a semiconductive helical structure, when functionalized with binding molecules, can be used for chemical sensing under the same principle as demonstrated with other types of nanostructures. With bilayers in the range of a few monolayers, the resulting structures would exhibit very high surface-to-volume ratio with the whole surface exposed to an incoming analyst.

18.8.4 Nanorobotic Devices

Nanorobotic devices involve tools, sensors, and actuators at the nanometer scale. Shrinking device size makes it possible to manipulate nanosized objects with nanosized tools, measure mass in femtogram ranges, sense force at piconewton scales, and induce GHz motion, among other amazing advancements.

Top-down and bottom-up strategies for manufacturing such nanodevices have been independently

investigated by a variety of researchers. Top-down strategies are based on nanofabrication and include technologies such as nanolithography, nanoimprinting, and chemical etching. Presently, these are 2-D fabrication processes with relatively low resolution. Bottom-up strategies are assembly-based techniques. At present, these strategies include such techniques as self-assembly, dip-pen lithography, and directed self-assembly. These techniques can generate regular nanopatterns at large scales. With the ability to position and orient nanoscale objects, nanorobotic manipulation is an enabling technology for structuring, characterizing and assembling many types of nanosystems [18.189]. By combining bottom-up and top-down processes, a hybrid nanorobotic approach based on nanorobotic manipulation provides a third way to fabricate NEMS by structuring as-grown nanomaterials or nanostructures. This new nanomanufacturing technique can be used

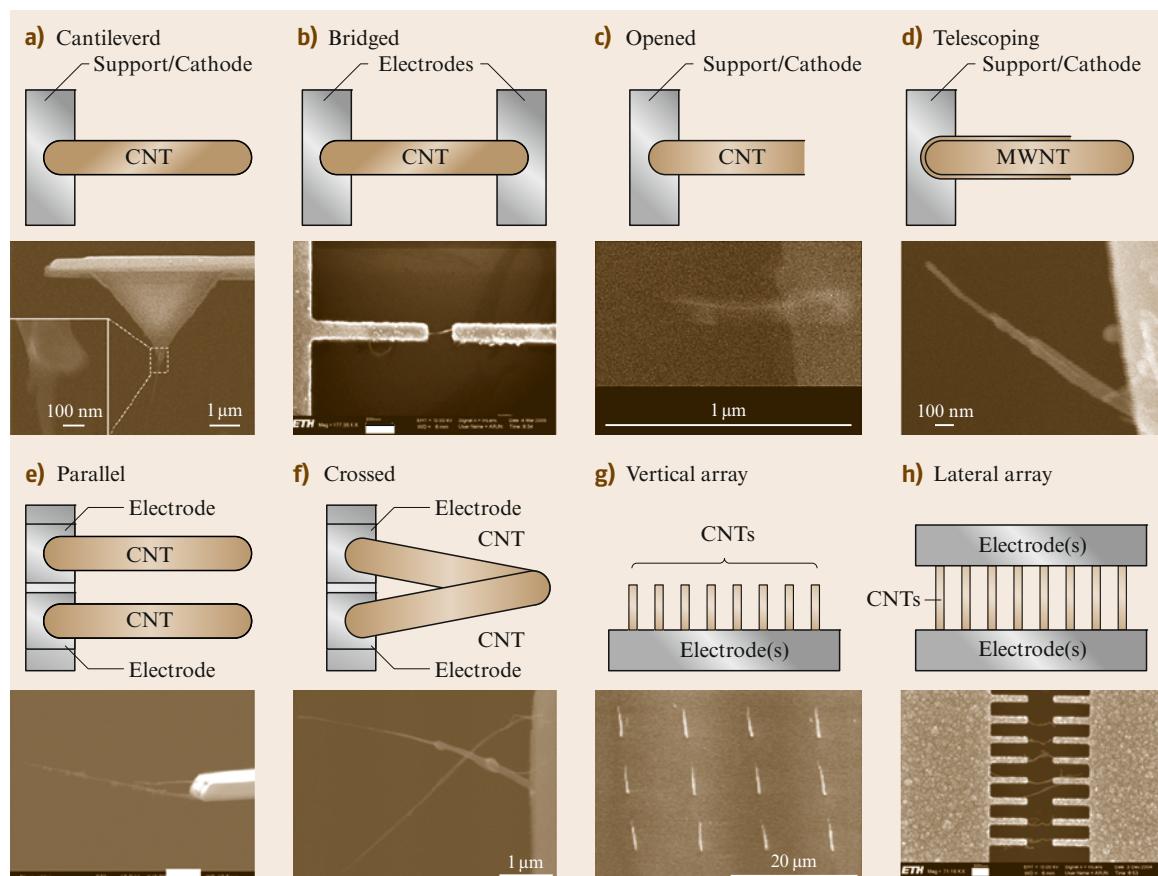

Fig. 18.22a–h Configurations of individual nanotube-based NEMS. Scale bars: (a) 1 μm (inset: 100 nm), (b) 200 nm, (c) 1 μm, (d) 100 nm, (e) and (f) 1 μm, (g) 20 μm, and (h) 300 nm. All examples are from the authors' work

to create complex 3-D nanodevices with such building blocks. Nanomaterial science, bio-nanotechnology, and nanoelectronics will also benefit from advances in nanorobotic assembly.

The configurations of nanotools, sensors, and actuators based on individual nanotubes that have been experimentally demonstrated are summarized as shown in Fig. 18.22.

For detecting deep and narrow features on a surface, cantilevered nanotubes (Fig. 18.22a, [18.191]) have been demonstrated as probe tips for an AFM [18.206], a **STM**, and other types of SPM. Nanotubes provide ultrasmall diameters, ultralarge aspect ratios, and excellent mechanical properties. Manual assembly, and direct growth [18.207] have proven effective for their construction. Cantilevered nanotubes have also been demonstrated as probes for the measurement of ultrasmall physical quantities, such as femtogram masses [18.162], piconewton-order force sensors, and mass flow sensors [18.189] on the basis of their static deflections or change of resonant frequencies detected within an electron microscope. Deflections cannot be measured from micrographs in real time, which limits the application of this kind of sensor. Interelectrode distance changes cause emission current variation of a nanotube emitter and may serve as a candidate to replace microscope images. Bridged individual nanotubes (Fig. 18.22b, [18.177]) have been the basis for electric characterization. Opened nanotubes (Fig. 18.22c, [18.208]) can serve as atomic or molecular containers, thermometers [18.209], or spot welders [18.210]. The electrostatic deflection of a nanotube has been used to construct a relay [18.211]. A new family of nanotube actuators can be constructed by taking advantage of the ultralow interlayer friction of

a multiwalled nanotubes. Linear bearings based on telescoping nanotubes and a microactuator with a nanotube as a rotation bearing have been demonstrated [18.195, 212], and batch fabrication has been realized based on dielectrophoretically assembled arrays [18.213]. A preliminary experiment on a promising nanotube linear motor with field-emission current serving as position feedback has been shown with nanorobotic manipulation (Fig. 18.22d, [18.208]). Cantilevered dual nanotubes have been demonstrated as nanotweezers [18.214] and nanoscissors (Fig. 18.22e) [18.179] by manual and nanorobotic assembly, respectively. Based on electric resistance change under different temperatures, nanotube thermal probes (Fig. 18.22f) have been demonstrated for measuring the temperature at precise locations. These thermal probes are more advantageous than nanotube-based thermometers because the latter require **TEM** imaging. The integration of the aforementioned devices can be realized using the configurations shown in Fig. 18.22g,h [18.177]. The arrays of individual nanotubes can also be used to fabricate nanosensors, such as position encoders [18.215].

Nanotube-based **NEMS** remains a rich research field with a large number of open problems. New materials such as nanowires, nanobelts, and polymer at the nanoscale will enable a new family of sensors and actuators for the detection and actuation of ultrasmall quantities or objects with ultrahigh precision and frequencies. Through random spreading, direct growth, optical tweezers, and nanorobotic manipulation, prototypes have been demonstrated. However, for integration into **NEMS**, self-assembly processes will become increasingly important. Among them, we believe that dielectrophoretic nanoassembly will play a significant role for large-scale production of regular 2-D structures.

18.9 Conclusions

Despite the claims of many *futurists*, such as Isaac Asimov's legendary submarine Proteus inside the human body [18.216] and Robert A. Freitas's nanomedical robots [18.217], the form that micro/nanorobots of the future will take and the tasks they will actually perform remain unclear. However, it is clear that technology is progressing towards the construction of intelligent sensors, actuators, and systems on small scales. These will serve as both the tools to be used for fabricating future micro/nanorobots as

well as the components from which these robots may be developed. Shrinking device size to these dimensions presents many fascinating opportunities such as manipulating nano-objects with nanotools, measuring mass in femtogram ranges, sensing forces at piconewton scales, and inducing GHz motion, among other new possibilities waiting to be discovered. These capabilities will, of course, drive the tasks that future micro/nanorobots constructed by and with **MEMS/NEMS** will perform.

25 Multisensor Data Fusion

Hugh Durrant-Whyte, Sydney, Australia
Thomas C. Henderson, Salt Lake City, USA

Part C of the Handbook is concerned with sensing and estimation. The world is not deterministic and, in addition, models of our robots are not perfect. Sensing is introduced to allow compensation for model approximations, and to estimate the layout of the environment to facilitate planning and execution of tasks.

