotics.

As the 21st century unfolds, the impact of nanotechnology on the health, wealth, and security of humankind is expected to be at least as significant as the combined influences in the 20th century of antibiotics, the integrated circuit, and human-made polymers. For example, N. Lane stated in 1998, “If I were asked for an area of science and engineering that will most likely produce the breakthroughs of tomorrow, I would point to nanoscale science and engineering.” [18.16] The great scientific and technological opportunities nanotechnol-

ogy presents have stimulated extensive exploration of the nanoworld and initiated an exciting worldwide competition, which has been accelerated by the publication of the *National Nanotechnology Initiative* by the US government in 2000 [18.17]. Nanorobotics will play a significant role as an enabling nanotechnology and could ultimately be a core part of nanotechnology if Drexler’s machine-phase nanosystems based on self-replicative molecular assemblers via mechanosynthesis can be realized [18.18].

By the early 1980s, scanning tunneling microscopes (STM) [18.19] radically changed the way in which we interacted with and even regarded single atoms and molecules. The very nature of proximal probe methods encourages the exploration of the nanoworld beyond conventional microscopic imaging. Scanning probes now allow us to perform *engineering* operations on single molecules, atoms, and bonds, thereby providing a tool that operates at the ultimate limits of fabrication. They have also enabled exploration of molecular properties on an individual nonstatistical basis.

STM and other nanomanipulators are nonmolecular machines that use bottom-up strategies. Although performing only one molecular reaction at a time is obviously impractical for making large amounts of a product, it is a promising way to provide the next generation of nanomanipulators. Most important, it is possible to realize the directed assembly of molecules or supermolecules to build larger nanostructures through nanomanipulation. The products produced by nanomanipulation could be the first step of a bottom-up strategy in which these assembled products are used to self-assemble into nanomachines.

One of the most important applications of nanorobotic manipulation will be nanorobotic assembly. However, it appears that, until assemblers capable of replication can be built, the combination of chemical synthesis and self-assembly are necessary when starting from atoms; groups of molecules can self-assemble quickly due to their thermal motion, enabling them to *explore* their environments and find (and bind to) complementary molecules. Given their key role in natural molecular machines, proteins are obvious candidates for early work in self-assembling artificial molecular systems. *Degrado* [18.20] demonstrated the feasibility of designing protein chains that predictably fold into solid molecular objects. Progress is also being made in artificial enzymes and other relatively small molecules that perform functions like those of natural proteins. Several bottom-up strategies using self-assembly appear feasible [18.21]. Chemical synthesis, self-assembly, and

supramolecular chemistry make it possible to provide building blocks at relatively large sizes beginning from the nanometer scale. Nanorobotic manipulation serves as the base for a hybrid approach to construct nanodevices by structuring these materials to obtain building blocks and assembling them into more complex systems.

Despite the claims of many *futurists*, the form nanorobots of the future will take and what tasks they will actually perform remain unclear. However, it is clear that nanotechnology is progressing towards the construction of intelligent sensors, actuators, and systems that are smaller than 100 nm. These nanoelectromechanical systems (**NEMS**) will serve as both the tools to be used for fabricating future nanorobots as well as the components from which these nanorobots may be developed. Shrinking device size to these dimensions presents many fascinating opportunities such as manipulating nano-objects with nanotools, measuring mass in

femtogram ranges, sensing forces at piconewton scales, and inducing gigahertz motion, among other new possibilities waiting to be discovered. These capabilities will, of course, drive the tasks that future nanorobots constructed by and with **NEMS** will perform. **NEMS** and the components of nanorobots will be the products of nanorobotic manipulation. Large nanorobotic manipulators will be able to shrink in size due to this development, thus enabling nanosized robotic manipulators and other forms of nanorobots. All of these form the scope of the area of nanorobotics.

This chapter focuses on micro- and nanorobotics including actuation, manipulation, and assembly at the micro- and nanoscale. The main goal of these fields of robotics is to provide an effective technology for the experimental exploration of the micro- and nanoworld, and to push the boundaries of this exploration from a robotics research perspective.

18.2 Scaling

18.2.1 The Size of Things

Things we can potentially observable range from 10^{-35} m (the Planck length) to 10^{26} m (the radius of the observable universe). A nanometer, 10^{-9} m, is about ten times the size of the smallest atoms, such as hydrogen and carbon, while a micron is barely larger than the average wavelength of visible light, thus invisible to the human eye. A millimeter, the size of a pinhead, is roughly the smallest part typically fabricated using traditional machining techniques. The range of scales from millimeters to nanometers is one million (Fig. 18.1), which is also about the range of scales in present-day mechanical technology from the largest skyscrapers to the smallest conventional mechanical machine parts. The vast opportunity to make new machines spanning almost six orders of magnitude from 1 mm to 1 nm, is one take on Richard Feynman's famous statement, "there is plenty of room at the bottom" [18.1]. If L is taken as a typical length, 0.1 nm for an atom, perhaps 2 m for a human, this scale range in L would be 2×10^{10} . If the same scale range were to apply to an area, $0.1 \text{ nm} \times 0.1 \text{ nm}$ versus $2 \text{ m} \times 2 \text{ m}$, the scale range for area L^2 is 4×10^{20} . Since a volume L^3 is enclosed by sides L , we can see that the number of atoms of size 0.1 nm in a $(2 \text{ m})^3$ volume is about 8×10^{30} , recalling that Avogadro's number $N_A = 6.022 \times 10^{23}$ is the number of atoms in a gram-mole, supposing that the atoms were ^{12}C , mo-

lar responding to a density $1.99 \times 10^4 \text{ kg/m}^3$. A primary working tool of the nanotechnologist is facility in scaling the magnitudes of various properties of interest, as the length scale L shrinks, e.g., from 1 mm to 1 nm.

Clearly, the number of atoms in a device scales as L^3 . If a transistor on the micron scale contains 10^{12} atoms, then on the nanometer scale, $L'/L = 10^{-3}$ it will contain 1000 atoms, likely too few to preserve its function.

Normally, we will think of scaling as an isotropic scale reduction in three dimensions. However, scaling can be thought of usefully when applied only to one or two dimensions, scaling a cube to a two-dimensional (2-D) sheet of thickness a or to a one-dimensional (1-D) tube or nanowire of cross-sectional area a^2 . The term *zero-dimensional* (0-D) is used to describe an object small in all three dimensions, having volume a^3 . In electronics, a zero-dimensional object (a nanometer-sized cube a^3 of semiconductor) is called a quantum dot (**QD**) or *artificial atom* because its electronic states are few and sharply separated in energy, and thus resemble the electronic states of an atom.

18.2.2 Predominate Physics at the Micro- and Nanoscales

The predominate physics at the micro- and nanoscale can be dramatically different from at the macroscale. Surface and intermolecular forces, such as adhesion forces

originating from surface tension forces, van der Waals forces, and electrostatic forces, become more significant than volumetric forces such as gravitational forces for objects with sizes well below 1000 μm [18.22]. Although the laws of classical Newtonian physics may well suffice to describe changes in behavior down to 10 nm (100 Å), the range of scaling is tremendous. Therefore, the changes in magnitudes of many important physical properties, such as resonant frequencies, are so great, that completely different applications may appear.

The more challenging question for the nanotechnologist is to understand and hopefully to exploit those changes in physical behavior that occur at the end of the classical scaling range. The *end of the scaling* is the size scale of atoms and molecules, where nanophysics [18.23] is the proven conceptual replace-

ment of the laws of classical physics. Modern physics, which includes quantum mechanics as a description of matter on a nanometer scale, is a very well-developed and proven subject whose application to real situations is limited only by modeling and computational competence.

In the modern era, simulations and approximate solutions increasingly facilitate the application of nanophysics to almost any problem of interest. Many central problems are already (adequately, or more than adequately) solved in the extensive literatures of theoretical chemistry, biophysics, condensed matter physics, and semiconductor device physics. The practical problem is to find the relevant work, and, frequently, to convert the notation and units systems to apply the results to the problem at hand.

18.3 Actuation at the Micro- and Nanoscales

The positioning of nanorobots and nanorobotic manipulators depends largely on nanoactuators. While nanosized actuators for nanorobots are still under exploration and relatively far from implementation, MEMS-based efforts are focused on shrinking their sizes [18.30]. Nanometer resolution motion has been extensively investigated and can be generated using various actuation principles. Electrostatics, electromagnetics, and piezoelectrics are the most common ways to realize actuation at nanoscales. For nanorobotic manipulation, besides nanoresolution and compact sizes, actuators generating large strokes and high forces are best suited for such applications. The speed criteria are of less importance as long as the actuation speed is in the range of a couple of hertz and above. Table 18.1 provides a small selection of early works on actua-

tors [18.24–29] suitable for micro- and nanorobotic applications (partially adapted from [18.30]).

Several extensive reviews on various actuation principles have been published [18.4, 31–34]. During the design of an actuator, the trade-offs among range of motion, force, speed (actuation frequency), power consumption, control accuracy, system reliability, robustness, load capacity, etc. must be taken into consideration. This section reviews basic actuation technologies and potential applications at nanometer scales.

18.3.1 Electrostatics

Electrostatic charge arises from a build up or deficit of free electrons in a material, which can exert an attractive force on oppositely charged objects, or a repulsive

Table 18.1 Actuation with MEMS

| Actuation principle | Type of motion | Volume (mm ³) | Speed (s ⁻¹) | Force (N) | Stroke (m) | Resolution (m) | Power density (W/m ³) | Ref. |
|---------------------|----------------|---------------------------------|--------------------------|----------------------|--------------------|--------------------|-----------------------------------|---------|
| Electrostatic | Linear | 400 | 5000 | 1×10^{-7} | 6×10^{-6} | NA | 200 | [18.24] |

force on similarly charged objects. Since electrostatic fields arise and disappear rapidly, such devices will likewise demonstrate very fast operation speeds and be little affected by ambient temperatures.

Previous investigations have produced many examples of miniature devices using electrostatic force for actuation including silicon micromotors [18.35, 36], microvalves [18.37], and microtweezers [18.38]. This type of actuation is important for achieving nanoscale actuation.

Electrostatic fields can exert great forces, but generally across very short distances. When the electric field must act over larger distances, a higher voltage will be required to maintain a given force. The extremely low current consumption associated with electrostatic devices makes for highly efficient actuation.

18.3.2 Electromagnetics

Electromagnetism arises from electric current moving through a conducting material. Attractive or repulsive forces are generated adjacent to the conductor and proportional to the current flow. Structures can be built which gather and focus electromagnetic forces, and harness these forces to create motion.

Electromagnetic fields arise and disappear rapidly, thus permitting devices with very fast operation speeds. Since electromagnetic fields can exist over a wide range of temperatures, performance is primarily limited by the properties of the materials used in constructing the actuator.

One example of a microfabricated electromagnetic actuator is a microvalve which uses a small electromagnetic coil wrapped around a silicon micromachined valve structure [18.39]. The downward scalability of electromagnetic actuators into the micro- and nano-

realm may be limited by the difficulty of fabricating small electromagnetic coils. Furthermore, most electromagnetic devices require perpendicularity between the current conductor and the moving element, presenting a difficulty for planar fabrication techniques commonly used to make silicon devices.

An important advantage of electromagnetic devices is their high efficiency in converting electrical energy into mechanical work. This translates into less current consumption from the power source.

18.3.3 Piezoelectrics

Piezoelectric motion arises from the dimensional changes generated in certain crystalline materials when subjected to an electric field or to an electric charge. Structures can be built which gather and focus the force of the dimensional changes, and harness them to create motion. Typical piezoelectric materials include quartz (SiO_2), lead zirconate titanate (PZT), lithium niobate, and polymers such as polyvinylidene fluoride (PVDF).

Piezoelectric materials respond very quickly to changes in voltages and with great repeatability. They can be used to generate precise motions with repeatable oscillations, as in quartz timing crystals used in many electronic devices. Piezoelectric materials can also act as sensors, converting tension or compression strains to voltages.

On the microscale, piezoelectric materials have been used in linear inchworm drive devices and micropumps [18.40]. STMs and most nanomanipulators use piezoelectric actuators.

Piezoelectric materials operate with high force and speed, and return to a neutral position when unpowered. They exhibit very small strokes (under 1%). Alternating electric currents produce oscillations in the piezoelec-

Table 18.2 Comparison of nanoactuators

| Method | Efficiency | Speed | Power density |
|---------------------|------------|--------|---------------|
| Electrostatic | Very high | Fast | Low |
| Electromagnetic | High | Fast | High |
| Piezoelectric | Very high | Fast | High |

tric material, and operation at the sample's fundamental resonant frequency produces the largest elongation and highest power efficiency [18.41]. Piezoelectric actuators working in the *stick-slip* mode can provide millimeter to centimeter strokes. Most commercially available nanomanipulators adopt this type of actuators, such as PicomotorsTM from New Focus and NanomotorsTM from Klock.

18.3.4 Other Techniques

Other techniques include thermomechanical, phase change, shape memory, magnetostrictive, electrorheological, electrohydrodynamic, diamagnetism, magnetohydrodynamic, shape changing, polymers, and biological methods (living tissues, muscle cells, etc.). Table 18.2 compares these techniques.

18.4 Sensing at the Micro- and Nanoscales

A brief overview is given of common imaging tools used in the research area of micro- and nanorobotics including optical, electron, and scanning probe microscopy. The application and integration of these tools for micro- and nanorobotics are discussed in separate sections.

In selecting a proper tool for imaging/sensing at these scales, the following factors should be first considered:

1. Specimen: size, conductivity, and environment compatibility are among the most important aspects to consider. For example, in vivo bioapplications generally require air or liquid, so lower-resolution, light microscopy should be the first choice. If higher resolution is needed, atomic force microscopy or scanning near-field optical microscopy can be used.
2. Resolution: the ability to see fine details of a specimen. Once you can resolve fine details then you can magnify them. Every microscope has a finite resolution; if you magnify objects beyond the resolution the result will be empty magnification. Roughly speaking, a light microscope cannot provide a resolution better than 200 nm. The best commercially available scanning electron micro-

scopes (SEM) have approximately 1 nm resolution, while transmission electron microscopes (TEM) can achieve approximately 0.2 nm, and a scanning tunneling microscope (STM) working in ultrahigh vacuum under very low temperature can resolve atomic-level structures. A comparison of optical microscopy and electron microscopy is given in Table 18.3.