Sensing is here considered the transformation of physical entities such as contact, force, distance, light intensity, etc. into an internal computer representation. Perception is the extraction of key properties from the sensory data and integration of sensory information over time. Perception is typically a data compression task in terms of extraction of the characteristics that allow recognition, tracking, and description of particular properties in the world, which are required to allow a robot to execute its tasks. This part of the Handbook covers the most typical sensor modalities used in robotics and the basic processes associated with these sensors.

Robotics is often paraphrased to be the intelligent coupling of perception and action. As such Part C complements Part B of the handbook and the following parts are all examples of such couplings in terms of sensing and mechanisms with associated intelligence.

This part is building on the foundations (Part A) and here in particular on Chap. 4, Sensing and Estimation. The material presented in this part is for obvious reasons tightly coupled to later chapters on systems and applications. Chapter 30 (Haptics) has a close coupling to the chapter on force and tactile sensing. Chapter 36 on world modeling is building on sensor models and the fusion methods presented in Chap. 25. The same applies for Chap. 37 on Simultaneous Localization and Mapping. Chapter 62 presents results from neuroscience and how it can be applied to robotics and has a strong coupling to many different sensory modalities and also integration of these into internal representations. Finally, Chap. 63 presents methods in human visual perception that are of relevance to robotics. These methods are in many ways the basis for techniques used in computer vision as discussed in Chaps. 23 and 24.

Part C contains chapters related to all the main sensory modalities from touch and proprioception to ranging and visual perception.

Chapter 19, Force and Tactile, discusses methods for detection of contact with objects in the external environment and also force as a reaction to acceleration and/or contact with external objects. Force sensing is essential to many high-precision assembly tasks, but increasingly also for interaction with nonrigid objects as, for example, experienced in medical applications. Contact and force sensing

is thus essential for many grasping and manipulation tasks.

Chapter 20, Inertial Sensors, GPS, and Odometry, covers methods for estimation of ego motion based on direct estimation from acceleration forces, shaft/wheel encoders or through exploitation of external reference systems such as GPS. Robot systems experience drift and slippage due to poor contact, but also due to material variations due to temperature etc. A fundamental capability is thus use of proprioception to estimate ego motion and internal state as a basis for decision making and action generation.

Chapter 21; Sonar Sensing, covers ranging and object detection based on sound information. Sound propagates significantly slower than light and as such allows use of electronics that it easier/cheaper to manufacture. This in part explains why much early work on mapping and position estimation for mobile platforms was based on ultrasonic sonars. Sonar is still a dominant modality for underwater applications and it often offers an economically attractive solution for basic mapping.

Chapter 22, Range Sensors, covers use of distance estimation based on light. Recently the use of laser radar has seen a significant increase in popularity. Laser-based sensors are active sensors in the meaning that the system emits energy of some form into the environment and measures the returned information, which allow use of matched techniques which simplifies the data-association problem and enable use in more noisy settings. Ranging can also be performed based on multiocular systems such as a stereo pair of cameras. The different methods for active and passive ranging are presented in this chapter.

Chapter 23, 3-D Vision and Recognition, covers 3-D modeling and recognition of objects based on image data. There is no doubt that vision is one of the most flexible and compelling sensory modalities. It has a significant potential for future applications. The flexibility poses, on the other hand, also a challenge as the detection of objects in cluttered environments can be very difficult. The chapter present methods for visual modeling of objects and the main steps and methods for recognition of objects.

Chapter 24, Visual Servoing and Visual Tracking, presents the main methods for tracking and control based on image data. Tracking of objects is essential in many applications either for interception or avoidance. Visual servoing addresses the problem of control to arrive at a goal location often associated with grasping of an object. The main techniques for tracking are presented

and the three major methods for visual servoing are introduced.

Chapter 25, Sensor Fusion, addresses the problem of integration of information across space and time. Sensor data are contaminated by noise in various forms and often there is a need to integrate data from multiple sensors or across time to provide robust and accurate estimates. This chapter presents the main techniques for sensory fusion and provides mathematical frameworks that are utilized in several of the following chapters.

Due to changes in materials and electronics, the area of sensors is changing rapidly. Within the last decade major changes in terms of laser ranging and visual sen-

sors have been fielded. In addition computer resources have changed dramatically to allow advanced processing of data to generate advanced perception systems. The availability of cheap, robust, and accurate sensing is also impacting other fields of robotics. Earlier robots were built to have a maximum of stiffness to avoid sensing. Today flexible robots are relying on sensors in the internal control loop to achieve hyperaccuracy at a reduced cost. There is no doubt that this is a trend that will continue as flexible robots can be made safer, cheaper and more efficient. The integration of sensing and actuation, especially with new nanotechnology, is going to change robotics significantly over the next decade.

Force and Tactile Sensors

Mark R. Cutkosky, Robert D. Howe, William R. Provancher

This chapter provides an overview of force and tactile sensing, with the primary emphasis placed on tactile sensing. We begin by presenting some basic considerations in choosing a tactile sensor and then review a wide variety of sensor types, including proximity, kinematic, force, dynamic, contact, skin deflection, thermal, and pressure sensors. We also review various transduction methods, appropriate for each general sensor type. We consider the information that these various types of sensors provide in terms of whether they are most useful for manipulation, surface exploration or being responsive to contacts from external agents.

Concerning the interpretation of tactile information, we describe the general problems and present two short illustrative examples. The first involves *intrinsic* tactile sensing, i. e., estimating contact locations and forces from force sensors. The second involves contact pressure sensing, i. e., estimating surface normal and shear stress distributions from an array of sensors in an elastic skin.

We conclude with a brief discussion of the challenges that remain to be solved in packaging and manufacturing damage-tolerant tactile sensors.

Tactile sensing has been a component of robotics for roughly as long as vision. However, in comparison to vision, for which great strides have been made in terms of hardware and software and which is now widely used in industrial and mobile robot applications, tactile sensing always seems to be *a few years away* from widespread utility. Therefore, before reviewing the technologies and approaches available it is worthwhile to consider some basic questions:

- How important is tactile sensing?
- What is it useful for?
- Why does it remain comparatively undeveloped?

In Nature, tactile sensing is an essential survival tool. Even the simplest creatures are endowed with large numbers of mechanoreceptors for exploring and responding to various stimuli. In humans, tactile sensing is indispensable for three distinct kinds of activities: manipulation, exploration, and response. The importance of tactile sensing for manipulation is most evident for fine motor tasks. When we are chilled, tasks like buttoning a shirt can become an exercise in frustration. The problem is primarily a lack of sensing; our muscles, snug in our coat sleeves, are only slightly affected but our cutaneous mechanoreceptors are anesthetized and we become clumsy. For exploration, we continually as-

simulate tactile information about materials and surface properties (e.g., hardness, thermal conductivity, friction, roughness) to help us identify objects. We may have difficulty distinguishing real leather from synthetic leather by sight, but not by touch. Finally, the importance of tactile response, whether to a gentle touch or an impact, is seen in the damage that patients with peripheral neuropathy (e.g., as a complication of diabetes) accidentally do to themselves.

As Fig. 19.1 indicates, the same functional categories apply to robots. However, in comparison to animals, with thousands of mechanoreceptors per square centimeter of skin, even the most sophisticated robots are impoverished. One reason for the slow development of tactile sensing technology as compared to vision is that there is no tactile analog to the charge-coupled device (CCD) or complementary metal–oxide–semiconductor (CMOS) optical array. Instead, tactile sensors elicit information through physical interaction. They must be incorporated into skin surfaces with compliance, to conform locally to surfaces, and with adequate friction to handle objects securely. The sensors and skin must also be robust enough to survive repeated impacts and abrasions. And unlike the image plane in a camera, tactile sensors must be distributed over the robot appendages, with particularly high concentrations in areas such as the fingertips. The wiring of tactile sensors is consequently another formidable challenge.

Fig. 19.1 Uses of tactile sensing in robotics

Nonetheless, considerable progress in tactile sensor design and deployment has been made over the last 20 years. In the following sections we review the main functional classes of tactile sensors and discuss their relative strengths and limitations. Looking ahead, new fabrication techniques offer the possibility of artificial skin materials with integrated sensors and local processing for interpreting sensor signals and communicating over a common bus to reduce wiring.

There is an extensive literature describing touch sensing research. Recent general reviews include [19.1] and [19.2], and these cite several older reviews from the 1980s and 1990s.

19.1 Sensor Types

This section outlines five main types of sensors: proprioceptive, kinematic, force, dynamic tactile, and array tactile sensors. A basic review of the first three of these is provided along with contact sensors that provide thermal or material composition data. However, greater emphasis is placed on tactile sensors that provide mechanoreception. Table 19.1 provides an overview of these tactile sensors. When considering tactile sensors, it is useful to begin by considering the fundamental physical quantities that can only be sensed through contact with the environment. The most important quantities measured with touch sensors are *shape* and *force*. Each of these may be measured either as an average quantity for some part of the robot or as a spatially resolved, distributed quantity across a contact area. In this chapter we follow the convention of studies of the human sense of touch and use the term *touch sensing* to refer to the combination of these two modes. Devices that measure

an average or resultant quantity are sometimes referred to as *internal* or *intrinsic* sensors. The basis for these sensors is force sensing, which precedes the discussion of tactile array sensors.

19.1.1 Proprioceptive and Proximity Sensing

Proprioceptive sensing refers to sensors that provide information about the net force or motion of an appendage, analogous to receptors that provide information in humans about tendon tensions or joint movements. Generally speaking the primary source for spatial proprioceptive information on a robot is provided by joint angle and force-torque sensors. Since joint angle sensors such as potentiometers, encoders, and resolvers are well-established technologies, they do not warrant discussion here. Instead, a brief review of proximity sensing via whiskers and antennae as well as noncontact proximity

sensing is provided. Force-torque sensors are discussed in greater detail in Sect. 19.1.4.

Whisker and Antenna Sensors

Whisker or antenna sensors are in essence a hybrid of proprioceptive and tactile information. This form of sensing was first explored in the early 1990s, for example, *Russell* [19.25] developed a whisker sensor with a base angle sensor and tip contact sensor that was attached to a robot arm to explore its environment. Another example by *Kaneko* et al. [19.26] is one of the earliest examples of active antenna sensing. *Kaneko* et al. affixed a rigid spring steel antenna to a one-degree-of-freedom (1-DOF) rotating axis used to sweep the antenna from side to side similar to the method an insect would employ. The sweeping motion, in combination with a joint angle sensor and torque sensor, was used to assess encountered contacts. *Clements* and *Rahn* [19.27] took a similar approach to *Kaneko*, but added an extra degree of freedom to the sweeping pattern of their whisker. *Clements* and *Rahn* used a motor-driven gimbal to drive their spring steel whisker in two DOFs to explore objects. *Cowan* et al. [19.28] used a multisegmented piezoresistive antenna to aid a bio-inspired insect hexapod robot in a wall-following control task.

For many animals, whiskers or antennae provide an extremely accurate combination of contact sensing and proprioceptive information, for example, cockroaches can steer themselves along curved walls at 20 body-lengths per second using only the position and rate information that they obtain from their antennae. Other insects, such as arthropods use numerous small hair sensors on their exoskeleton to localize contacts.

Proximity

While proximity sensing does not strictly fall under the category of tactile sensing, a number of researchers have employed various proximity sensors for the application of collision detection between a robot arm and the environment and thus we briefly review these technologies here. Three primary sensor technologies which include capacitive, infrared (IR) optical, and ultrasonic sensors have been used in this application. *Vranish* et al. developed an early capacitive sensor for collision avoidance between the environment and a grounded robot arm [19.29]. Examples of distributed IR emitter-detector pairs utilized within artificial skin for the purposes of proximity sensing have been presented by *Lumelsky*'s research group [19.30, 31]. A more recent design using optical fibers is reported in [19.32]. Other researchers have developed robot skins that include both distributed ultrasonic and IR optical sensors for the purposes of collision avoidance [19.33]. *Wegerif* and *Rosinski* provide a comparison of the performance of all three of these proximity sensing technologies [19.34]. For a more detailed review of this variety of sensors, see Chap. 21 on sonar sensing and Chap. 22 on range sensors.

19.1.2 Other Contact Sensors

There are a variety of other contact-based sensors that are capable of discerning object properties such as electromagnetic characteristics, density (via ultrasound), or chemical composition (cf. animals, senses of taste and smell). While this is beyond the scope of the current chapter, Chap. 60 on biologically inspired robots briefly discusses biologically inspired chemical sensors related

to smell and taste. For completeness, thermal sensors and material composition sensors are also briefly discussed below.

Thermal Sensors

Thermal sensing can be used to determine the material composition of an object as well as to measure surface temperatures. Since most objects in the environment are at about the same (*room*) temperature, a temperature sensor that contains a heat source can detect the rate at which heat is absorbed by an object. This provides information about the heat capacity of the object and the thermal conductivity of the material from which it is made, making it easy, for example, to distinguish metals from plastics.

Buttazzo et al. [19.35] note that the piezoelectric polymer used in their tactile sensing system is also strongly pyroelectric, and use a superficial layer as a thermal sensor. Other sensors use thermistors as transducers, with *Siegel* et al. [19.36] reporting a 4×4 array and *Russell* [19.37] a 2×10 array. Some systems purposely provide an internal temperature reference and use the temperature differential from the environment as a means of finding contacts [19.38, 39]. However, objects with a temperature the same as the reference will not be detected. Most of these sensors have a relatively thick outer skin covering the heat-sensitive elements, thus protecting delicate components and providing a conformal surface at the expense of slower response time.

A more recent example of thermal sensing can be found in the work of *Engel* et al., who present a flexible tactile sensor design that includes integrated gold-film heaters and a resistance temperature device (RTDs) on a polymer micromachined substrate [19.40]. While there is a high level of integration presented by *Engel* et al., these sensing elements still remain fragile, hence tradeoffs concerning construction, performance, and the protection of sensing elements in these systems remains an ongoing challenge.

Material Composition Sensors

There has been a little work on sensors for material composition. In analogy with the human senses of taste and smell, liquid- and vapor-phase chemical sensors could potentially determine the chemical composition of a surface ([19.41, 42]). Another sensing modality which provides information about material properties is electromagnetic field sensing, using devices such as eddy-current or Hall-effect probes to measure ferromagnetism or conductivity [19.43, 44].

19.1.3 Kinematic Sensors

Although they are not generally thought of as tactile sensors, sensors that detect the position of a limb can provide the robot with geometric information for manipulation and exploration, particularly when the limb also includes sensors that register contact events. Examples of such sensors include the ubiquitous joint angle encoders found in virtually all robots as well as potentiometers, resolvers, and other joint angle measuring devices. For limbs that do not undergo large rotations one can also embed flexible structures such as elements composed of piezoresistive ink, e.g., as used by *Cowan* et al. [19.28], as discussed in Sect. 19.1.1. Examples of combining information about joint angles with contact status sensors for manipulation include *Kaneko*'s work [19.45] on the *posture changeability* of fingers.

19.1.4 Force and Load Sensing

Actuator Effort Sensors

For some actuators such as electric servo motors, a measure of the actuator effort can be obtained directly by measuring the motor current (typically using a sensing resistor in series with the motor and measuring the voltage drop across the sense resistor). However, because motors are typically connected to robot limbs via gearboxes with output/input efficiencies of 60% or less, it is usually much more accurate to measure the torque at the output of the gearbox. Solutions to this problem include shaft torque load cells (typically using strain gages) and mechanical structures at the robot joints whose deflections can be measured using electromagnetic or optical sensors. For cable- or tendon-driven arms and hands it is useful to measure the cable tension – both for purposes of compensating for friction in the drive-train and as a way of measuring the loads upon the appendage [19.46]. When fingers or arms make contact with objects in the environment, cable tension sensing becomes an alternative to endpoint load sensing for measuring components of the contact forces. Of course, only those components that produce significant torques can be measured with any accuracy. Section 15.3.2 (Robot Hands: Sensors) contains more details concerning cable tension measurement.

Force Sensors

When actuator effort sensors are not sufficient to measure the forces exerted by or on a robot appendage, discrete force sensors are typically utilized. These sensors are found most often at the base joint or wrist of

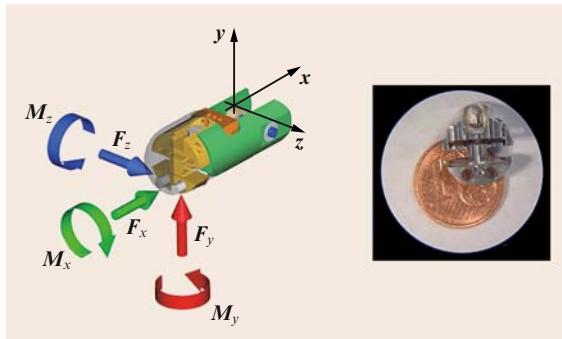

Fig. 19.2 Miniature fingertip force-torque sensor for a prosthetic hand (after [19.47] with permission)

a robot, but could be distributed throughout the links of a robot.

In principle, any type of multiaxis load cell could be used for manipulator force-torque sensing. However, the need for small, lightweight units with good static response eliminates many commercial sensors. The design of force sensors for mounting above the gripper at the wrist has received the most attention [19.48, 49], but fingertip sensors for dexterous hands have also been devised. Often these sensors are based on strain gauges mounted on a metal flexure [19.50, 51], which can be fairly stiff and robust. *Sinden and Boie* [19.52] propose a planar six-axis force-torque sensor based on capacitive measurements with an elastomer dielectric. Design considerations for force sensors include stiffness, hysteresis, calibration, amplification, robustness, and mounting. *Dario* et al. present an integrated fingertip for robotic hands: an integrated force sensing resistor (FSR) pressure array, piezoceramic bimorph dynamic sensor, and force-torque sensor [19.21]. More recently *Edin* et al. [19.47] have developed a miniature multiaxis fingertip force sensor (Fig. 19.2). For applications where immunity to electromagnetic noise is desirable, *Park* [19.53] presents a design for a robot fingertip with embedded fiber optic Bragg gratings, used as optical strain gages. *Bicchi* [19.54] and *Uchiyama* et al. [19.55] consider the optimal design of multiaxis force sensors in general.