3. Depth of field: the range of depth that a specimen is in acceptable focus. A microscope that has a small depth of field will have to be continuously focused up and down to view a thick specimen.
4. Contrast: the ratio between dark and light. Typically, most microscopes use absorption contrast, i.e., the specimen is subjected to stains in order to be seen. This is called bright-field microscopy. There are other types of microscope that use more exotic means to generate contrast, such as phase contrast, dark field, and differential interference contrast.
5. Brightness: the amount of light. The higher a microscope magnifies the more light will be required. The illumination source should also be at a wavelength (color) that will facilitate interaction with the specimen. All microscopes fall into either of two cat-

Table 18.3 Comparison of optical microscopes and electron microscopes

| Feature | OM | TEM | SEM |
|--------------------------|-------------------------------------------|----------------------------------------------------------|------------------------------------|
| General use | Surface morphology and sections (1–40 µm) | Section (40–150 nm) or small particles on thin membranes | Surface morphology |
| Source of illumination | Visible light | High-speed electrons | High-speed electrons |
| Best resolution | ca. 200 nm | ca. 0.2 nm | ca. 3–6 nm |
| Magnification range | 10–1000 × | 500–500 000 × | 20–150 000 × |
| Depth of field | 0.002–0.05 nm (N.A. 1.5) | 0.004–0.006 mm (N.A. 10 ⁻³) | 0.003–1 mm |
| Lens type | Glass | Electromagnetic | Electromagnetic |
| Image ray-formation spot | On eye by lenses | On phosphorescent plate by lenses | On cathode tube by scanning device |

egories based on how the specimen is illuminated. In the typical compound microscope the light passes through the specimen and is collected by the image forming optics. This is called diascopic illumination. Dissecting (stereo) microscopes generally use episcopic illumination for use with opaque specimen. The light is reflected onto the specimen and then into the objective lens.

18.4.1 Optical Microscopy

Since their invention in the late 1500s, light microscopes have enhanced our knowledge in basic biology, biomedical research, medical diagnostics, and materials science. Light microscopes can magnify objects up to 1000 times, revealing microscopic details. Light-microscopy technology has evolved far beyond the first microscopes of Robert Hooke and Antoni van Leeuwenhoek. Special techniques and optics have been developed to reveal the structures and biochemistry of living cells. Most optical microscopes in current use are known as compound microscopes, where a magnified image of an object is produced by the objective lens, and this image is magnified by a second lens system (the ocular or eyepiece) for viewing. Microscopes have even entered the digital age, using charge-coupled devices (CCDs) and digital cameras to capture images.

The development of modern microscopy has enabled a large family of optical microscopes. For special purposes, other types of optical microscopes can be selected. These include phase-contrast microscopy, fluorescence microscopy, confocal scanning optical microscopy, and deconvolution microscopy image reconstruction.

18.4.2 Electron Microscopy

Scanning Electron Microscope (SEM)

Since the commercial availability of the SEM in 1966, it has been a valuable resource for viewing samples at a much higher resolution and depth of field than the typical optical microscope. Conventional SEMs can resolve down to the nanometer scale ($\approx 1 \text{ nm}$) whereas an optical microscope can only resolve down to approximately 200 nm [18.42]. Unlike conventional optical microscopes, SEMs have a high depth of field which gives imaged samples a three-dimensional appearance. Early SEMs were limited to viewing conductive samples. However, many of today's SEMs can image nonconductive samples in addition to conductive samples using variable-pressure chambers.

Transmission Electron Microscope (TEM)

The TEM can resolve to an atomic scale down to about 1 Å (i.e., 0.1 nm). The TEM mode of operation is similar to that of the SEM in that both microscopes contain an electron gun source of illumination. However, the TEM detects the electrons that pass through a given sample. As a result, the electron gun of the TEM operates at higher energy levels between 50–1000 kV, while the SEM's electron gun operates at around 1–30 kV. In order for proper imaging to take place, the sample must be very thin so that electrons from the beam can pass through the specimen. Electrons that do not pass through the sample cannot be detected. Unlike the SEM, the TEM produces images that are two dimensional in appearance.

18.4.3 Scanning Probe Microscopy

Scanning Tunneling Microscope (STM)

Similar to the TEM, the STM [18.19] can also resolve specimens down to the atomic scale. The scanning probe of the STM is comprised of a noble metal sharpened to an atomic-sized tip, which is mounted on a piezoelectrically driven (x, y, z) linear stage. The STM makes use of the quantum-mechanical effect known as tunneling. Electron tunneling occurs when electrons, driven by a small potential difference, flow across the gap between the probe tip and sample. This event takes place at Ångström-scale distances between the probe tip and the sample [18.43]. The tunneling current, which is typically on the order of a few nanoamperes, is directly related to the tip–sample separation distance. Thus, the tunneling current can be measured and is kept at a constant value by controlling the tip–sample gap distance (z) with a feedback control system. The probe tip is then scanned (x, y) along the entire surface of the sample. Since the control system maintains a constant tunneling current, and thus maintains a constant tip–sample distance (z), the result of a scan yields a $z(x, y)$ terrain map of the sample with enough resolution to detect atomic-scale features. The STM can achieve faster imaging by operating in so-called constant-height mode in which the probe tip is scanned in a plane parallel to the average surface portion. The tip–sample distance (z) can then be inferred directly from the measured tunneling current [18.43].

Atomic Force Microscope (AFM)

The AFM [18.44] is considered to be a spin-off of the STM. One shortcoming of the STM is that it requires conductive probe tips and samples to work properly. The AFM was developed in order to view nonconduc-

tive samples, giving it a wider applicability than the **STM**. In addition to imaging nonconductive samples, the AFM can also image samples immersed in liquid, which is useful for biological applications [18.45]. Although the **STM** and AFM are similar in that they both scan the surface of a sample with an atomically sharp probe, they operate under slightly different principles. The AFM is based on interatomic forces as opposed to the electron tunneling used in the **STM**. The AFM probe tip is mounted on the end of a microscale cantilever beam. At very short separations, the forces between atoms in the probe tip and atoms in the sample cause the cantilever to deflect. This deflection is usually measured by striking the back of the cantilever with a laser. The reflection of the laser beam hits a photodetector, which can be used to recover the deflection of the cantilever. The force can then be cal-

culated by using Hooke's law, which simply relates the applied force to the stiffness and deflection of a material. The forces that are measured can be on the scale of piconewtons [18.43]. The AFM has three main modes of operation known as contact mode, noncontact mode, and tapping mode.

Unlike the **SEM** and **TEM**, both the **STM** and AFM do not require a vacuum environment in order to function. However, a high vacuum is advantageous in order to keep the samples from becoming contaminated from the surrounding environment as well as controlling humidity. In addition, atomic resolution in air is hardly possible with an AFM due to humidity. As a result of humidity, a water film is formed and creates problems because of capillary forces. This can be resolved by operating in vacuum environment or completely in a liquid solution [18.43].

18.5 Fabrication

The design of micro- and nanorobotic devices is intrinsically linked to available fabrication techniques. However, though the development of microfabrication processes has become somewhat stable over the past decade, nanofabrication processes are still being actively pursued, and the design constraints generated by these processes are relatively unexplored. This section will briefly highlight the processes used in conventional microfabrication including lithography, thin-film deposition, chemical etching, and electrodeposition, and describe some emerging techniques for nanofabrication.

Most micro- and nanofabrication techniques have their roots in the standard fabrication methods developed for the semiconductor industry [18.46–48]. Therefore, a clear understanding of these techniques is necessary for anyone embarking on a research and development path in the micro/nano area.

18.5.1 Microfabrication

In this section, we will discuss the major microfabrication techniques used most frequently in the manufacturing of microstructures.

Photolithography

Lithography is the technique used to transfer a computer-generated pattern onto a substrate (silicon, glass, GaAs, etc.). This pattern is subsequently used to etch an under-

lying thin film (oxide, nitride, etc.) for various purposes (doping, etching, etc.). Although photolithography, i.e., lithography using an ultraviolet (UV) light source, is by far the most widely used lithography technique in microelectronic fabrication, electron-beam (e-beam) and X-ray lithography are two alternatives that have attracted considerable attention in the **MEMS** and nanofabrication areas. We will discuss photolithography in this section and postpone the discussion of e-beam and X-ray techniques to the subsequent sections dealing with nanofabrication.

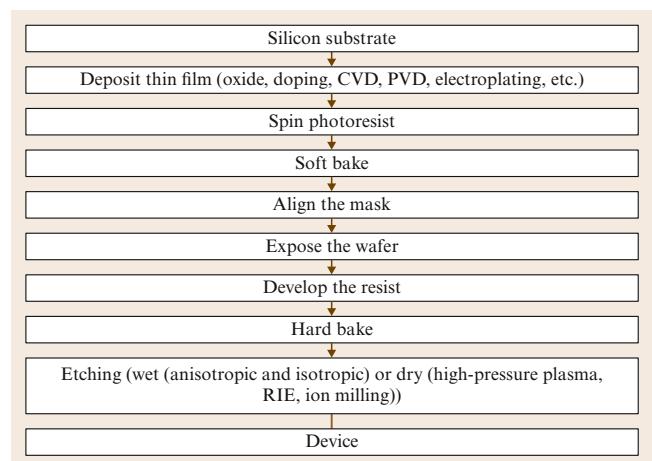

Fig. 18.2 Typical microfabrication process flow

The starting point following the creation of the computer layout for a specific fabrication sequence is the generation of a photomask. This involves a sequence of photographic processes (using optical or e-beam pattern generators) that results in a glass plate having the desired pattern in the form of a thin (≈ 100 nm) chromium layer. Following the generation of photomask, the lithography and etching process can proceed as shown in Fig. 18.2. After depositing the desired material on the substrate, the photolithography process starts with spin-coating the substrate with a photoresist. This is a polymeric photosensitive material that can be spun onto the wafer in liquid form; usually an adhesion promoter such as hexamethyldisilazane (HMDS) is used prior to the application of the resist. The spinning speed and photoresist viscosity will determine the final resist thickness, which is typically 0.5–2.5 μm . Two different kinds of photoresist are available: positive and negative. With a positive resist, the UV-exposed areas will be dissolved in the subsequent development stage, whereas with a negative photoresist, the exposed areas will remain intact after the development. After spinning the photoresist on the wafer, the substrate is soft-baked (5–30 min at 60°–100 °C) in order to remove the solvents from the resist and improve the adhesion. Subsequently, the mask is aligned to the wafer and the photoresist is exposed to a UV source.

After exposure, the photoresist is developed in a process similar to the development of photographic film. The resist is subsequently hard-baked (20–30 min at 120°–180 °C) in order to further improve the adhesion. The hard-bake step concludes the photolithography sequence by creating the desired pattern on the wafer. Next, the underlying thin film is etched, and the photoresist is stripped in acetone or other organic solvent. Figure 18.3 shows a schematic of the photolithography steps with a positive photoresist.

Thin-Film Deposition and Doping

Thin-film deposition and doping are used extensively in micro- and nanofabrication technologies. Most of the fabricated structures contain materials other than that of the substrate, which are obtained by various deposition techniques, or by modification of the substrate. These techniques include oxidation, doping, chemical vapor deposition (CVD), physical vapor deposition (PVD), and electroplating.

Etching and Substrate Removal

For micro- and nanofabrication, in addition to thin film etching, often the substrate (silicon, glass, GaAs, etc.)

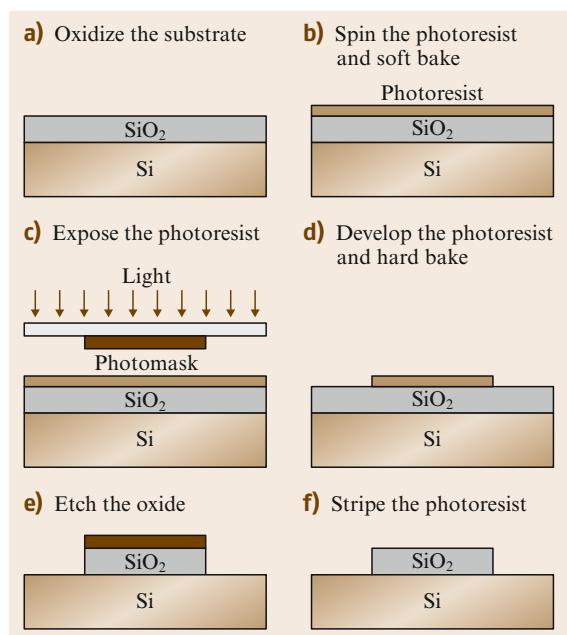

Fig. 18.3a–f Schematic drawing of the photolithographic steps with a positive photoresist (PR)

needs to be removed in order to create various mechanical structures (beams, plates, etc.). Two important figures of merit for any etching process are selectivity and directionality.

Selectivity is the degree to which the etchant can differentiate between the masking layer and the layer to be etched. Directionality has to do with the etch profile under the mask. In an isotropic etch, the etchant attacks the material in all directions at the same rate, creating a semicircular profile under the mask (Fig. 18.4a). In an anisotropic etch, the dissolution rate depends on specific directions, and one can obtain straight sidewalls or other noncircular profiles (Fig. 18.4b). One can also divide the various etching techniques into wet and dry categories. Due to the lateral undercut, the minimum feature size achievable with wet etchants is limited to $> 3 \mu\text{m}$. Photoresist and silicon nitride are the two most common masking materials for the wet oxide etch. Anisotropic and isotropic wet etching of crystalline (silicon and gallium arsenide) and noncrystalline (glass) substrates are important topics in micro- and nanofabrication [18.49–53].

The anisotropic behavior of these etchants with respect to the (111) planes have been used extensively to create beams, membranes, and other mechanical and structural components. Figure 18.5 shows the typical

cross sections of (100) silicon wafers etched with an anisotropic wet etchant. As can be seen, the (111) slow planes are exposed and creating 54.7° sloped sidewalls. Depending on the dimensions of the mask opening, a V-groove or a trapezoidal trench is formed in the (100) wafer. A large enough opening will allow the silicon to be etched all the way through the wafer, thus creating a thin dielectric membrane of the other side. It should be mentioned that exposed convex corners have a higher etch rate than the concave ones, resulting in an undercut that can be used to create dielectric (e.g., nitride) cantilever beams.

Dry etching techniques are largely plasma based. They have several advantages compared with wet etching. These include smaller undercut (allowing smaller lines to be patterned) and higher anisotropy (allowing high-aspect-ratio vertical structures). However, the selectivity of dry etching techniques is lower than the wet etchants, and one must take into account the finite etch rate of the masking materials. The three basic dry etching techniques, namely high-pressure plasma etching, reactive-ion etching (RIE), and ion milling, utilize different mechanisms to obtain directionality.

18.5.2 Nanofabrication

The design and fabrication of **NEMS** is an emerging area being pursued by an increasing number of researchers. Two approaches to nanofabrication, top-down and bottom-up, have been identified by the nanotechnology research community and are being independently investigated by various researchers. Top-down approaches are based on microfabrication and include technologies such as nanolithography, nanoimprinting, and chemical etching. Presently, these are 2-D fabrication processes with relatively low resolution. Bottom-up strategies are assembly-based techniques. Currently these strategies include techniques such as self-assembly, dip-pen lithography, and directed self-assembly. These techniques can generate regular nanopatterns at large scales.

In this section, we will discuss three major nanofabrication techniques. These include:

1. e-beam and *nanoimprint* fabrication,
2. *epitaxy* and *strain engineering*, and
3. dip-pen nanolithography.