It is interesting to note that more than just force information can be gained by the use of fingertip load sensors. Information from the force sensors can be combined with knowledge of fingertip geometry to estimate contact location, as implied in Fig. 19.3. This method of contact sensing is referred to as *intrinsic tactile sensing*, and was first presented by *Bicchi* et al. [19.56]. A comparison between intrinsic and extrinsic contact sensing

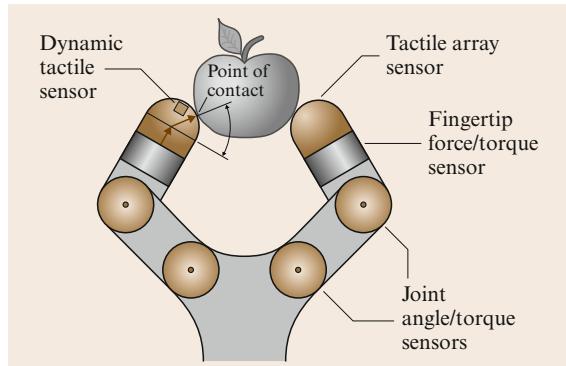

Fig. 19.3 Robot hand with fingertip force and tactile sensing. Information from the force sensors can be combined with knowledge of fingertip geometry to estimate contact location, referred to as *intrinsic tactile sensing*

(i.e., using distributed contact sensors) is presented by *Son* et al. [19.11]. This is also discussed in further detail in Sect. 19.2.1

19.1.5 Dynamic Tactile Sensors

Early special-purpose slip sensors based on displacement detected the motion of a moving element such as a roller or needle in the gripper surface (e.g., *Ueda* et al. [19.57]). A more recent approach uses a thermal sensor and a heat source: when the grasped object begins to slip, the previously warmed surface under the sensor moves away, causing a drop in surface temperature beneath the sensor. A noncontact optical approach uses correlation to reveal motion of the object surface [19.58]. A number of researchers have suggested using conventional arrays for slip detection, but the array resolution must be good and the scanning rate high to detect the motion of object features soon enough to prevent dropping the grasped object.

In a systematic investigation of the feasibility of using vibration to detect slip, *Rebman* and *Kallhammer* [19.59] used single elements from an array sensor to detect normal vibrations at the contact surface. *Dario* and *DeRossi* [19.60] and *Cutkosky* and *Howe* [19.61] note that piezoelectric polymer transducers located near the contact surface are very sensitive to vibrations and may be used for slip detection. *Howe* and *Cutkosky* [19.24] show that using a small accelerometer to sense minute vibrations of a compliant sensor skin is an effective means of detecting slip at its earliest stages. For hard objects held in metal grippers, acoustic emissions may reveal incipient slip [19.62, 63]. Mor-

rell [19.64] and Tremblay [19.65] investigated the use of slip sensors in grasp force control.

Buttazzo et al. [19.35] have built a texture-sensing fingernail as part of their anthropomorphic tactile sensing system. A piezoelectric element at the base of the rigid plastic nail produces a large signal as it is dragged over a textured surface. The stress rate sensor [19.22, 61, 66], the skin acceleration sensor [19.22, 24], and the induced vibration sensor [19.67] described above in the context of shape or slip sensing also respond to the small vibrations produced by sliding over fine surface textures. More recent adaptations of these sensors include piezoceramic bimorph dynamic sensors, with integrated FSR pressure array, and force-torque sensor [19.21]. Yamada et al. [19.68], who have developed a piezoelectric artificial skin, are able to distinguish between rolling and slip. Waldron et al. [19.23] describe a tactile sensor that integrates skin acceleration with a piezoelectric array for the application of teledermatology. Ellis has also investigated the use of a very high-resolution tactile array data for discriminating surface textures [19.69]. Omata and Terunuma present a sensor that measures changes in compliance by detecting changes in the resonant frequency of an active piezoelectric element [19.70].

19.1.6 Array Sensors

Array sensors can be subdivided into two primary categories: those that measure pressure and those that measure the deflection of the sensor skin. Tactile pressure arrays are by far more common. Pressure arrays tend to be relatively stiff and utilize a variety of transduction methods along with solid mechanics to calculate contact pressure distribution. Skin deflection sensors are constructed in a manner that permits gross sensor skin deformation during contacts, which can be advantageous for grasp stability (see Chaps. 27 and 28).

Hundreds of designs for tactile array sensors have appeared in the literature in the last 15 years, and a few of them are suitable for use with dexterous hands. In terms of transducers, the fundamental requirement is to recover either the shape or pressure distribution across the contact unambiguously from beneath a compliant elastomer layer. This can be done by directly sensing shape [19.71, 72] or by sensing multiple components of subsurface strain [19.73, 74]. Solid mechanics models (Sect. 19.2.2) can then be used to determine the desired quantities. While the approach used in the models

developed to date is quite successful, they must be extended to three dimensions and to incorporate multiple components of strain. Since these models are complex, real-time execution must be addressed.

Contact Location Sensors

There have been a number of tactile sensors that solely provide contact location. Discrete switches placed on the outer chassis of mobile robots were quite common before the proliferation of ultrasonic sensors. Other researchers have presented work using discrete switch arrays. Some such sensors utilize a membrane switch design, found in keyboards. A visually transparent example of such a design is presented by Arai et al. for use in combination with a touch screen display [19.75]. Alternately, Griffin [19.76] shows a membran-switch-inspired contact switch array designed by W. Provancher that consists of flexible circuits separated by thin dielectric strips. Contacts are registered when pressure deflects one flexible circuit into the other, as shown in Fig. 19.4a. More recent work presented by Edin et al. [19.47]

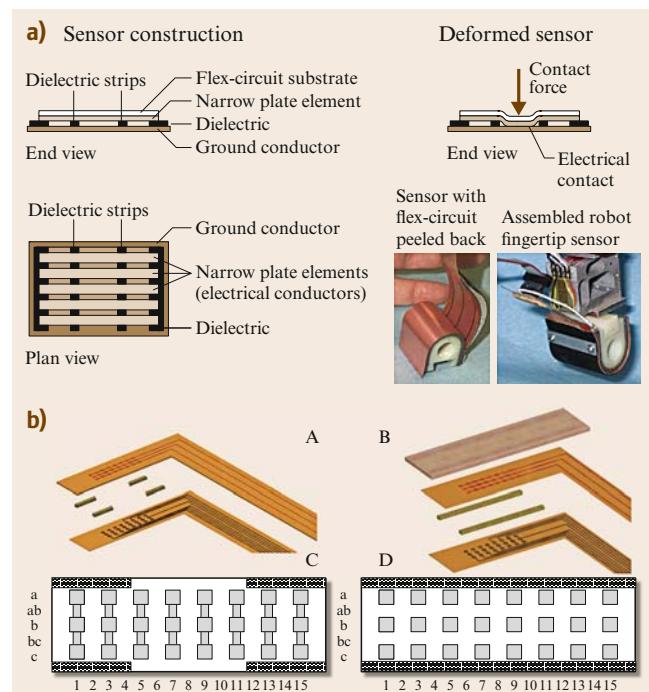

Fig. 19.4a, b Contact switch arrays fabricated from flexible printed circuits. (a) A simple 16×1 switch array used on the fingertip of a dexterous robot hand (drawn by W. Provancher). (b) Contact switch array embedded in the skin of a prosthetic hand (after [19.47] with permission)

shows a nice extension on this idea, with a two-dimensional switch array embedded in a prosthetic hand; see Fig. 19.4b. Some optical tactile sensors [19.77] have also been used primarily as contact location sensors. However, because they can also measure the magnitude of the contact force they are discussed under tactile arrays.

Pressure Sensing Arrays

Capacitive Pressure Sensing Arrays. Tactile pressure arrays are one of the oldest and most common tactile sensor types. Some of the earliest work in this area was done by *Fearing* [19.78] and *Fearing and Binford* [19.9]. These researchers produced capacitive tactile pressure arrays within a robot fingertip, suitable for dexterous manipulation. The sensor array consisted of overlapping row and column electrodes separated by an elastomeric dielectric, forming an array of capacitors. A change in capacitance results from compressing the dielectric between row–column plates at a particular intersection. The equation for capacitance, based on the physical parameters, is expressed as $C \approx (\epsilon A)/d$, where ϵ is the permittivity of the dielectric between the plates of the capacitor, A is the area of the plates, and d is the spacing between them. Compressing the dielectric between the capacitive plates thus reduces the plate spacing d , providing a linear response with displacement.

Through appropriate switching circuitry, a particular region of a sensor array can be isolated at a particular row–column intersection. Pressure is calculated by means of solid mechanics, as outlined by *Fearing* [19.79]. Examples of similar capacitive tactile arrays can be found in [19.10,11] and commercially at [19.12]. More recently, *Shinoda*'s group has investigated conductive fabric to form pairs of conforming, stacked capacitors more appropriate for covering larger areas than a robot hand [19.13]. The fabric electrodes in the stacked capacitive sensor elements are alternately separated by stiff or soft urethane foam, permitting simultaneous estimation of contact pressure and area within a single sensor element.