E-beam Lithography and Nanoimprint Fabrication

In previous sections, we discussed several important lithography techniques commonly used in **MEMS** and

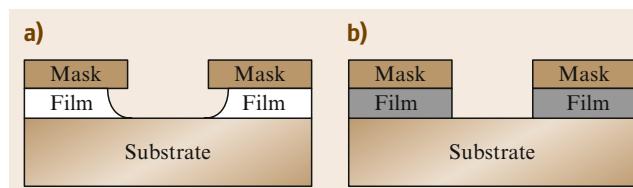

Fig. 18.4a,b Profile for isotropic (a) and anisotropic (b) etch through a photoresist mask

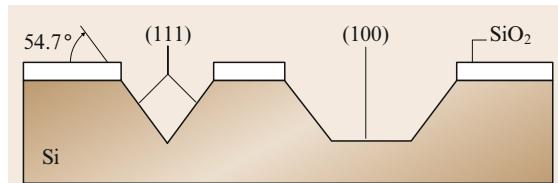

Fig. 18.5 Anisotropic etch profiles for (100) silicon wafers

microfabrication. These include various forms of UV (regular, deep, and extreme) and X-ray lithography. However, due to the lack of resolution (in the case of the UV), or the difficulty in manufacturing mask and radiation sources (X-ray), these techniques are not suitable for nanometer-scale fabrication. E-beam lithography is an attractive alternative technique for fabricating nanostructures [18.53]. It uses an electron beam to expose an electron-sensitive resist such as polymethyl methacrylate (**PMMA**) dissolved in trichlorobenzene (positive) or polychloromethylstyrene (negative).

The e-beam gun is usually part of an **SEM**, although a **TEM** can also be used. Although electron wavelengths on the order of 1 Å can easily be achieved, electron scattering in the resist limits the attainable resolutions to > 10 nm. The beam control and pattern generation are achieved through a computer interface.

E-beam lithography is serial and hence has a low throughput. Although this is not a major concern in fabricating devices used in studying fundamental micro-physics, it severely limits large-scale nanofabrication. E-beam lithography, in conjunction with such processes as lift-off, etching, and electrodeposition, can be used to fabricate various nanostructures.

An interesting new technique that circumvents the serial and low-throughput limitations of the e-beam lithography for fabricating nanostructures is nanoimprint technology [18.54]. This technique uses an e-beam-fabricated hard material master (or mold) to stamp and deform a polymeric resist. This is usually followed by a reactive-ion etching step to transfer the stamped pattern to the substrate. This technique is eco-

nomically superior, since a single stamp can be used repeatedly to fabricate a large number of nanostructures.

Epitaxy and Strain Engineering

Atomic-precision deposition techniques such as molecular-beam epitaxy (**MBE**) and metallo-organic chemical vapor deposition (**MOCVD**) have proven to be effective tools in fabricating a variety of quantum confinement structures and devices (quantum well lasers, photodetectors, resonant tunneling diodes, etc.) [18.55–57].

Dip-Pen Nanolithography

In dip-pen nanolithography (**DPN**), the tip of an AFM operated in air is *inked* with a chemical of interest and brought into contact with a surface. The ink molecules flow from the tip onto the surface as with a fountain pen. Line widths down to 12 nm with spatial resolution of 5 nm have been demonstrated with this technique [18.58]. Species patterned with **DPN** include conducting polymers, gold, dendrimers, deoxyribonucleic acid (DNA), organic dyes, antibodies, and alkanethiols.

18.6 Microassembly

Assembly is often required in macroscale product manufacturing in order to reduce the complexity and cost of the manufacturing process. Assembly makes it possible to build complex products from relatively simple parts and to integrate incompatible manufacturing processes. It also makes maintenance and replacement possible. The extension of assembly techniques into the microscale is driven by the development of modern design and manufacturing technologies in the pursuit of miniaturization and function integration, especially by the development of integrated circuit (IC) [18.59] and **MEMS** fabrication techniques. With the extension of manufacturing technology into the microscale and even nanoscale domain, the term microassembly has been created to refer specifically to assembly operations performed at the micro/mesoscale [18.60]. To give a formal definition, microassembly is the assembly of objects with microscale and/or mesoscale features under microscale tolerances [18.61].

18.6.1 Automated Microassembly Systems

Microassembly plays the role of an enabling technology in various processes of **MEMS** fabrication, including device fabrication, packaging, and interconnection. **MEMS** device fabrication is fundamentally different from the highly modular IC fabrication in that it often requires the machining of complex-shaped 3-D mechanical structures [18.51]. However, almost all current **MEMS** fabrication techniques are subject to constraints in limited allowable materials, limited capabilities in true 3-D fabrication, and the requirement of fabrication process compatibility. Microassembly provides a possible solution to these constraints. For example, incompatible fabrication processes can be integrated

through assembly. This makes it possible to use *nontraditional* fabrication techniques that are not necessarily based on semiconductor materials, such as laser cutting, microwire electrical discharge machining (**EDM**), and micromilling [18.62]. Complex 3-D structures can also be developed using parts with relatively simple geometry [18.63, 64]. Microassembly is also crucial to **MEMS** packaging and interconnection [18.65, 66].

From the perspective of robotic systems and automation, **MEMS** device fabrication and packaging share many common assembly requirements. A fundamental commonality of both processes is the requirement of the ability to manipulate micro/mesoscale objects so that precise (i.e., microscale tolerance) spatial relations can be established (e.g., die alignment, part insertion) and certain physical/chemical processes (e.g., die bonding, surface coating) can be performed. Another common requirement is to control the interaction force involved. **MEMS** devices often have fragile structures such as thin beams or membranes. This requires controlling the interactive force in manipulation operations. Typically, the force magnitude resides in the range from millinewtons to micronewtons.

MEMS devices are often three-dimensional. **MEMS** packaging requires both electrical interconnection for signal transmission and mechanical interconnection for the interaction of the packaged device with its external environment [18.51, 67]. Many such mechanical interconnections require three-dimensional manipulation and three-dimensional force control. The actual operations are highly application specific, which pose great challenges to the development of automated microassembly systems. Automated IC packaging systems can be used for the packaging of certain **MEMS** devices such as accelerometers and gyros. However, packaging of mi-

microfluidic devices, optical MEMS devices, and hybrid microsystems often require the development of new automated microassembly techniques and systems.

The selection of assembly mode is among the first decisions to be made in developing automated microassembly systems. Sequential microassembly requires the use of micromanipulators and sensory feedback. At each moment, only one or a few parts are being assembled. Depending on the physical effects used, parallel microassembly can be either deterministic or stochastic [18.68]. Die bonding is an example of deterministic parallel microassembly. In stochastic parallel microassembly, large numbers of parts are assembled simultaneously using distributed physical effects such as electrostatic force, capillary force, centrifugal force, or vibration [18.60, 69–71]. In fact, the basic philosophy of stochastic parallel microassembly is to minimize the use of sensory feedback.

Each of these assembly modes has both advantages and disadvantages. Each has its own suitable applications. Deterministic parallel assembly shares several commonalities with sequential microassembly. For example, sensory feedback is often used in deterministic parallel microassembly. However, deterministic parallel microassembly requires high relative positioning accuracy between parts. In addition, only simple planar structure features can be assembled in order to make parallel operation possible.

Due to the requirement of MEMS packaging for three-dimensional manipulation and microassembly, it can be expected that automated sequential microassembly will be the most widely adopted solution. In particular, those MEMS packaging applications that require the control of multiple-degree-of-freedom (DOF) interaction force should use sequential microassembly. The major possible disadvantage of sequential microassembly is its low throughput. This constraint can often be overcome by appropriate system design.

Here we introduce a three-dimensional microassembly example that originates from an industrial appli-

cation [18.61]. It is significantly different from wire bonding and die bonding applications in that high-precision 3-D part insertion is required. Together with other examples, it will be used throughout this section to illustrate the major concepts and techniques and the logic connections between each functional unit of an automated microassembly system.

The assembly task is to pick up micromachined thin metal parts that are transferred to the assembly work-cell on a vacuum-release tray (Fig. 18.6a, b and c), and insert them into vertically deep reactive ion etching (DRIE) etched holes in a silicon wafer (Fig. 18.6d). The wafers can have diameters up to 8 inches. The holes on each wafer form regular arrays consisting of approximately 50 holes each. However, these arrays may not be regularly distributed on the wafer. Typically, hundreds of parts are to be assembled on each wafer. In general, each assembly operation is a typical rectangular-peg-into-a-rectangular-hole problem. Each metal part is approximately half a millimeter in width and less than 100 µm in thickness at its rectangular tip. The total assembly tolerance is typically smaller than 10 µm in the vertical direction, and smaller than 20 µm in the horizontal direction. This task is a typical application of 3-D microassembly techniques.

18.6.2 Microassembly System Design

This section discusses the design of automated microassembly systems from the perspective of robotic systems and automation. Performance objects to be achieved include high reliability, high throughput, high flexibility, and low cost.

General Guidelines

Taking a system perspective. An automated microassembly system consists of many functional units and must integrate techniques from a diverse range of areas such as robotics, computer vision, microscope op-

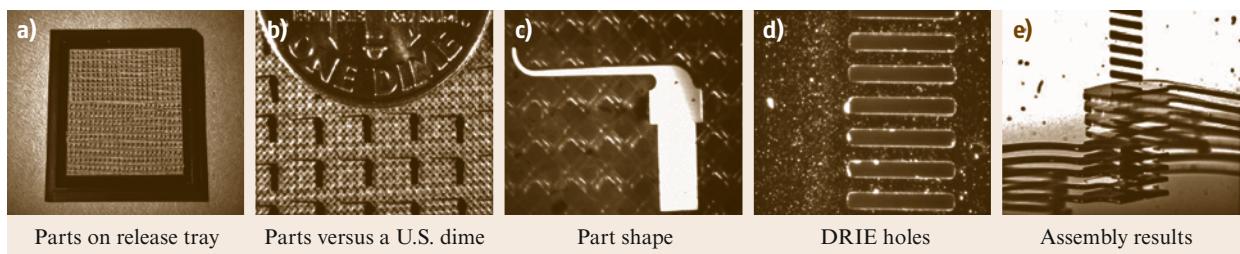

Fig. 18.6a–e A 3-D microassembly example

tics, physics, and chemistry. It is therefore important to consider the interaction between these units.

Emphasizing the coupling with packaging processes. Although in this section microassembly techniques are addressed primarily from the perspective of robotics for the clarity of presentation, robotic system designers must recognize the strong dependence of architecture design of the robotic systems on the packaging process being implemented. This connection should be emphasized from the beginning of system development.

Design for reconfigurability. Automated packaging machines must be designed so that they can be customized for a wide variety of applications. Reconfigurability is therefore a basic design requirement. Typically, modular design based on function decomposition is desirable. Support for tool replacement is essential.

The design of automated microassembly systems is strongly dependent on the assembly tolerance required. First of all, the repeatability of the motion control system and the micromanipulator used is determined by the required assembly tolerance. In addition, assembly tolerance often determines the minimum resolution of the microscope optics. General microassembly tasks may only require microscopic vision feedback and manipulators with microscale repeatability, while complex microassembly tasks may also require the integration of microforce and vision feedback [18.72, 73].

Automated microassembly systems must be able to support a wide variety of material-handling tools, which include part transfer tools, bulk feeders, wafer-handling tools, magazine loaders and unloaders, etc.

The role of the micromanipulator is to provide multiple-DOF fine motion control. The role of the microgripper is to grasp objects in pick-and-place and

other assembly operations. Their efficiency and robustness will to a great extent decide the performance of the entire system. Microgripper design is also closely related to the design of fixtures for microassembly operations.

Major environment factors include clean-room requirements, temperature, humidity, airflow, etc. Certain assembly operations must be performed in a clean room. This requires that the design of automated microassembly systems comply with relevant standards. Some packaging processes such as eutectic bonding must be performed under high temperature. Consequently, the potential influence of high temperature on motion control system and microscope optics must be considered. For the manipulation of microscale objects, environment conditions such as temperature and humidity can have a major influence on adhesion forces [18.74, 75]. Therefore, it is often important to consider environment control in system design.

Assembly Process Flow: An Example

The micromachined metal parts (Fig. 18.6c) are horizontally transferred to the workcell on the vacuum-release tray (Fig. 18.6b). The wafer is placed on a wafer mount perpendicular to the horizontal plane (Fig. 18.6b). This configuration does not require the flipping of the thin metal parts and is advantageous in terms of reliability and efficiency. There are two major operations in each assembly cycle: pickup and insertion. Under the configuration shown in Fig. 18.7a, all the operations are performed by the same workcell. Complex packaging operations must often be decomposed and performed by multiple workcells [18.76].

General System Architecture

An automated microassembly system typically consists of the following functional units.

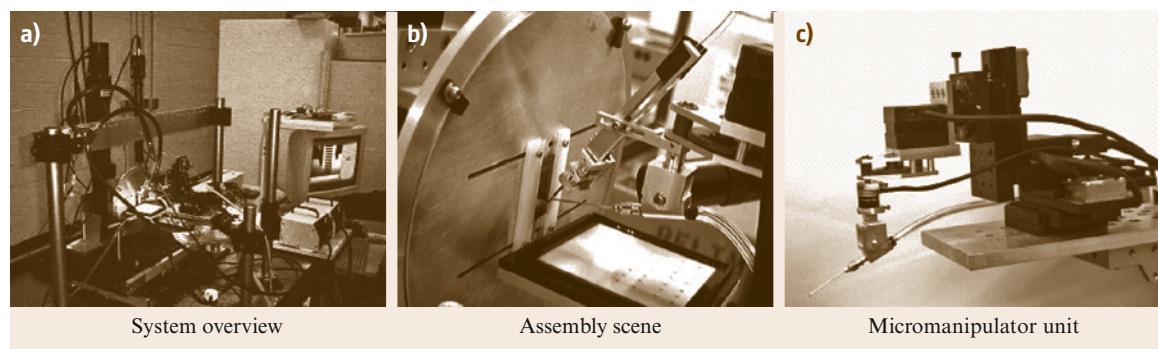

Fig. 18.7a–c An experimental microassembly workcell

Large workspace positioning unit. A large workspace and long-range positioning motion are required in most microassembly operations. The large workspace is necessary to accommodate different functional units, part feeders, and various tools.

In general, off-the-shelf motion control systems developed for automated IC packaging equipment can be adopted directly. For the task described in Sect. 18.6.1, the DRIE-etched holes are distributed on wafers up to 8 inches in diameter. This requires the assembly system to have a commensurate working space and high positioning speed. The coarse positioning unit has four DOFs (Fig. 18.7a). Planar motion in the horizontal direction is provided by an open-frame high-precision XY table with a travel of 32 cm (12 inch) and a repeatability of 1 μm in both directions. Position feedback with a resolution of 0.1 μm is provided by two linear encoders. A dual-loop PID plus feedforward control scheme is used for each axis. The internal speed loop is closed on the rotary encoder on the motor. The external position loop is closed on the linear encoder. Each wafer is placed on the vertical wafer mount that provides both linear and rotational control (Fig. 18.7b). Vertical motions of the wafer mount are provided by a linear slide with a travel of 20 cm (8 inch) and a repeatability of 5 μm . It is also controlled using a PID plus feedforward algorithm. Both the XY table and the vertical linear slides are actuated using alternating-current (AC) servo motors. The rotation of the wafer mount is actuated by an Oriental PK545AUA microstep motor with a maximum resolution of 0.0028°/step. All low-level controllers are commanded and coordinated by a host computer [18.61].