Piezoresistive Pressure Sensing Arrays. A variety of researchers have produced tactile sensor arrays that are piezoresistive in nature. These sensors generally either utilize a conductive rubber that is bulk molded or a piezoresistive ink that is generally patterned via screen printing or stamping. Each of these employ a conductive additive (typically carbon black) to create its conductive/piezoresistive behavior. However, because of the fragility and hysteresis that these sensor mor-

phologies exhibit, some researchers have also developed fabric-based piezoresistive sensors.

Russell [19.80] presented one of the first molded conductive rubber tactile sensor arrays composed of conductive rubber column and row electrodes with piezoresistive junctions. However, this sensor exhibited significant drift and hysteresis, which became the topic of later research to try to minimize these effects through proper selection of molding material [19.3]. These issues were never completely solved due to the hysteretic nature of elastomers, but this sensing approach remains attractive due to its ease of manufacturing. Hence it has continued to find applications in the appendages of humanoid robots where extreme accuracy is not required [19.81].

A number of researchers and companies have developed tactile sensors that utilize conductive (piezoresistive) ink, generally referred to as force sensitive resistors (**FSRs**). This is by far the most common, simplest, and most readily available means to incorporate tactile sensing via off-the-shelf discrete sensors (see Tekscan Flexiforce **FSRs**). However, to make highly integrated, dense sensor arrays, custom fabrication is necessary. Examples of such sensors are presented by *Papakostas* et al. [19.4] and *Dario* et al. [19.21]. To take this approach one step further, *Someya* [19.5] has produced robotic skin that employs patterned organic semiconductors for local amplification of the piezoresistive sensor array, printed on flexible polyimide film. However, despite being fabricated on a flexible substrate, these sensor arrays are still susceptible to bending fatigue.

Piezoresistive fabrics have been developed to address fatigue and fragility issues found in tactile arrays. Examples of these sensors are presented by *De Rossi* et al. [19.7], *Tognetti* et al. [19.8], and *Shimojo* et al. [19.6]. These sensors tend to be larger (i.e., have lower spacial resolution) and are utilized in applications such as the arms or legs of humanoid robots. Because this technology has the potential to replace ordinary cloth, it is a promising technology for applications in wearable computing or even smart clothing.

One final design that does not fall under the above fabrication categories is a sensor designed by *Kageyama* et al. that utilizes a piezoresistive conductive gel pressure array along with a multilevel contact switch array via variable contact resistance within sensor layers that they developed for use in humanoid robots [19.82].

MEMS Pressure Sensing Arrays. Micro-electromechanical (**MEMS**) technology is quite attractive for producing

highly integrated packaging for tactile sensing and associated interconnects and electronics. Early devices were produced in silicon through standard silicon micromachining techniques, including the silicon micromachined CMOS-compatible tactile array capable of measuring shear and normal force developed by *Kane* et al. [19.14]. These sensors functioned well on the laboratory desktop, but were too fragile to survive impact or harsh environments. More recently, researchers have applied **MEMS** techniques to produce sensor arrays appropriate for embedding within an elastomeric skin with flexible substrates. This has the advantage of improved durability because of the protective skin. *Engel* et al. have produced a tactile sensor with combined temperature and cantilever elements grown on a polyimide backing [19.40]. Polymer micromachining of the polyimide was performed to give the polyimide substrate preferential compliance. An interesting variation on this design is presented by *Noda* and *Shimoyama* [19.83]. These researchers also produced cantilever shear stress elements on their array sensor, however, they do this in a planar fabrication process to fabricate cantilevers with NiCr piezoresistors that are subsequently released from the fabrication substrate and made to stand up off the substrate like hairs by applying a magnetic field and subsequently fixing the cantilevered beams by covering them with Parylene-C (used for sensing

shear) [19.83]. Returning to the idea of using silicon load cells for tactile sensing, *Valdastri* et al. [19.15] have developed a miniature **MEMS** silicon-based load cell that resembles a joystick and that is appropriate for embedding within an elastomeric skin (see Fig. 19.5). These sensors could be distributed beneath the skin surface to detect complex stress states in the elastomeric skin.

Skin Deflection Sensing

Brocket [19.84] was one of the first to propose the idea of using a deformable membrane robot fingertips. As noted by *Shimoga* and *Goldenberg* [19.85], there are several advantages to using deformable fingertips over more rigid robot fingertips, which include: (1) improved grasp stability, (2) reduced shock, and (3) reduced fatigue for embedded sensor elements. Early work on deformable fingertips includes *Russell*'s work to create a compliant silicone rubber robot finger [19.80]. His sensor finger used a rigid backing and polyurethane foam to provide a restoring force for the sensor skin. An array of conductive rubber strain gauge elements and their associated interconnects were cut to the correct shape and bonded to the backside of the silicone rubber skin. The conductive rubber was simply silicone rubber, chosen with minimal mechanical hysteresis, mixed with graphite. The electrical interconnects of a given row tapped into the conductive rubber strain gauge at regular intervals along its length, thus subdividing it into several individual strain measurements, forming a potential divider. *Russell* shows results for both an 8×1 line array and an 8×5 array.

Nowlin used Bayesian algorithms to improve data interpretation of a deformable tactile sensor that used magnetic field sensing [19.72]. A 4×4 array of magnets were supported above paired Hall-effect sensors off a rigid base by individual fluid-filled balloons. Hall-effect sensors measure the strength of the local magnetic field and should therefore increase with closer proximity to the magnets; however, this is complicated by the proximity of neighboring magnets in the sensor array. Hence, noisy data from the Hall-effect sensors were combined using Bayesian algorithms to predict membrane deformation for a deformable fingertip [19.72].

Later *Russell* and *Parkinson* [19.19] developed an impedance tomographic tactile sensor capable of measuring skin deformation over an 8×5 array. This sensor was constructed with neoprene rubber and filled with distilled water. Row and column electrodes were made from copper and conductive rubber for the rigid substrate and neoprene skin, respectively. Like the capacitive

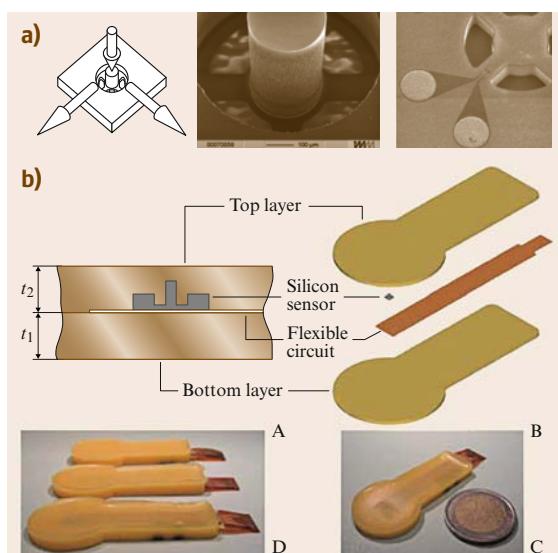

Fig. 19.5 (a) SEM micrographs of a **MEMS** three-axis tactile force sensor. (b) **MEMS** force sensor wire-bonded to a flex-circuit and embedded within a silicone rubber skin [19.15]

tactile sensors described above, this sensor utilized multiplexing electronics to reduce the number of electrical interconnects. Square-waveform driver electronics are used to estimate the resistance of a column of water formed between row and column elements, providing a signal that is proportional to the current skin height.

After suggesting the idea of using deformable tactile sensors, *Ferrier* and *Brocket* [19.17] implemented a tactile sensor which used optical tracking in combination with models of the sensors skin deformation to predict sensor fingertip skin deformations. The fingertip sensor consists of a tiny [CCD](#) camera focused on a 7×7 array of dots that are marked on the inside of the gel-filled silicone fingertip membrane. An algorithm is used to construct a 13×13 grid over the array of dots. This algorithm uses a combination of the position that is sensed by the [CCD](#) camera, which provides the location along a line radially outward from the focal point, and a mechanical model used to solve for the radial distance from the camera focal point based on energy minimization.

Provancher and *Cutkosky* present another design that uses piezoresistive strain gauges to measure fingertip membrane curvature directly [19.20]. The sensor is constructed on a polyimide substrate with commercial strain gauge strips (used to investigate strain gradients) bonded back to back to isolate bending strains, which are proportional to curvature. This curvature information is important for motion planning in dexterous manipulation. The authors present a mathematical model which uses a set of basis functions and least-squares minimization to calculate a curvature-space curve fit that is insensitive to sensor noise and capable of reconstruction of the deformed membrane shape. Results from a 11×1 line array sensor prototype are presented in Sect. 19.2.2.

Other Tactile Array Sensors

An early example of an optical tactile sensor was presented by *Maekawa* et al. [19.77], who used a single optical position sensing device (PSD) or a [CCD](#) camera array to detect the position of scattered light off of

a hemispherical optical waveguide fingertip with a silicone rubber cover. Light is scattered at the location of contact and, based on a simple model, multiple points of contact can be estimated. With a textured skin, the magnitude of the force can also be estimated, as the contact area grows in proportion to the pressure. However, an issue with fingertips that use a compliant skin covering a hard substrate is that adhesion between the two materials results in hysteresis. In addition, when the fingertip is dragged over a surface, the friction can produce a shift in the estimated contact position.