For applications requiring repeatability of one micron or greater, it is convenient to use conventional positioning tables to implement coarse range motions. These tables typically use leadscrew or ballscrew drives and ball or roller bearings. For applications requiring submicron or nanometer repeatability, a few solutions are also commercially available. For example, piezoactuators are often used for nanometer repeatability motion. The disadvantage of piezoactuators is that their travel range is small, typically on the order of 100 microns. As another example, a series of positioning stages with submicron repeatability based on direct-drive linear actuators and air bearings is available from Aerotech. It is also possible to use parallel structure mechanisms such as a Stewart platform [18.77]. In general, the development of IC manufacturing towards the deep submicron level provides a major driving force behind the development of these motion control techniques.

Micromanipulator unit. Fine pose (position and orientation) control is required in operations such as 3-D precision alignment and assembly. For example, the six DOFs required by the task introduced in Sect. 18.6.1 are implemented on separate structures. The three Cartesian DOF are provided by an adapted Sutter MP285 micromanipulator, which also provides yaw motions with its rotational DOF (Fig. 18.7c). Roll motions are implemented on the wafer mount (Fig. 18.7b). The pitch movement of the metal part after pickup is not motorized and is implemented through manual adjustment and calibration before assembly. More discussion of micromanipulator configuration can be found in [18.61].

Two principles need to be considered in implementing motion control for automated 3-D microassembly. The first is the partition of large-workspace coarse positioning unit and the fine positioning micromanipulator unit. The second is the decomposition and distributed implementation of multiple DOFs. In practice, the actual implementations of these principles are highly application specific. For certain applications, if a large-range positioning unit is sufficient to satisfy assembly tolerance requirements, the separate implementation of a micromanipulator may even be unnecessary.

In general, the separation of a micromanipulator unit will facilitate the implementation of high-bandwidth motion control. However, this separation normally brings redundancy to the entire motion control system. The functioning of the high-precision micromanipulator must also rely on closed-loop feedback control, especially microscopic vision feedback.

Automated microgripper unit. The function of a microgripper is to provide geometrical and physical constraints (grasping) in pick-and-place and assembly operations. The reliability and efficiency of the microgripper is critical to the performance of the entire automated microassembly system. Several factors must be considered in micromanipulator design. First of all, as the micromanipulator end-effector, the microgripper must be constantly monitored under a microscope. Therefore, it must be small in size and suitable in shape to remain in the microscope's field of view and to minimize occlusion. Secondly, it is important to consider the different governing physics and to explore the use of various gripping forces [18.77]. Thirdly, microgrippers are used in both part pick-and-place and assembly. Since assembly operations typically require more constraints, microgrippers designed for pick-and-place operations may not necessarily be suitable for assembly operations. In fact, the microassembly task described in Sect. 18.6.2

is performed using a combined microgripper [18.61]. Microgripper development is often closely related to the development of fixtures that can also have microscale sizes.

Microscope optics and imaging unit. The function of the microscope optics and imaging unit is to provide noncontact measurement of the geometry, motion, and spatial relations of assembly objects. Typical configurations of commercial device bonding systems use one or two vertical microscopes. An inverted microscope configuration is commonly used for backside alignment. On the other hand, 3-D microassembly may require two camera views in a stereo configuration. In the system shown in Fig. 18.7a, a total of four different views can be provided to its human operator: a global view of the entire assembly scene, a vertical microscopic view for part pickup, and two lateral microscopic views for the fine position and orientation adjustments during the final microassembly operations. Each view uses a **CCD** camera with a matching optical system. All images are captured using a Matrox Corona PCI frame grabber.

Microscopic visual feedback is crucial for precise 3-D alignment. Provided that resolution requirements of the assembly task can be satisfied, microscope optics with larger working distances is desirable. For the assembly task addressed in Sect. 18.6.1, an Edmund Scientific VZM 450i zoom microscope with a $1\times$ objective is used to provide the right view. Its working distance is approximately 90 mm, with a resolution of $7.5\text{ }\mu\text{m}$. The vertical view is also provided by a VZM 450i microscope with a $0.5\times$ objective to guide pickup operations. Its field of view can range from $2.8\times 2.8\text{ mm}$ to $17.6\times 17.6\text{ mm}$. Its working distance is approximately 147 mm.

If visual servoing is required in automate assembly operations, a stereo configuration formed by adding another lateral view may be necessary. Higher resolution may be necessary in some microassembly tasks. In such cases, the same configuration can be used with higher-resolution microscope optics, for example, two Navitar TenX zoom microscopes with Mitutoyo ultralong-working-distance M Plan Apo $10\times$ objectives have been used in this configuration by the authors. The resolution of each microscope is $1\text{ }\mu\text{m}$, with a working distance of 33.5 mm. Consequently, the usable workspace of the micromanipulator is reduced [18.61].

The global view is implemented using a miniature Marshall V-1260 board camera to monitor the status of the entire assembly scene. It plays an important role in helping the operator to understand gross spatial relations and preventing operation errors.

From the perspective of robotic systems, the development of automation microassembly systems for complex 3-D microassembly operation will rely on the development of:

1. Compact, robust and high-speed micromanipulators with 5–6 DOFs.
2. Highly reliable and efficient microgrippers that are suitable for working under microscopes. Such grippers should have active force control or passive compliance to avoid damage to **MEMS** devices.
3. Three-dimensional microscopic computer vision techniques, three-dimensional microforce measurement and control techniques, and their integration.

18.6.3 Basic Microassembly Techniques

This section introduces a few supporting techniques important to automated microassembly systems, including machine vision techniques, microforce control techniques, and simulation verification of assembly strategy.

Machine Vision Techniques

Machine vision techniques are widely used in the semiconductor industry. The major difference between machine vision and general computer vision [18.78] is that, unlike natural objects and scenes, industrial objects and scenes can often be artificially designed and configured. This advantage often makes it possible to significantly reduce the complexity and enhance the robustness of vision techniques. The applications of machine vision techniques can generally be categorized into the following two classes based on the requirement of real-time processing.

Non-time-critical vision applications. These applications do not require visual feedback for high-bandwidth real-time control. Examples include object recognition and packaging quality inspection [18.79].

Time-critical vision applications. These applications require real-time visual feedback. Examples include vision-guided pick-and-place, alignment, insertion, etc. [18.80]. An introduction to 3-D computer vision techniques can be found in [18.81]. A standard introduction to visual servoing techniques can be found in [18.82].

Several commercial software packages are available from suppliers such as Cognex, Coreco Imaging, and National Instruments.

Microforce Control Techniques

The theory of force control has been studied by the robotics community for more than 50 years [18.83, 84]. Several theoretical frameworks and many control algorithms have been proposed and experimentally verified. A variety of macroscale multiple-DOF force sensors have been developed.

Force control is also crucial to microassembly. For example, contact forces in device bonding must often be programmed and precisely controlled. In general, many of the macroscale force control techniques can be applied at micro/mesoscales. Force control for device bonding is essentially 1-D and involves force on the order of several newtons. On the other hand, in the manipulation of micro/mesoscale parts, the magnitude of interactive force typically ranges from millinewtons (10^{-3} N) to micronewtons (10^{-6} N). Forces of this magnitude are often referred to as *microforces*. A major technical challenge in implementing microforce control is the lack of multiple-DOF microforce sensors. A basic requirement for multiple-DOF microforce sensors is that they must be miniature in size. The manufacturing of these sensors normally requires the use of micromachining, including **MEMS** techniques. There are two major microforce sensing configurations.

Stand-alone force sensor. The advantage of this configuration is that the sensor is general purpose and can be used with different microgrippers. Most macroscale multiple-DOF force sensors are of this type. However, this also requires the sensor to have sufficient structural stiffness to support the static load of microgripper, which is often significantly larger than the force resolution to be reached.

Embedded force sensor. Micro strain gages can be attached to microgrippers [18.85]. Force-sensitive materials can also be deposited on microgrippers. This configuration avoids the issue of static load. However, such force sensing capabilities are dependent on the microgripper design, which often is not necessarily optimal for the measurement of multiple-DOF microforce/torque.

Complex and high-precision microassembly tasks also require the integration of microscopic machine vision with microforce control. Simple integration techniques use a gating/switching scheme [18.72, 86]. For more integrated approaches, visual impedance can be used [18.73].

Simulation Verification of Assembly Strategies

In many microassembly tasks, the distances between adjacent features are often on the meso/microscale. Therefore, selecting the correct assembly sequence is important for collision avoidance. In addition, due to the limited working distance of microscopes, microassembly operations must often be performed in a limited space using micromanipulators. Collision avoidance is critical to avoiding equipment or device damage. Potential collisions can be found and avoided by using offline simulation software. Many commercially available offline robot programming tools can provide this function.

Microassembly Tool

The end-effector of a micromanipulator in an automated microassembly system is often in the form of a microgripper, whose reliability and efficiency greatly influence the reliability and efficiency of the entire system. The microgripper must often be as small as possible. Its design must also minimize potential damage to fragile **MEMS** parts. This often requires passive compliance in structural design.

Microgrippers with integrated **MEMS** actuators can be fabricated monolithically and thus can be more compact in size. Several physical effects are commonly used in **MEMS** actuators, including electrostatic force and piezoelectric force [18.87], **SMA** (shape memory alloy) [18.88, 89], and thermal deformation [18.63, 90]. Currently, the major limitation is that it is difficult for **MEMS** actuators to generate sufficient travel, force, and power output. Alternatively, another solution is to provide actuation externally [18.61, 91]. The advantage is that sufficient travel and force and power output can be more easily obtained. The major disadvantage is that the microgripper is less compact in size. This could become a major obstacle to its applications.

18.7 Microrobotics

Today, more and more microrobotic devices are enabling new applications in various fields. Besides microassem-

bly, microrobotics can play important roles in other industry fields for manipulation, characterization, in-

spection, and maintenance, and in biotechnology for, e.g., manipulating cells, a field referred to as bio-microrobotics.

18.7.1 Microrobots

Microrobotics is a field that combines the established theory and techniques of robotics with the exciting new tools provided by [MEMS](#) technology in order to create intelligent machines that operate at micron scales. As stated by authors reviewing the microrobotics field [18.31, 92], many *micro* terms such as *micromechatronics*, *micromechanism*, *micromachines*, and *microrobots* are used synonymously to indicate a wide range of devices whose function is related to a *small* scale; however, *small* scale is a relative term so a clearer definition is needed.

The obvious difference between a macrorobot and a microrobot is the size of the robot. Thus, one definition of a microrobot is *a device having dimensions smaller than classical watch-making parts (i.e., μm to mm) and having the ability to move, apply forces and manipulate objects in a workspace with dimensions in the micrometer or submicrometer range* [18.94]. However, in many cases it is important that the robot can move over much larger distances. This task-specific definition

is quite wide and includes several types of very small robots as well as stationary micromanipulation systems, which are a few decimeters in size but can carry out very precise manipulation (in the micron or even nanometer range) [18.92].

Besides classification by task or size, microrobots can also be classified by their mobility and functionality [18.31, 93]. Many robots usually consist of sensors and actuators, a control unit, and an energy source.

Depending on the arrangement of these components, one can classify microrobots according to the following criteria: locomotive and positioning possibility (yes or no), manipulation possibility (yes or no), control type (wireless or tethered), and autonomy. Figure 18.8 illustrates 15 different possible microrobot configurations by combining the four criteria [18.31, 93].

As depicted in Fig. 18.8 (taken from [18.30]), the classification is dependent on the following microrobot components: the control unit (**CU**), the power source (**PS**), the actuators necessary for moving the robot platform (i.e., the robot drive for locomotion and positioning; **AP**), and the actuators necessary for operation (i.e., manipulation using robot arms and hands; **AM**). Besides the different actuation functions, sensory functions are also needed, for example, tactile sensors for microgrippers or charge-coupled device (**CCD**) cam-

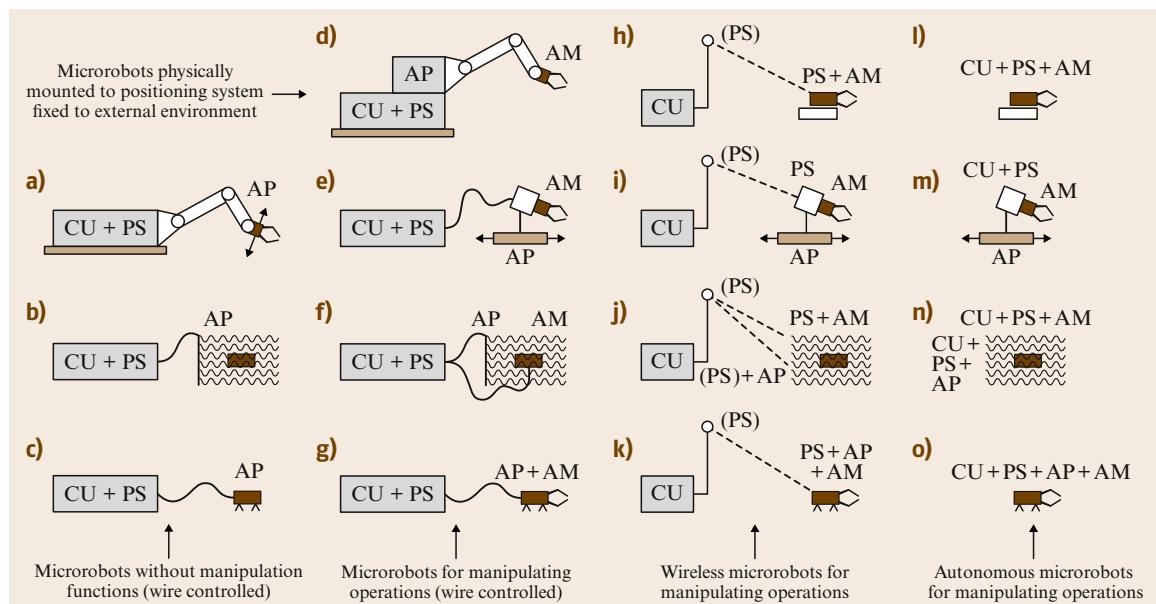

Fig. 18.8a-o Classification of microrobots by functionality (modification of earlier presented classification schemes [18.12, 31, 92, 93]). (**CU** indicates the control unit; **PS**, the power source or power supply; **AP**, the actuators for positioning; **AM**, the actuators for manipulation)

eras for endoscopic applications (compare Fig. 18.8d and a).

The ultimate goal is to create a fully autonomous, wireless mobile microrobot equipped with suitable microtools according to Fig. 18.8o. Because this is a very difficult task, a good start is to investigate the possibility of making silicon microrobot platforms that are steered and powered through wires, like the one in Fig. 18.8c, and to study their locomotion capability.

The majority of **MEMS**-based microrobotic devices developed so far could be categorized as moveable links – microcatheters [18.95, 96], according to Fig. 18.8a, or microgrippers [18.24], such as those in Fig. 18.8d, or the microgrippers [18.97, 98] shown in Fig. 18.8e. Among the research publications covering locomotive microrobots, most publications have addressed microconveyance systems (Fig. 18.8b) [18.99–102]. Robots using external sources for locomotion could be used (compare Fig. 18.8b,f,j,n). According to *Fatikow and Rembold* [18.92], several researchers are working on methods to navigate micromechanisms through human blood vessels; however, these microrobots are difficult to control. Examples of partially autonomous systems (compare Fig. 18.8j) are the concept for so-called *smart pills*. Centimeter-sized pills for sensing temperature and/or pH inside the body have been presented [18.103, 104] as well as pills equipped with video cameras [18.105]. The pill is swallowed and transported to the part of the body where one wants to measure or record a video sequence. The information of the measured parameter or the signals from the camera is then transmitted (telemetrically) out of the body. More sophisticated approaches involving actuators for drug delivery of various kinds have also been proposed [18.92, 104]. The position of the pill inside the body is located by an X-ray monitor or ultrasound. As soon as the pill reaches an infected area, a drug encapsulated in the pill can be released by the actuators onboard. External communication could be realized through radio signals.

Several important results have been presented regarding walking microrobots (Fig. 18.8c,g,k) fabricated by **MEMS** technologies and batch manufacturing. Different approaches for surface-micromachined robots [18.106, 107] and for a piezoelectric dry-reactive-ion-etched microrobot should be mentioned. A suitable low-power application-specific integrated circuit (**ASIC**) for robot control has been successfully tested and is planned to be integrated on a walking microrobot [18.108]. The large European Esprit project *MINIMAN* (1997) has the goal of developing

moveable microrobotic platforms with integrated tools with six degrees of freedom for applications such as microassembly within an **SEM** and involves different **MEMS** research groups from several universities and companies across Europe. Further, miniature robot systems with **MEMS/MST** (MicroSystem Technology) components have been developed [18.109].

Several research publications on *gnat* microrobots and actuator technologies for **MEMS** microrobots [18.3, 110] were reported by **US** researchers in the early 1990s, and several groups in Japan are also currently developing miniaturized robots based on **MEMS** devices [18.8]. In Japan, an extensive ten-year program on *micromachine technology*, supported by the Ministry of International Trade and Industry (**MITI**), started in 1991. One of the goals of this project is to create microsized and miniature robots for microfactory, medical technology, and maintenance applications. Several microrobotic devices, including locomotive robots and microconveyors, have been produced within this program. Miniature robot devices or vehicles [18.111] for locomotive tasks, containing several **MEMS** components, have been presented. Even though great efforts have been made on robot miniaturization using **MEMS** technologies, no experimental results on **MEMS** batch-fabricated microrobots suitable for autonomous walking (i.e., robust enough to be able to carry its own power source or to be powered by telemetric means) have been presented yet. The first batch-fabricated **MEMS**-based microrobot platform able to walk was presented in 1999 [18.112]. However, this robot was powered through wires and was not equipped with manipulation actuators. Besides walking microrobotic devices, several reports on flying [18.113–115] and swimming [18.116] robots have been published. Micromotors and gear boxes made using **LIGA** technology (a high-precision, lithographically defined plating technology) are used to build small flying microhelicopters, which are commercially available from the Institute of Microtechnology in Mainz, Germany, as rather expensive demonstration objects [18.114]. Besides the pure mechanical microrobots, hybrid systems consisting of electromechanical components and living organisms such as cockroaches have also been reported [18.117].

18.7.2 Bio-microrobotics

Biomanipulation entails such operations as positioning, grasping, and injecting material into various locations in cells. Research topics in bio-microrobotics include the autonomous manipulation of single cells or molecules,

the characterization of biomembrane mechanical properties using microrobotic systems with integrated vision and force sensing modules, and more. The objective is to obtain a fundamental understanding of single-cell biological systems and provide characterized mechanical models of biomembranes for deformable cell tracking during biomanipulation and cell injury studies.

Existing biomanipulation techniques can be classified into noncontact manipulation including laser trapping [18.118–121] and electrorotation [18.122–124], and contact manipulation, referred to as mechanical micromanipulation [18.125]. When laser trapping [18.118–121] is used for noncontact biomanipulation, a laser beam is focused through a large-numerical-aperture objective lens, converging to form an optical trap in which the lateral trapping force moves a cell in suspension toward the center of the beam. The

longitudinal trapping force moves the cell in the direction of the focal point. The optical trap levitates the cell and holds it in position. Laser traps can work in a well-controlled manner. However, two features make laser trapping techniques undesirable for automated cell injection. The high dissipation of visible light in aqueous solutions requires the use of high-energy light close to the UV spectrum, raising the possibility of damage to the cell. Even though some researchers claim that such concerns could be overcome using wavelengths in the near-infrared (IR) spectrum [18.120], the question as to whether the incident laser beam might induce abnormalities in the cells' genetic material still exists. One alternative to using laser beams is the electrorotation technique. Electric-field-induced rotation of cells was demonstrated by *Mischel* [18.126], *Arnold* [18.127], and *Washizu* [18.124]. This noncontact cell manipulation technique is based on controlling the phase shift and magnitude of electric fields. These fields, appropriately applied, produce a torque on the cell. Different system configurations have been established for cell manipulation based on this principle [18.122, 123], which can achieve high accuracy in cell positioning. However, it lacks a means to hold the cell in place for further manipulation, such as injection, since the magnitude of the electric fields has to be kept low to ensure the viability of cells. The limits of noncontact biomanipulation in the laser trapping and electrorotation techniques make mechanical micromanipulation desirable. The damage caused by laser beams in the laser trapping technique and the lack of a holding mechanism in the electrorotation technique can be overcome by mechanical micromanipulation.

To improve the low success rate of manual operation, and to eliminate contamination, an autonomous robotic system (shown in Fig. 18.9) has been developed to deposit DNA into one of the two nuclei of a mouse embryo without inducing cell lysis [18.11, 128]. The laboratory's experimental results show that the success rate for the autonomous embryo pronuclei DNA injection is dramatically improved over conventional manual injection methods. The autonomous robotic system features a hybrid controller that combines visual servoing and precision position control, pattern recognition for detecting nuclei, and a precise auto-focusing scheme. Figure 18.10 illustrates the injection process.

To realize large-scale injection operations, a **MEMS** cell holder was fabricated using anodic wafer-bonding techniques. Arrays of holes are aligned on the cell holder, which are used to contain and fix individual cells for

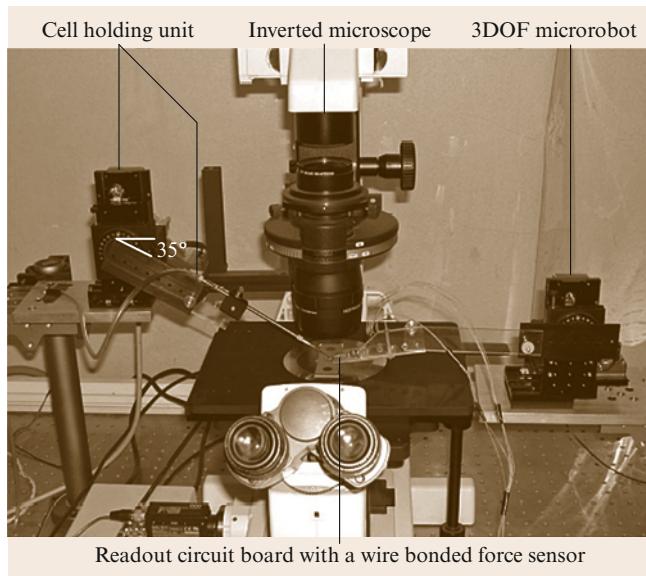

Fig. 18.9 Robotic biomanipulation system with vision and force feedback

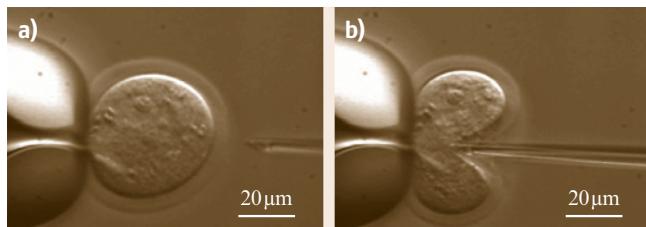

Fig. 18.10a,b Cell injection process. (a)(b) Mouse oocyte zona pellucida (ZP)

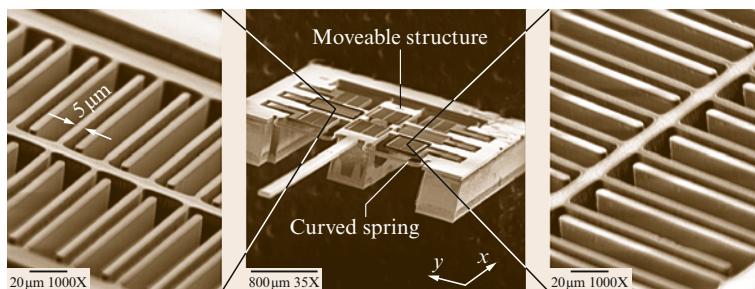

Fig. 18.11 A cellular force sensor with orthogonal comb drives detailed

injection. When well calibrated, the system with the cell holder makes it possible to inject large numbers of cells using position control. The cell injection operation can be conducted in a move–inject–move manner.

A successful injection is determined greatly by injection speed and trajectory, and the forces applied to cells. To further improve the robotic system's performance, a multi-axis MEMS-based capacitive cellular force sensor is being designed and fabricated to provide realtime force feedback to the robotic system. The MEMS cellular force sensor also aids research in biomembrane mechanical property characterization.

MEMS-Based Multi-Axis Capacitive Cellular Force Sensor

The MEMS-based two-axis cellular force sensor [18.129] shown in Fig. 18.11 is capable of resolving normal forces applied to a cell as well as tangential forces generated by improperly aligned cell probes. A high-yield microfabrication process was developed to form the 3-D high-aspect-ratio structure using deep reactive ion etching (DRIE) on silicon-on-insulator (SOI) wafers. The constrained outer frame and the inner movable structure are connected by four curved springs. A load applied to the probe causes the inner structure to move, changing the gap between each pair of interdigitated comb capacitors. Consequently, the total capacitance change resolves the applied force. The interdigitated capacitors are orthogonally configured to make the force sensor capable of resolving forces in both the x - and y -directions. The cellular force sensors used in the experiments are

capable of resolving forces up to $25 \mu\text{N}$ with a resolution of $0.01 \mu\text{N}$.

Tip geometry affects the quantitative force measurement results. A standard injection pipette (Cook K-MPIP-1000-5) tip section with a tip diameter of $5 \mu\text{m}$ is attached to the probe of the cellular force sensors.

The robotic system and high-sensitivity cellular force sensor are also applied to biomembrane mechanical property studies [18.130]. The goal is to obtain a general parameterized model describing cell membrane deformation behavior when an external load is applied. This parameterized model serves two chief purposes. First, in robotic biomanipulation, it allows online parameter recognition so that cell membrane deformation behavior can be predicted. Second, for a thermodynamic model of membrane damage in cell injury and recovery studies, it is important to appreciate the mechanical behavior of the membranes. This allows the interpretation of such reported phenomena as mechanical resistance to cellular volume reduction during dehydration, and its relationship to injury. The establishment of such a biomembrane model will greatly facilitate cell injury studies.

Experiments demonstrate that robotics and MEMS technology can play important roles in biological studies such as automating biomanipulation tasks. Aided by robotics, the integration of vision and force sensing modules, and MEMS design and fabrication techniques, investigations are being conducted in biomembrane mechanical property modeling, deformable cell tracking, and single-cell and biomolecule manipulation.

18.8 Nanorobotics

Nanorobotics represents the next stage in miniaturization for maneuvering nanoscale objects. Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size, i. e., nanorobots,

and large robots capable of manipulating objects that have dimensions in the nanoscale range with nanometer resolution, i. e., nanorobotic manipulators. Robotic manipulation at nanometer scales is a promising tech-

nology for structuring, characterizing, and assembling nanoscale building blocks into **NEMS**. Combined with recently developed nanofabrication processes, a hybrid approach is realized to build **NEMS** and other nanorobotic devices from individual carbon nanotubes and SiGe/Si nanocoils. Material science, biotechnology, electronics, and mechanical sensing and actuation will benefit from advances in nanorobotics.

18.8.1 Introduction to Nanomanipulation

Nanomanipulation, or positional and/or force control at the nanometer scale, is a key enabling technology for nanotechnology by filling the gap between top-down and bottom-up strategies, and may lead to the appearance of replication-based molecular assemblers [18.18]. These types of assemblers have been proposed as general-purpose manufacturing devices for building a wide range of useful products as well as copies of themselves (self-replication).

Presently, nanomanipulation can be applied to the scientific exploration of mesoscopic physical phenomena, biology, and the construction of prototype nanodevices. It is a fundamental technology for property characterization of nanomaterials, nanostructures, and nanomechanisms, for the preparation of nanoscale building blocks, and for the assembly of nanodevices such as **NEMS**.

Nanomanipulation was enabled by the inventions of the **STM** [18.19], AFMs [18.44], and other types of SPMs. Besides these, optical tweezers (laser trapping) [18.131] and magnetic tweezers [18.132] are also

potential nanomanipulators. Nanorobotic manipulators (**NRMs**) [18.133,134] are characterized by the capability of 3-D positioning, orientation control, independently actuated multiple end-effectors, and independent real-time observation systems, and can be integrated with scanning probe microscopes. **NRMs** largely extend the complexity of nanomanipulation.

A concise comparison of **STM**, AFM, and **NRM** technology is shown in Fig. 18.12. With its incomparable imaging resolution, an **STM** can be applied to particles as small as atoms with atomic resolution. However, limited by its 2-D positioning and available strategies for manipulations, standard **STMs** are ill-suited for complex manipulation and cannot be used in 3-D space. An **AFM** is another important type of nanomanipulator. Manipulation with an **AFM** can be done in either contact or dynamic mode. Generally, manipulation with an **AFM** involves moving an object by touching it with a tip. A typical manipulation starts by imaging a particle in noncontact mode, then removing the tip oscillation voltage and sweeping the tip across the particle in contact with the surface and with the feedback disabled. Mechanical pushing can exert larger forces on objects and, hence, can be applied for the manipulation of relatively larger objects. 1- to 3-D objects can be manipulated on a 2-D substrate. However, the manipulation of individual atoms with an **AFM** remains a challenge. By separating the imaging and manipulation functions, nanorobotic manipulators can have many more degrees of freedom including rotation for orientation control, and hence can be used for the manipulation of 0-D (symmetric spheres) to 3-D objects in 3-D free space. Limited by the lower resolution of electron microscopes, **NRMs** are difficult to use for the manipulation of atoms. However, their general robotic capabilities, including 3-D positioning, orientation control, independently actuated multiple endeffectors, separate real-time observation system, and integration with SPMs inside, make **NRMs** quite promising for complex nanomanipulation.