Another interesting tactile sensor uses vision to track an array of spherical markers embedded in a transparent elastomer to infer the stress state of the skin material due to applied forces [19.16]. This sensor is currently being commercialized under the tradename GelForce.

A number of sensors have been developed that monitor changes in acoustic energy reflected off of a skin surface or due to the distortion of an acoustic subsurface cavity. *Shinoda* et al. [19.86] present a sensor that looks at the change in reflected acoustic energy from an acoustic resonator chamber near the surface of the skin and its application for instantaneous friction measurement [19.87]. *Ando* et al. [19.88] present a more sophisticated ultrasound sensor that achieves 6-DOF displacement sensing via paired plate elements that utilize four ultrasound transducers per plate.

Several researchers have developed sensors with multiple sensing modalities. Examples of sensors that combine tactile and thermal sensing are presented by *Siegel* et al. [19.89] and *Castelli* [19.90]. *Shimizu* et al. [19.91] present a sensor for measuring force and the hardness of an object. This sensor actively uses pneumatic pressure to drive sensing elements into an object's surface.

Another interesting sensor includes a combination of tactile sensing and ultrasound imaging [19.92], in which *Methil* et al. have developed a haptic system for performing breast examinations that utilizes an optical waveguide tactile sensor.

19.2 Tactile Information Processing

19.2.1 Tactile Information Flow: Means and Ends of Tactile Sensing

In discussing the processing of tactile information we return first to the three main uses depicted in Fig. 19.1. For

manipulation, we require, foremost, information about contact locations and forces so that we can grasp objects securely and impart desired forces and motions to them. For exploration, we are concerned with obtaining and integrating information about the object, including the

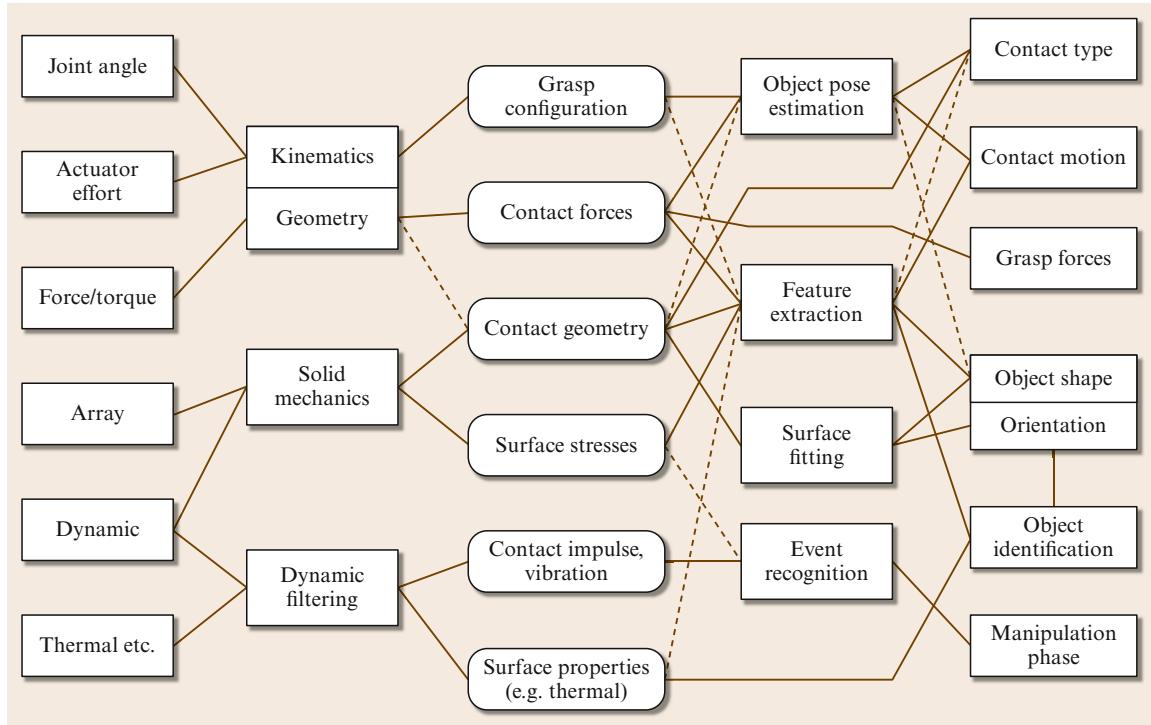

Fig. 19.6 Force and tactile sensor information flow and signal processing

local geometry, hardness, friction, texture, thermal conductivity, etc. For response, we are concerned especially with the detection of events, such as contacts produced by an external agent, and in assessing their types and magnitudes. The uses of information are often coupled; for example, we manipulate objects in order to explore them and we use the information obtained through object exploration to improve our ability to control forces and motions in manipulation. Recognizing contact events is also important for manipulation and exploration, as it is for response.

Figure 19.6 summarizes the general flow of information from each type of sensor reviewed in the previous section through primary sensed quantities to information provided for manipulation, exploration and response. A useful thought exercise is to consider exactly what information we use to perform a task such as turning a pen end over end between the fingers. We can easily perform this task with our eyes closed. What information are we using? We need to track the position and orientation of the pen and to monitor the forces that we impose on it to maintain stable manipulation. In other words, we need to know the *configuration* of our grasp, the *locations and movements of contacts* over the surfaces of

our fingers, the *magnitudes of grasp forces*, the *contact conditions* with respect to friction limits, etc. The same requirements apply for robots and are provided by the information flow in Fig. 19.6.

At the upper left corner of the figure, joint angles, combined with the forward kinematic model of the manipulator and knowledge of external link geometries, establish the positions and orientations of coordinate frames embedded in the fingertips. This information is needed to integrate local information about object shape, surface normal orientation, etc. so that the overall geometry and pose of the object can be determined.

Actuator effort sensors provide information about the resultant forces, using the Jacobian transpose: $J^\top f = \tau$, where f is an $n \times 1$ vector of external forces and moments taken with respect to a coordinate frame embedded in the appendage. J^\top is the Jacobian transpose, mapping external forces and moments to joint torques and τ is an $m \times 1$ vector of joint torques for a serial kinematic chain with m degrees of freedom. We require that the k -th column of J^\top have elements that are relatively large compared to the overall condition number of J in order to provide an accurate measurement of

the k -th element of f . Eberman and Salisbury [19.93] show that it is possible to measure contact force and location using only joint torque measurements if the manipulator has clean dynamics.

Alternatively, we can use a multiaxis force/torque sensor in the fingers, as indicated in Fig. 19.3, or robot wrist to obtain contact forces. This approach has the advantage of providing dynamic force signals with a higher signal-to-noise ratio because they are not masked by the inertias of the robot arm or fingers and their transmissions. If the geometry of the fingertip is known, one can use *intrinsic tactile sensing* [19.50, 94] to compute the contact location as well as the contact force by examining ratios of resultant forces and torques at the sensor.

When the contacts are small compared to the fingertips, so that a point-contact approximation applies, and the fingertips are convex shapes, the contact location is easily computed. Figure 19.7 shows a contact force, f , contacting the fingertip surface at a location r . A force/torque sensor such as that in Fig. 19.2 measures the moment, $\tau = \mathbf{r} \times \mathbf{f}$ with respect to the origin. If we consider the lever arm, \mathbf{h} , perpendicular to the line of action of \mathbf{f} , then $\mathbf{h}/h = f/f \times \mathbf{r}/\tau$, where $h = \tau/f$ is the magnitude of \mathbf{h} . We can then write that $\mathbf{r} = \mathbf{h} - \alpha\mathbf{f}$, where α is a constant obtained by solving for the intersection of the line of action and the fingertip surface. For a convex fingertip, there will be two such points, of which only one corresponds to a positive (inward) contact force.

Going a couple of steps further, from the contact location one can deduce the local contact normal and contact kinematic type from a small number of force

measurements. *Bicchi* presents algorithms for extending these methods to soft fingers [19.94]. *Brock* and *Chiu* [19.51] describe the use of force sensors for the perception of object shape using this approach, and for measuring the mass and center of mass of a grasped object.

For precision tasks involving small objects or small forces and motions, cutaneous sensors provide the most sensitive measurements. In general, as task requirements get smaller, the sensor must be located closer to the contact so that the compliance and inertia of the intervening parts of the manipulator do not interfere with the measurement. *Dario* [19.95] suggests that fingertip force sensors are useful for forces of 0.1–10.0 N while array sensors can measure distributed forces of 0.01–1.0 N. *Son* et al. [19.11] find that intrinsic tactile sensing and array sensors can both provide accurate (within 1 mm) estimates of contact location; however the intrinsic tactile sensing method is inherently sensitive to the accuracy of the force/torque sensor calibration and can produce transient errors due to unmodeled dynamic forces.

Proceeding down the left side of Fig. 19.6 we come to the large category of cutaneous array sensors. The interpretation of information from array sensors depends initially on the transducer type. For arrays of binary contact or proximity sensors interpretation amounts mainly to establishing the location and general shape of the contact area. Techniques common to binary vision can be used to obtain subpixel resolution and to identify contact features. This information, in combination with measurements of the grasp forces from actuator effort or force/torque sensors, is sufficient for basic manipulation tasks [19.47].