The first nanomanipulation experiment was performed by *Eigler and Schweizer* in 1990 [18.135]. They used an **STM** and materials at low temperatures (4 K) to position individual xenon atoms on a single-crystal nickel surface with atomic precision. The manipulation enabled them to fabricate rudimentary structures of their own design, atom by atom. The result is the famous set of images showing how 35 atoms were moved to form the three-letter logo **IBM**, demonstrating that matter could indeed be maneuvered atom by atom as *Feynman* suggested [18.1].

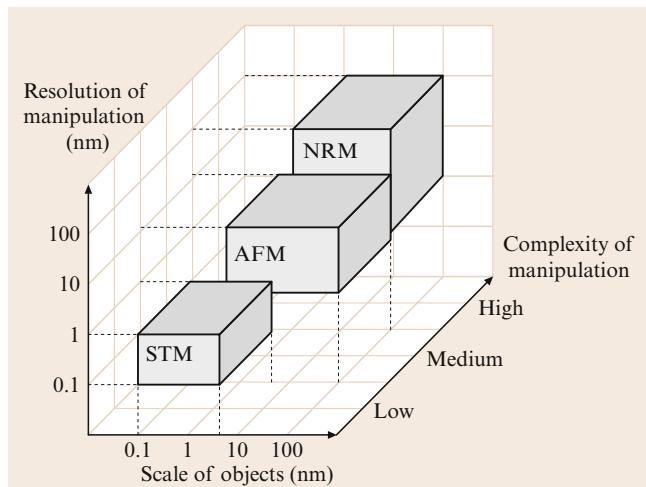

Fig. 18.12 Comparison of nanomanipulators

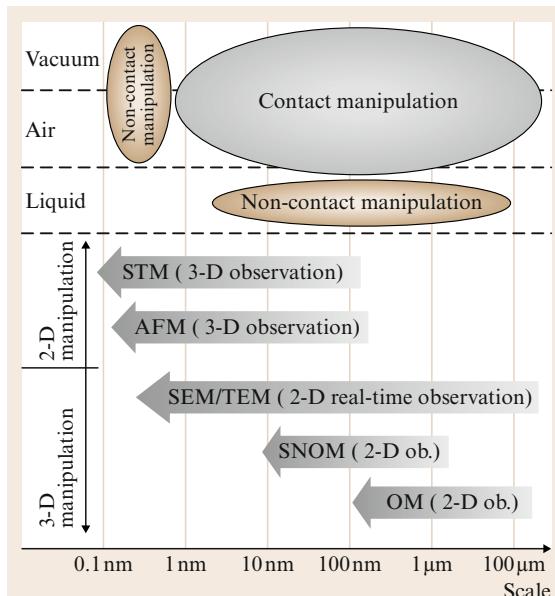

Fig. 18.13 Microscopes, environments, and strategies of nanomanipulation

A nanomanipulation system generally includes nanomanipulators as the positioning device, microscopes as *eyes*, various end-effectors including probes and tweezers among others as its *fingers*, and various types of sensors (force, displacement, tactile, strain, etc.) to facilitate the manipulation and/or to determine the properties of the objects. Key technologies for nanomanipulation include observation, actuation, measurement, system design and fabrication, calibration and control, communication, and the human-machine interface.

Strategies for nanomanipulation are basically determined by the environment – air, liquid or vacuum – which is further decided by the properties and size of the objects and observation methods. Figure 18.13 depicts the microscopes, environments, and strategies of nanomanipulation. In order to observe manipulated objects, **STMs** can provide sub-Ångström imaging resolution, whereas **AFMs** can provide atomic resolutions. Both can obtain 3-D surface topology. Because **AFMs** can be used in an ambient environment, they provide a powerful tool for biomanipulation that may require a liquid environment. The resolution of **SEM** is limited to about 1 nm, whereas field-emission **SEM (FESEM)** can achieve higher resolutions. **SEM/FESEM** can be used for real-time 2-D observation for both the objects and end-effectors of manipulators, and large ultrahigh-vacuum

(UHV) sample chambers provide enough space to contain an **NRM** with many degrees of freedom (**DOFs**) for 3-D nanomanipulation. However, the 2-D nature of the observation makes positioning along the electron-beam direction difficult. High-resolution transmission electron microscopes (**HRTEM**) can provide atomic resolution. However, the narrow UHV specimen chamber makes it difficult to incorporate large manipulators. In principle, optical microscopes (**OMs**) cannot be used for nanoscale (smaller than the wavelength of visible lights) observation because of diffraction limits. Scanning near-field **OMs (SNOMs)** break this limitation and are promising as a real-time observation device for nanomanipulation, especially for ambient environments. **SNOMs** can be combined with **AFMs**, and potentially with **NRMs** for nanoscale biomanipulation.

Nanomanipulation processes can be broadly classified into three types:

1. lateral noncontact
2. lateral contact
3. vertical manipulation

Generally, lateral noncontact nanomanipulation is mainly applied for atoms and molecules in UHV with an **STM** or bio-object in liquid using optical or magnetic tweezers. Contact nanomanipulation can be used in almost any environment, generally with an **AFM**, but is difficult for atomic manipulation. Vertical manipulation can be performed by **NRMs**. Figure 18.14 shows the processes of the three basic strategies.

Motion of the lateral noncontact manipulation processes is shown in Fig. 18.14a. Applicable effects [18.136] able to cause the motion include long-range van der Waals (**vdW**) forces (attractive) generated by the proximity of the tip to the sample [18.137], electric-field-induced fields by the voltage bias between the tip and the sample [18.138, 139], tunneling current local heating or inelastic tunneling vibration [18.140, 141]. With these methods, some nanodevices and molecules have been assembled [18.142, 143]. Laser trapping (optical tweezers) and magnetic tweezers are possible for noncontact manipulation of nanoscale biosamples, e.g., DNA [18.144, 145].

Noncontact manipulation combined with **STMs** has revealed many possible strategies for manipulating atoms and molecules. However, for the manipulation of carbon nanotubes (**CNTs**) no examples have been demonstrated.

Pushing or pulling nanometer objects on a surface with an **AFM** is a typical manipulation using this method as shown in Fig. 18.14b. Early work showed

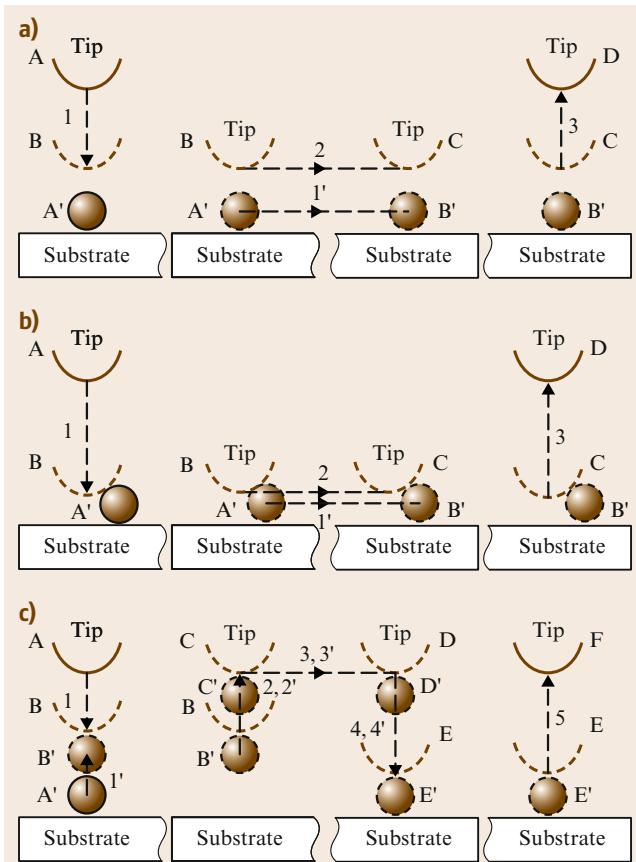

Fig. 18.14a–c Basic strategies of nanomanipulation. In the figure, A, B, C, ... represent the positions of end-effector (e.g., a tip); A', B', C', ... the positions of objects; 1, 2, 3, ... the motions of end-effector; and 1', 2', 3', ... the motions of objects. Tweezers can be used in pick-and-place to facilitate the picking-up, but are generally not necessarily helpful for placing. **(a)** Lateral noncontact nanomanipulation (sliding). **(b)** Lateral contact nanomanipulation (pushing/pulling). **(c)** Vertical nanomanipulation (picking and placing)

the effectiveness of this method for the manipulation of nanoparticles [18.146–150]. This method has also been shown in nanoconstruction [18.151] and biomanipulation [18.152]. A virtual-reality interface facilitates such manipulation [18.153–155] and may create an opportunity for other types of manipulation. This technique has been used in the manipulation of nanotubes on a surface, and some examples will be introduced later in this chapter.

The pick-and-place task as shown in Fig. 18.14c is especially significant for 3-D nanomanipulation since

its main purpose is to assemble prefabricated building blocks into devices. The main difficulty is in achieving sufficient control of the interaction between the tool and object and between the object and the substrate. Two strategies have been presented for micromanipulation [18.156] and have also proven to be effective for nanomanipulation [18.134]. One strategy is to apply a dielectrophoretic force between a tool and an object as a controllable additional external force by applying a bias between the tool and the substrate on which the object is placed. Another strategy is to modify the van der Waals and other intermolecular and surface forces between the object and the substrate. For the former, an AFM cantilever is ideal as one electrode to generate a nonuniform electrical field between the cantilever and the substrate.

18.8.2 Nanorobotic Manipulation Systems

Nanorobotic manipulators are the core components of nanorobotic manipulation systems. The basic requirements for a nanorobotic manipulation system for 3-D manipulation include nanoscale positioning resolution, a relative large working space, enough DOFs including rotational ones for 3-D positioning and orientation control of the end-effectors, and usually multiple end effectors for complex operations.

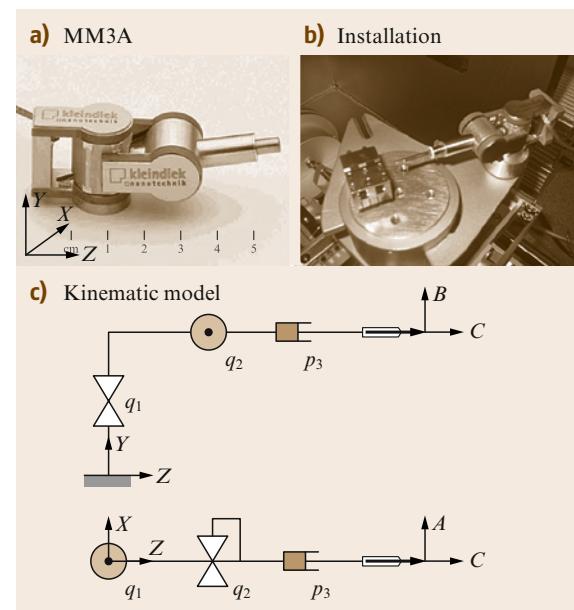

Fig. 18.15 **(a)** Nanomanipulator (MM3A)TM from Klein-diek **(b)** inside an SEM

Table 18.4 Specifications of MM3A

| Item | Specification |
|---------------------------------|------------------------|
| Operating range q_1 and q_2 | 240° |
| Operating range Z | 12 mm |
| Resolution A (horiz.) | 10^{-7} rad (5 nm) |
| Resolution B (vert.) | 10^{-7} rad (3.5 nm) |
| Resolution C (linear) | 0.25 nm |
| Fine (scan) range A | 20 μm |
| Fine (scan) range B | 15 μm |
| Fine (scan) range C | 1 μm |
| Speed A, B | 10 mm/s |
| Speed C | 2 mm/s |

A commercially available nanomanipulator (MM3A™ from Kleindiek) installed inside an SEM (Carl Zeiss DSM962) is shown in Fig. 18.15. The manipulator has three degrees of freedom, and nanometer-

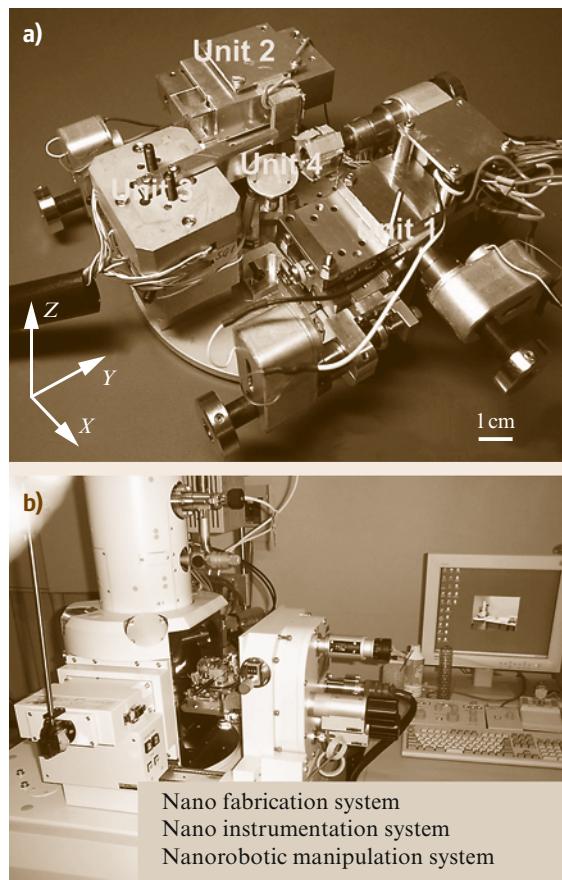

Fig. 18.16a,b Nanorobotic system. (a) Nanorobotic manipulators. (b) System setup

to subnanometer-scale resolution (Table 18.4). Calculations show that when moving/scanning in the A/B direction at joint q_1/q_2 , the additional linear motion in C is very small. For example, when the arm length is 50 mm, the additional motion in the C direction is only 0.25 nm to 1 nm when moving 5–10 μm ; in the A direction; these errors can be ignored or compensated with an additional motion of the prismatic joint p_3 , which has a 0.25 nm resolution.

Figure 18.16a shows a nanorobotic manipulation system that has 16 DOFs in total and can be equipped with three or four AFM cantilevers as end-effectors for both manipulation and measurement. The positioning resolution is sub-nanometer and strokes are on the order of centimeters. The manipulation system is not only for nanomanipulation, but also for nanoassembly, nanoinstrumentation, and nanofabrication. Four-probe semiconductor measurements are perhaps the most complex manipulation that this system can perform, because it is necessary to actuate four probes independently by using four manipulators. With the advancement of nanotechnology, one could shrink the size of nanomanipulators and insert more DOFs inside the limited vacuum chamber of a microscope, and perhaps the molecular version of manipulators such as that dreamed of by Drexler could be realized [18.18].

For the construction of multi-walled carbon nanotube (MWNT)-based nanostructures, manipulators position and orient nanotubes for the fabrication of nanotube probes and emitters, for performing nanosoldering with electron-beam-induced deposition (EBID) [18.157], for the property characterization of single nanotubes for selection purposes and for characterizing junctions to test connection strength.

A nanolaboratory is shown in Fig. 18.16b. The nanolaboratory integrates a nanorobotic manipulation system with a nanoanalytical system and a nanofabrication system, and can be applied for manipulating nanomaterials, fabricating nanoscale building blocks, assembling nanodevices, and for in situ analysis of the properties of such materials, building blocks, and devices. Nanorobotic manipulation within the nanolaboratory has opened a new path for constructing nanosystems in 3-D space, and will create opportunities for new nanoinstrumentation and nanofabrication processes.

18.8.3 Nanorobotic Assembly

Nanomanipulation is a promising strategy for nanoassembly. Key techniques for nanoassembly include the structuring and characterization of nanoscale building

blocks, the positioning and orientation control of the building blocks with nanoscale resolution, and effective connection techniques. Nanorobotic manipulation, which is characterized by multiple DOFs with both position and orientation controls, independently actuated multiprobes, and a real-time observation system, have been shown effective for assembling nanotube-based devices in 3-D space.

The well-defined geometries, exceptional mechanical properties, and extraordinary electric characteristics, among other outstanding physical properties of CNTs [18.158] qualify them for many potential applications, especially in nanoelectronics [18.159], NEMS, and other nanodevices [18.160]. For NEMS, some of the most important characteristics of nanotubes include their nanometer diameter, large aspect ratio (10–1000), TPa-scale Young's modulus [18.161–163], excellent elasticity [18.133], ultralow interlayer friction, excellent capability for field emission, various electric conductivities [18.164], high thermal conductivity [18.165], high current-carrying capability with essentially no heating [18.166], sensitivity of conductance to various physical or chemical changes, and charge-induced bond-length change.

Helical 3-D nanostructures, or nanocoils, have been synthesized from various materials, including

helical carbon nanotubes [18.167] and zinc oxide nanobelts [18.168]. A new method of creating structures with nanoscale dimensions has recently been presented [18.169] and can be fabricated in a controllable way [18.170, 171]. The structures are created through a top-down fabrication process in which a strained nanometer-thick heteroepitaxial bilayer curls up to form 3-D structures with nanoscale features. Helical geometries and tubes with diameters between 10 nm and 10 μm have been achieved. Because of their interesting morphology, mechanical, electrical, and electromagnetic properties, potential applications of these nanostructures in NEMS include nanosprings [18.172], electromechanical sensors [18.173], magnetic field detectors, chemical or biological sensors, generators of magnetic beams, inductors, actuators, and high-performance electromagnetic wave absorbers.

NEMS based on individual carbon nanotubes and nanocoils are of increasing interest, indicating that capabilities for incorporating these individual building blocks at specific locations on a device must be developed. Random spreading [18.174], direct growth [18.175], self-assembly [18.176], dielectrophoretic assembly [18.177, 178], and nanomanipulation [18.179] have been demonstrated for positioning as-grown nanotubes on electrodes for the construction of these devices. However, for nanotube-based structures, nanorobotic assembly is still the only technique capable of in situ structuring, characterization, and assembly. Because the as-fabricated nanocoils are not free-standing from their substrate, nanorobotic assembly is virtually the only way to incorporate them into devices at present.

Nanorobotic Assembly of Carbon Nanotubes

Nanotube manipulation in two dimensions on a surface was first performed with an AFM by contact pushing on a substrate. Figure 18.17 shows the typical methods for 2-D pushing. Although similar to that shown in Fig. 18.14b, the same manipulation caused various results because nanotubes cannot be regarded as a 0-D point. The first demonstration was given by Lieber and coworkers for measuring the mechanical properties of a nanotube [18.180]. They adopt the method shown in Fig. 18.17b, i.e., to bend a nanotube by pushing one end of it and fixing the other end. The same strategy was used for the investigation of the behavior of nanotubes under large strain [18.181]. Dekker and coworkers applied the strategies shown in Fig. 18.17c,d to obtain a kinked junction and crossed nanotubes [18.182]. Avouris and coworkers combined this technique with an inverse process, namely straightening by pushing

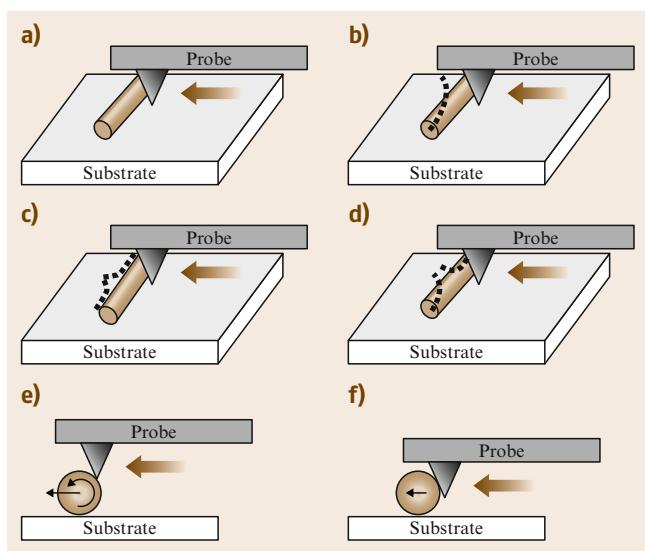

Fig. 18.17a–f Two-dimensional manipulation of CNTs. Starting from the original state shown in (a), pushing the tube at different site with different force may cause the tube to deform as in (b) and (c), to break as in (d), or to move as in (e) and (f). (a) Original state. (b) Bending. (c) Kinking. (d) Breaking. (e) Rolling. (f) Sliding

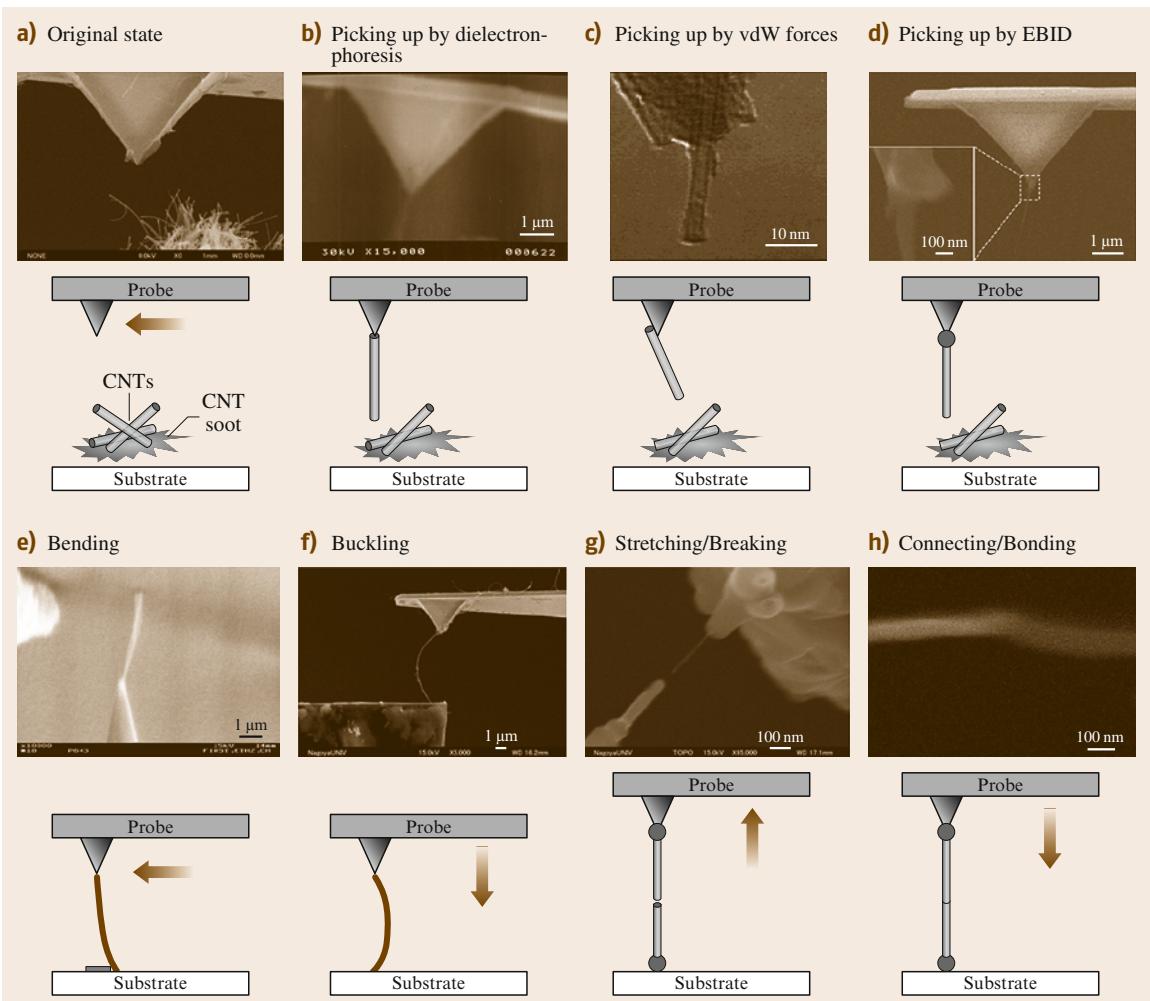

Fig. 18.18a–h Nanorobotic manipulation of CNTs. The basic technique is to pick up an individual tube from CNT soot (as in **(a)**) or from an oriented array; **(b)** shows a free-standing nanotube picked up by dielectrophoresis generated by a nonuniform electric field between the probe and substrate, **(c)** (after [18.188]) and **(d)** show the same manipulation by contacting a tube with the probe surface or fixing (e.g., with EBID) a tube to the tip (inset shows the EBID deposit). Vertical manipulation of nanotubes includes bending **(e)**, buckling **(f)**, stretching/breaking **(g)**, and connecting/bonding **(h)**. All examples with the exception of **(c)** are from the authors' work

along a bent tube, and realized the translation of the tube to another location [18.183] and between two electrodes to measure the conductivity [18.184]. This technique was also used to place a tube on another tube to form a single-electron transistor (SET) with a cross-junction of nanotubes [18.185]. Pushing-induced breaking (Fig. 18.17d) has also been demonstrated for a nanotube [18.183]. The simple assembly of two bent tubes and a straight one formed a Greek letter θ . To invest-

igate the dynamics of rolling at the atomic level, rolling and sliding of a nanotube (as shown in Fig. 18.17e,f) are performed on graphite surfaces using an AFM [18.186]. Besides pushing and pulling, another important process is indentation. By indenting a surface, mechanical property characterization [18.187] and data storage [18.188] can be realized.

Manipulation of CNTs in 3-D space is important for assembling CNTs into structures and devices. Basic

techniques for the nanorobotic manipulation of carbon nanotubes are shown in Fig. 18.18 [18.189]. These serve as the basis for handling, structuring, characterizing, and assembling NEMS.

The basic procedure is to pick up a single tube from nanotube soot (Fig. 18.18a). This has been shown first by using dielectrophoresis [18.134] through nanorobotic manipulation (Fig. 18.18b). By applying a bias between a sharp tip and a plane substrate, a nonuniform electric field can be generated between the tip and the substrate with the strongest field near the tip. This field can cause a tube to orient along the field or further *jump* to the tip by electrophoresis or dielectrophoresis (determined by the conductivity of objective tubes). Removing the bias, the tube can be placed at other locations at will. This method can be used for free-standing tubes on nanotube soot or on a rough surface on which surface van der Waals forces are generally weak. A tube strongly rooted in CNT soot or lying on a flat surface cannot be picked up in this way. The interaction between a tube and the atomic flat surface of AFM cantilever tip has been shown to be strong enough for picking up a tube onto the tip [18.190] (Fig. 18.18c). By using EBID, it is possible to pick up and fix a nanotube onto a probe [18.191] (Fig. 18.18d). For handling a tube, weak connection between the tube and the probe is desired.

Bending and buckling a CNT as shown in Fig. 18.18e,f are important for *in situ* property characterization of a nanotube [18.192], which is a simple way to obtain the Young's modulus of a nanotube without damaging the tube (if performed within its elastic range) and hence can be used for the selection of a tube with desired properties. By buckling an MWNT over its elastic limit, a kinked structure can be obtained [18.193]. To obtain any desired angle for a kinked junction it is possible to fix the shape of a buckled nanotube within its elastic limit by using EBID [18.193]. For a CNT, the maximum angular displacement will appear at the fixed left end under pure bending or at the middle point under pure buckling. A combination of these two kinds of loads will achieve a controllable position of the kinked point and a desired kink angle. If the deformation is within the elastic limit of the nanotube, it will recover as the load is released. To avoid this, EBID can be applied at the kinked point to fix the shape.

Stretching a nanotube between two probes or a probe and a substrate has generated several interesting results (Fig. 18.18g). The first demonstration of 3-D nanomanipulation of nanotubes took this as an example to show the breaking mechanism and to measure the tensile strength of CNTs [18.133]. By breaking an MWNT in

a controlled manner, interesting nanodevices have been fabricated. This technique – destructive fabrication – has been presented to get sharpened and layered structures of nanotubes, and to improve the length control of a nanotube [18.193]. Typically, a layered and a sharpened structure can be obtained from this process, similar to that achieved from electric pulses [18.194]. Bearing motion has also been observed in an incompletely broken MWNT [18.193]. The interlayer friction has been shown to be very small [18.195, 196].

The reverse process, namely the connection of broken tubes (Fig. 18.18h), has been demonstrated recently, and the mechanism is revealed as rebonding of unclosed dangling bonds at the ends of broken tubes [18.197]. Based on this interesting phenomenon, mechanochemical nanorobotic assembly has been performed [18.197].

Assembly of nanotubes is a fundamental technology for enabling nanodevices. The most important tasks include the connection of nanotubes and placing of nanotubes onto electrodes. Pure nanotube circuits [18.198] created by interconnecting nanotubes of different diameters and chirality could lead to further size reductions in devices. Nanotube intermolecular and intramolecular junctions are basic elements for such systems [18.199]. Room-temperature (RT) single-electron transistors (SETs) [18.200] have been shown with a short (≈ 20 nm) nanotube section that is created by inducing local barriers into the tube with an AFM, and Coulomb charging has been observed. With a cross-junction of two single-walled carbon nanotubes (SWNTs) (semiconducting/metallic), three- and four-terminal electronic devices have been made [18.201]. A suspended cross-junction can function as an electromechanical nonvolatile memory [18.202].

Although some kinds of junctions have been synthesized with chemical methods, there is no evidence yet showing that a self-assembly-based approach can provide more complex structures. SPMs were also used to fabricate junctions, but they are limited to a 2-D plane. We have presented 3-D nanorobotic manipulation-based nanoassembly, which is a promising strategy both for the fabrication of nanotube junctions and for the construction of more complex nanodevices with such junctions as well.