19.2.2 Solid Mechanics and Deconvolution

A basic problem associated with tactile array sensors is to reconstruct what is happening at the surface of the skin from a finite set of measurements obtained beneath the surface. Typically we are interested in determining pressure and perhaps shear stress distributions associated with contacts on the skin. In other cases, as when the fingertips consist of a gel or soft foam covered by a thin membrane so that the pressure is nearly constant, the local geometry of the contact is of interest.

In the following example we consider the case of an array of elements located at a depth d below the surface of an elastomeric skin. A contact has resulted in a pressure distribution over the region of interest. We establish a coordinate system with z pointing in the inward normal direction and, for simplicity, we examine a one-

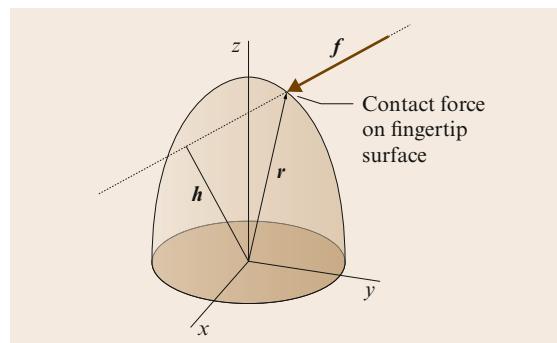

Fig. 19.7 Intrinsic tactile sensing: a contact produces a unique line of action and moment about the origin of a coordinate system in the fingertip. The contact location can be obtained by solving for the intersection of the line of action and the fingertip surface

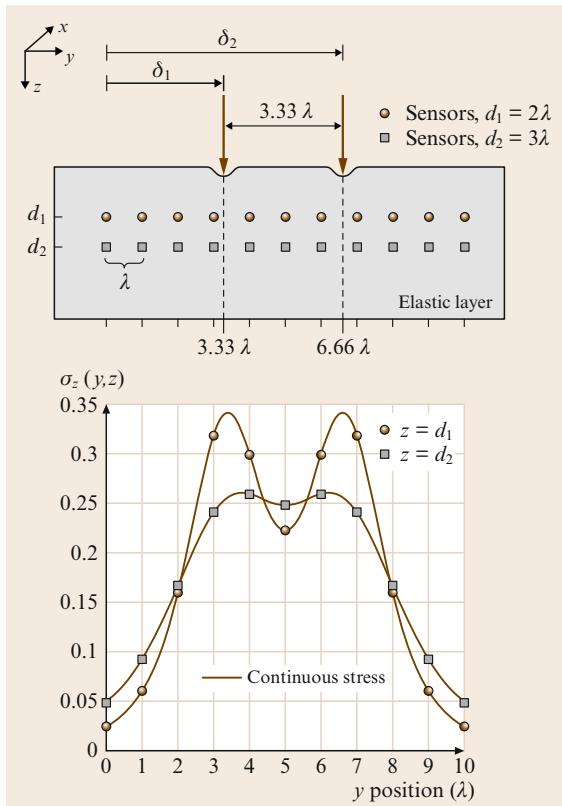

Fig. 19.8 Plane-strain stress response for two (unit-magnitude) line loads. Note the *blurring* that occurs with greater depth

dimensional loading case, $p(y)$, in which the pressure distribution is unchanging in the x -direction. We further assume that the extent of the skin in the x -direction is large compared to the skin thickness so that strains in the x -direction are inhibited, leading to a plane-strain elasticity problem and we assume that the skin is a homogeneous, isotropic material and that the strains are small enough that linear elasticity theory can be applied. Of course, none of these assumptions is entirely valid in practical cases; however, the results do agree qualitatively with the measurements obtained with actual robot fingers and tactile arrays. A thorough discussion of the general approach and of the accuracy of the linear elastic models can be found in [19.22, 79, 96–98].

Figure 19.8 illustrates the case of two line loads, or knife edges, pressed against the surface of the skin (akin to a planar version of the two-point discrimination test for human tactile acuity). The solution for a single line load, or impulse response, was derived by Boussinesq in

1885. For the case of plane strain the principal stresses in the (y, z) -plane from a normal unit impulse can be expressed in Cartesian coordinates as [19.99]:

$$\sigma_z(y, z) = \left(\frac{-2}{\pi z} \right) \frac{1}{[1 + (y/z)^2]^2}, \quad (19.1)$$

$$\sigma_y(y, z) = \left(\frac{-2}{\pi z} \right) \frac{(y/z)^2}{[1 + (y/z)^2]^2}, \quad (19.2)$$

$$\sigma_x(y, z) = v(\sigma_y + \sigma_z), \quad (19.3)$$

where v is Poisson's ratio for the material (typically 0.5 for elastomeric materials).

For two such line loads located at distances δ_1 and δ_2 from the origin, the solution can be obtained by superposition:

$$\sigma_z(y, z) = \left(\frac{-2}{\pi z} \right) \left(\frac{1}{\left[1 + \left(\frac{y-\delta_1}{z} \right)^2 \right]^2} + \frac{1}{\left[1 + \left(\frac{y-\delta_2}{z} \right)^2 \right]^2} \right), \quad (19.4)$$

$$\sigma_y(y, z) = \left(\frac{-2}{\pi z} \right) \left(\frac{\left(\frac{y-\delta_1}{z} \right)^2}{\left[1 + \left(\frac{y-\delta_1}{z} \right)^2 \right]^2} + \frac{\left(\frac{y-\delta_2}{z} \right)^2}{\left[1 + \left(\frac{y-\delta_2}{z} \right)^2 \right]^2} \right). \quad (19.5)$$

For more general pressure distributions the stresses can be found by convolution of the pressure distribution $p(y)$ and the impulse response $G_i(y, z)$:

$$\sigma_i = \int_{\tau=-\infty}^{\tau=y} [p(\tau) d\tau] G_i(y - \tau, z). \quad (19.6)$$

Also plotted in Fig. 19.8 are curves corresponding to the vertical stress components, σ_z , at two different depths, $d_1 = 2\lambda$ and $d_2 = 3\lambda$, where λ is the sensor spacing. As we go deeper beneath the skin, the stresses become smoothed or blurred, and the ability to distinguish between closely spaced impulses diminishes. However, the blurring of concentrated pressure distributions can also provide an advantage when we have a limited number of sensors because the stresses and strains spread over a larger area and are more likely to affect at least one sensor. The elastic skin also provides a kind of automatic *edge enhancement* because stresses are high at the

transitions between loaded and unloaded regions of the skin.

In most cases, for example, in the case of capacitive or magnetic sensors, the sensing elements will measure strains or local deformations of the skin material in the vertical direction. In a few cases, such as pieces of piezoelectric film embedded in an elastomeric skin [19.22], the sensors are sufficiently stiff compared to the surrounding material that they can be considered to measure stresses directly.

For the case of elastic plane strain, the strains are related to the stresses by [19.100]:

$$\epsilon_y = \frac{1}{E} [\sigma_y - \nu(\sigma_x + \sigma_z)], \quad (19.7)$$

$$\epsilon_z = \frac{1}{E} [\sigma_z - \nu(\sigma_x + \sigma_y)], \quad (19.8)$$

where E is the Young's modulus and ν is the Poisson's ratio, which we assume is 0.5 for an elastomeric skin.

Figure 19.9 shows the typical measurements that might be obtained from a row of sensing elements from the two line loads applied in Fig. 19.8. Each bar corresponds to the strain, ϵ_{zi} measured by a corresponding element and computed using (19.8), with stresses obtained from (19.4), (19.5), and (19.3).

The problem at this point is to produce a best estimate of the surface pressure distribution, $p(y)$, from this finite set of subsurface strain measurements. The problem is a classic example of estimating a signal from a sparse set of remote measurements. One approach to this process is based on deconvolution techniques [19.22, 79, 97]. The measured signal from the sensors ϵ_z is convolved with the inverse of the impulse strain response $H(y)$ to find

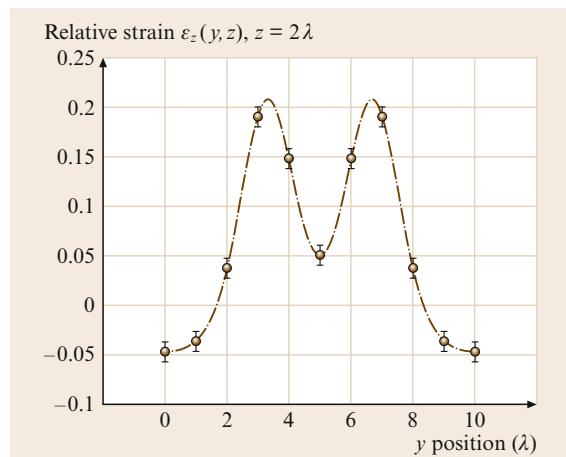

Fig. 19.9 Measured strain with assumed 5% noise

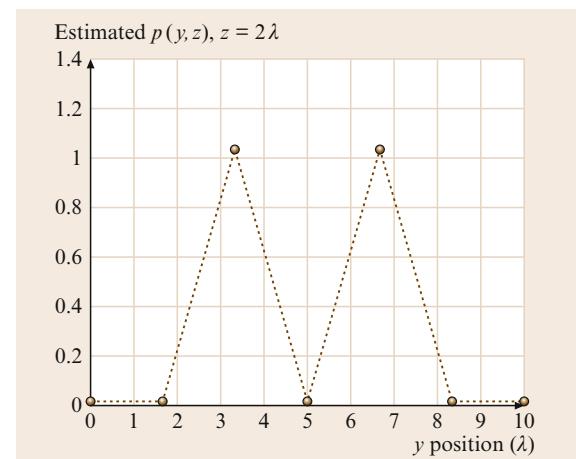

Fig. 19.10 Estimated surface pressure distribution using pseudoinverse method for 11 sensors and seven assumed impulses

an estimate of the surface pressure that produced the signals. The inversion tends to amplify high-frequency noise and the inverse filter bandwidth must be limited according to the spatial density of the sensors and their depth below surface.