Nanotube junctions can be classified into different types by the kinds of components (SWNTs or MWNTs), geometric configurations (V kink, I, X cross, T, Y branch, and 3-D junctions) conductivity (metallic or semiconducting), and connection methods (intermolecular (connected with van der Waals force, EBID, etc.) or intramolecular (connected with chemical bonds) junc-

tions]. Here we show the fabrication of several kinds of MWNT junctions by emphasizing the connection methods. These methods will also be effective for SWNT junctions. Figure 18.19 shows CNT junctions constructed by connecting with van der Waals forces (a), joining by electron-beam-induced deposition (b), and bonding through mechanochemistry (c).

Figure 18.19a shows a T-junction connected with van der Waals forces, which is fabricated by positioning the tip of an MWNT onto another MWNT until they form a bond. The contact is checked by measuring the shear connection force.

EBID provides a soldering method to obtain stronger nanotube junctions than those connected through van der Waals forces. Hence, if the strength of nanostructures is emphasized, **EBID** can be applied. Figure 18.19b shows an MWNT junction connected through **EBID**, in which the upper MWNT is a single one with 20 nm in diameter and the lower one is a bundle of MWNTs with an extruded single CNT with \varnothing 30 nm. The development of conventional **EBID** has been limited by the expensive electron filament used and low productivity. We have presented a parallel **EBID** system by using **CNTs** as emitters because of their excellent field-emission properties [18.203]. The feasibility of parallel **EBID** is presented. It is a promising strategy for large-scale fabrications of nanotube junctions. As in its macroscale counterpart, welding, **EBID** works by adding materials to obtain stronger connections, but in some cases, the added material might influence normal functions for nanosystems. So, **EBID** is mainly applied to nanostructures rather than nanomechanisms.

To construct stronger junctions without adding additional materials, mechanochemical nanorobotic assembly is an important strategy. Mechanochemical nanorobotic assembly is based on solid-phase chemical reactions, or mechanosynthesis, which is defined as chemical synthesis controlled by mechanical systems operating with atomic-scale precision, enabling direct positional selection of reaction sites [18.18]. By picking up atoms with dangling bonds rather than natural atoms only, it is easier to form primary bonds, which provides a simple but strong connection. Destructive fabrication provides a way to form dangling bonds at the ends of broken tubes. Some of the dangling bonds may close with neighboring atoms, but generally a few bonds will remain dangling. A nanotube with dangling bonds at its end will bind more easily to another to form intramolecular junctions. Figure 18.19c shows such a junction.

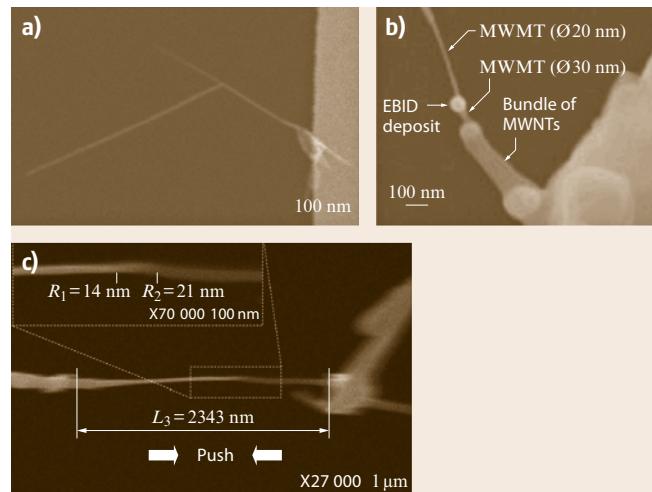

Fig. 18.19a–c MWNT junctions. (a) MWNTs connected with van der Waals forces. (b) MWNTs joined with **EBID**. (c) MWNTs bonded with a mechanochemical reaction

Three-dimensional nanorobotic manipulation has opened a new route for the structuring and assembly of nanotubes into nanodevices. However, at present nanomanipulation is still performed in a serial manner with master-slave control, which is not a large-scale production-oriented technique. Nevertheless, with advances in the exploration of mesoscopic physics, better control on the synthesis of nanotubes, more accurate actuators, and effective tools for manipulation, high-speed and automatic nanoassembly will be possible. Another approach might be parallel assembly by positioning building blocks with an array of probes [18.204] and joining them together simultaneously, e.g., with the parallel **EBID** [18.191] we presented. Further steps might progress towards exponential assembly [18.205], and in the far future to self-replicating assembly [18.18].

Nanorobotic Assembly of Nanocoils

The construction of nancoil-based **NEMS** involves the assembly of as-grown or as-fabricated nanocoils, which is a significant challenge from a fabrication standpoint. Focusing on the unique aspects of manipulating nanocoils due to their helical geometry, high elasticity, single-end fixation, and strong adhesion of the coils to the substrate from wet etching, a series of new processes has been presented using a manipulator (MM3A, Kleindiek) installed in an **SEM** (Zeiss DSM962). As-fabricated SiGe/Si bilayer nanocoils (thickness 20 nm without Cr layer or 41 nm with Cr layer; diameter $D = 3.4 \mu\text{m}$) are manipulated. Special tools have been

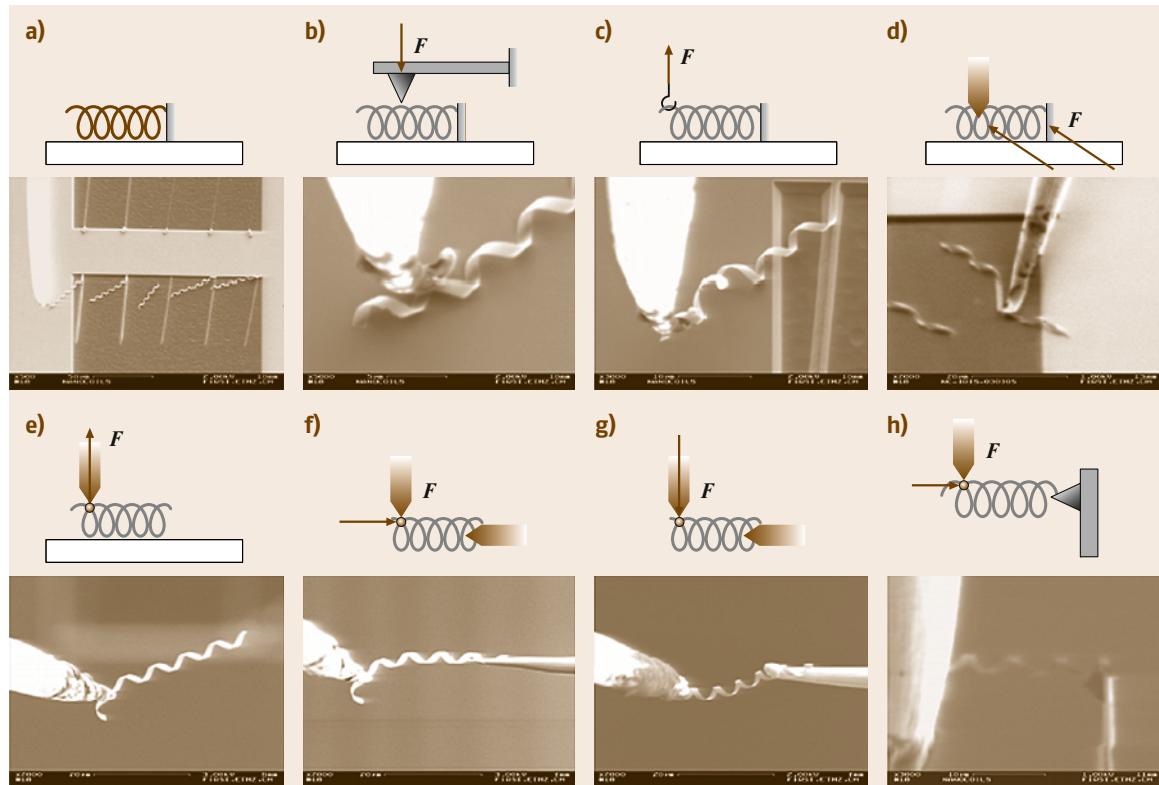

Fig. 18.20a–h Nanorobotic manipulation of nanocoils (a) original state, (b) compressing/releasing, (c) hooking, (d) lateral pushing/breaking, (e) picking, (f) placing/inserting, (g) bending, and (h) pushing and pulling

fabricated including a nanohook prepared by controlled *tip-crashing* of a commercially available tungsten sharp probe (Picoprobe T-4-10-1 mm and T-4-10) onto a substrate, and a *sticky* probe prepared by tip dipping into a double-sided **SEM** silver conductive tape (Ted Pella, Inc.). As shown in Fig. 18.20, experiments demonstrate that nanocoils can be released from a chip by lateral pushing, picked up with a nanohook or a *sticky* probe, and placed between the probe/hook and another probe or an AFM cantilever (Nano-probe, NP-S). Axial pulling/pushing, radial compressing/releasing, and bending/buckling have also been demonstrated. These processes have shown the effectiveness of manipulation for the characterization of coil-shaped nanostructures and their assembly for **NEMS**, which have been otherwise unavailable.

Configurations of nanodevices based on individual nanocoils are shown in Fig. 18.21. Cantilevered nanocoils as shown in Fig. 18.21a can serve as nanosprings. Nanoelectromagnets, chemical sensors, and nanoinductors involve nanocoils bridged between

two electrodes as shown in Fig. 18.21b. Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode as shown in Fig. 18.21c. Mechanical stiffness and electric conductivity are fundamental properties for these devices that must be further investigated.

As shown in Fig. 18.20h, axial pulling is used to measure the stiffness of a nanocoil. A series of **SEM** images are analyzed to extract the AFM tip displacement and the nanospring deformation, i.e., the relative displacement of the probe from the AFM tip. From this displacement data and the known stiffness of the AFM cantilever, the tensile force acting on the nanospring versus the nanospring deformation was plotted. The deformation of the nanospring was measured relative to the first measurement point. This was necessary because the proper attachment of the nanospring to the AFM cantilever must be verified. Afterwards, it was not possible to return to the point of zero deformation. Instead, the experimental data as presented in Fig. 18.21d has been shifted such that with the calculated linear elastic spring

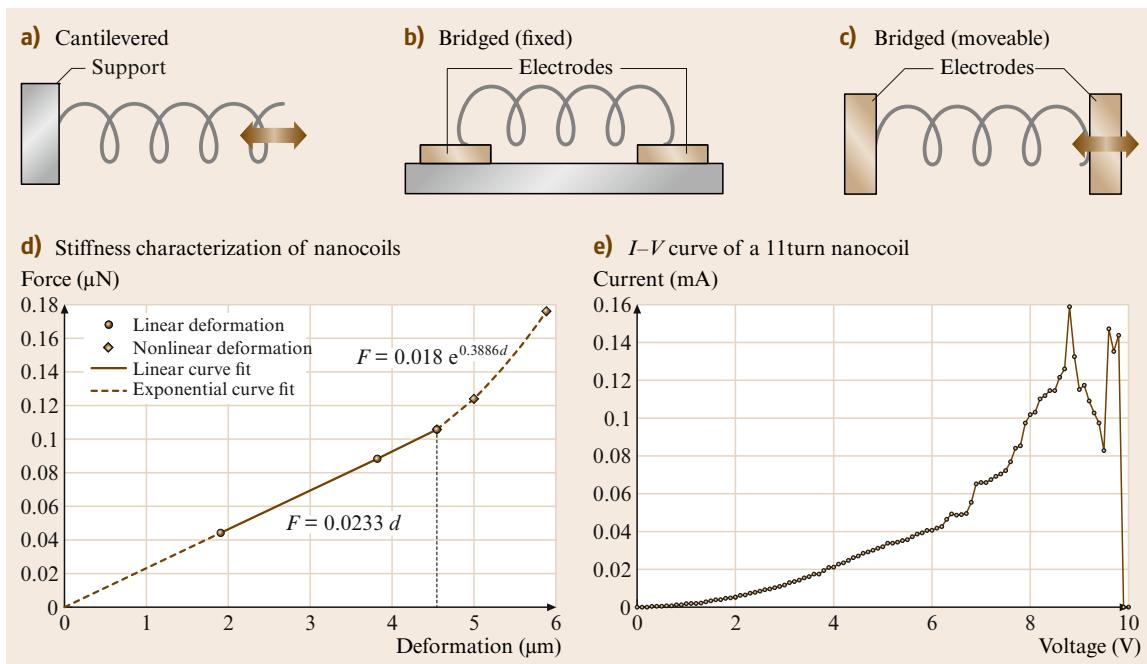

Fig. 18.21a–e Nanocoil-based devices. Cantilevered nanocoils (a) can serve as nanosprings. Nanoelectromagnets, chemical sensors, and nanoinductors involve nanocoils bridged between two electrodes (b). Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode (c). Mechanical stiffness (d) and electric conductivity (e) are basic properties of interest for these devices

stiffness the line begins at zero force and zero deformation. From Fig. 18.21d, the stiffness of the spring was estimated to be 0.0233 N/m . The linear elastic region of the nanospring extends to a deformation of $4.5 \mu\text{m}$. An exponential approximation was fitted to the nonlinear region. When the applied force reached $0.176 \mu\text{N}$, the attachment between the nanospring and the AFM cantilever broke. Finite-element simulation (ANSYS 9.0) was used to validate the experimental data [18.173]. Since the exact region of attachment cannot be identified from the SEM images, simulations were conducted for 4, 4.5, and 5 turns to estimate the possible range according to the apparent number of turns of the nanospring. The nanosprings in the simulations were fixed at one end and had an axial load of $0.106 \mu\text{N}$ applied at the other end. The simulation results for the spring with four turns yield a stiffness of 0.0302 N/m ; for the nanospring with 5 turns it is 0.0191 N/m . The measured stiffness falls within this range with 22.0% above the minimum value and 22.8% below the maximum value, and very close to the stiffness of a 4.5-turn nanospring, which has a stiffness of 0.0230 N/m according to the simulation.

Figure 18.21e shows the results from electrical characterization experiments on a nanospring with 11 turns using the configuration shown in Fig. 18.20g. The I - V curve is nonlinear, which may be caused by the resistance change of the semiconductive bilayer due to ohmic heating. Another possible reason is the decrease in contact resistance caused by thermal stress. The maximum current was found to be 0.159 mA under an 8.8 V bias. Higher voltage causes the nanospring to *blow off*. From the fast scanning screen of the SEM, an extension of the nanospring on probes was observed around the peak current so that the current does not drop abruptly. At 9.4 V , the extended nanospring is broken down, causing an abrupt drop in the I - V curve.

From fabrication and characterization results, the helical nanostructures appear to be suitable to function as inductors. They would allow further miniaturization compared to state-of-the-art microinductors. For this purpose, higher doping of the bilayer and an additional metal layer would result in the required conductance. Conductance, inductance, and quality factor can be further improved if, after curling up, additional metal is electroplated onto the helical structures. Moreover,