Another approach [19.16, 96] is to assume that the surface pressure distribution can be approximated by a finite set of impulses $\mathbf{p} = [p_1, p_2 \dots p_n]^t$. The sensor readings form a vector, $\boldsymbol{\epsilon} = [\epsilon_1, \epsilon_2 \dots \epsilon_m]^t$, where $m > n$ for the bandwidth limitations discussed above. The strain response can then be written as a matrix equation

$$\boldsymbol{\epsilon} = H\mathbf{p}. \quad (19.9)$$

Each element of H is computed using (19.8) with σ_z and σ_y computed using equations similar to (19.4) and (19.5), and with σ_x from (19.3). The estimated discrete pressure distribution is then found by taking the pseudoinverse of H :

$$\hat{\mathbf{p}} = H^+ \boldsymbol{\epsilon}. \quad (19.10)$$

Using the strain measurements from Fig. 19.9, at a depth $d = 2\lambda$, the estimated pressure distribution using the pseudoinverse method is seen in Fig. 19.10. In this example, because the assumed set of seven impulses matches fortuitously with the actual loading, the reconstruction is fairly accurate despite the assumed 5% noise.

An alternative approach to constructing soft robot finger tips is to enclose a compliant medium such as

foam rubber or fluid in a thin elastic membrane [19.18, 80, 84, 101–104]. Some of the tactile array sensors developed for these fingers are able to measure directly the shape of the membrane, so that a physical model is not needed for interpretation of the signal [19.18]. Another sensing scheme uses an array of magnetic sensors at the center of the finger to measure the changes in the magnetic field generated by deformations of the magnet-loaded membrane [19.104]. A statistical algorithm that can robustly determine the membrane shape from the sensor signals has been developed [19.18]. However, a mechanical model is still required to find the pressure distribution across the contact from the shape information provided by all of these sensors.

19.2.3 Curvature and Shape Information

Another alternative to measuring subsurface strains or deflections is to measure directly the local curvature at each element of an array of sensors [19.105, 106]. The curvature information can be applied directly toward identifying contact type and centroid location or it can be integrated to obtain the local shape of the contact as with sensors just described that measure the profile of a membrane. To reduce the effects of noise it is useful to assume a simple model for the membrane and use basis functions to fit the curvature data before integrating [19.20].

Returning to Fig. 19.6, once the local contact shape or geometry has been established the next steps typically include feature identification (e.g., identifying corners or ridges on an object) and determining the overall shape and pose of the object in the hand.

Often the object shape is at least partially known a priori, in which case a variety of surface or data fitting methods can be used, for example, *Fearing* [19.107] developed a method for calculation of the radius of curvature and orientation of generalized cylinders from tactile array data and [19.108] developed a neural network that performs a similar calculation. Other schemes use contact locations, surface normals, and contact forces to determine information about object shape and orientation with respect to the hand [19.109–112].

Allen [19.113] uses several different primitive representations for object shape attributes based on the particular exploratory procedure used to sense the object. Object volume and approximate shape are perceived with enclosure grasping, and the resulting shape is modeled using superquadric surfaces. Similarly, measurement of the lateral extent of object faces leads to

a face–edge–vertex model and contour following to a generalized cylinder representation.

The question of what constitutes an appropriate set of features is not well understood, although it clearly depends upon the intended application. *Ellis* [19.69] considers appropriate feature sets and methodologies for acquiring the needed data. *Lederman* and *Browse* [19.114] suggest that surface roughness, surface curvature, and oriented edges are used in human haptic perception.

19.2.4 Object and Surface Identification

The most common application of touch information has been in object recognition and classification. In object recognition the goal is to identify one object from a set of known objects using information derived from touch. In classification the goal is to categorize objects according to preselected sensed properties. These systems are usually based on geometric information derived from tactile array or force sensors. Recently the use of other types of touch information (e.g., compliance, texture, thermal properties) in exploration and identification has received some attention [19.115–117].

A number of systems have used statistical pattern recognition, which can improve noise immunity since only statistics derived from the sensed data are used. Unfortunately, this also means that only a few object types can be discriminated. Systems have been based on the statistics of tactile array sensor data [19.118, 119], and on the statistics of finger joint angles while grasping the object [19.120–122].

Many different features derived from tactile array data have been used for model-based recognition and classification. Systems have used geometric features such as holes, edges, and corners [19.105, 114, 123] and object surfaces [19.124]. Other feature sets include geometric moments [19.125, 126], linear transforms [19.127], and sequences of surface tangents [19.128]. *Gaston* and *Lozano-Perez* [19.110] use local surface normals and contact locations as features, which could be derived from array, force, or joint sensor information. *Siegel* [19.129] presents a method for finding the pose of a known object grasped in a robot hand from measurements of the finger joint angles and torques.

19.2.5 Active Sensing Strategies

Because touch provides only local information, movement is an integral part of touch sensing for recognition

and exploration. Several workers in object recognition applications have developed strategies for scheduling sensor movements so that each additional observation decreases the number of objects which are consistent with prior observations. This is sometimes described as a *hypothesize and test* approach. Early examples include *Gurfinkel et al.* [19.105] and *Hillis* [19.123]. *Schneiter* [19.111], *Grimson* and *Lozano-Perez* [19.109], and *Ellis* [19.130] and *Cameron* [19.131] have developed algorithms for scheduling sensor moves to rapidly recognize polygonal objects using touch measurements of contact location and local surface normal. In Schneiter's scheme, each sensing move should cross the boundary of the intersection of all objects consistent with previous sensor observations. *Yap* and *Cole* [19.112] show that a probing strategy to determine the shape of a convex planar polygon with V vertices requires at least $3V - 1$ measurements. *Roberts* [19.132] proposes a movement strategy for recognition that includes tracing the robot finger along object surfaces and edges, rather than moving the finger through free space between readings.

In non-model-based approaches, *Klatzky et al.* [19.117] have suggested that robotics systems can employ the same exploratory procedures used by humans in haptic exploration. These procedures prescribe the finger motions needed for tasks such as tracing object contours, measuring compliance, and determining the lateral extent of object surfaces. *Stansfield* [19.116,133] and *Allen* [19.113] have implemented some of these exploratory procedures using multifingered robot hands with tactile array sensors. *Dario et al.* [19.134] have created similar *tactile subroutines*, which they have used in a number interesting applications, including the detection of hardened lumps (e.g., tumors) beneath a compliant surface. *Kaneko* and *Tanie* [19.45] describe a method for using small finger motions to find the location of finger-object contacts without distributed tactile sensors.

Edge tracking and surface following have also received considerable attention. *Muthukrishnan et al.* [19.135] look at edge finding algorithms for matching segments between successive tactile array impressions. *Berger* and *Khosla* [19.136] have demonstrated curved edge tracking in real time using tactile array information. *Pribadi et al.* [19.137] propose a control strategy for tracking an unknown object surface using tactile information, and *Bay* [19.138] designs a surface shape estimator for exploration by a multi-

fingered hand which uses contact location and surface normal information from a force sensor. *Zhang* and *Chen* [19.139] present an approach to *tactile servoing* in which they model the contact between a compliant tactile sensor and an object to obtain a tactile Jacobian, which is used to produce incremental motion commands for a manipulator. They demonstrate the approach for rolling contact and edge tracking tasks.

In practice, surface following and manipulation are often combined. *Okamura* and *Cutkosky* [19.140] present an approach in which a rounded fingertip equipped with a tactile sensor is used to trace object surfaces and locate features, which are defined as regions having local curvature that is high in comparison to that of the fingertip.

19.2.6 Dynamic Sensing and Event Detection

For dynamic tactile sensors used to detect such events as gentle contacts or slippage between the fingertips and an object, the main challenge is to detect the event in question reliably, without false positives. The dynamic tactile sensors that produce large signals in response to contact events are also prone to producing large signals in response to vibrations from the robot drive train and to rapid accelerations of the robot hand. Solutions for more robustly detecting contact events include comparing the signals from dynamic tactile sensors at and away from the contact regions and statistical pattern recognition methods to identify the *signature* of true contact events [19.65,68,93].

19.2.7 Integration of Thermal and Other Sensors

Sensors such as thermal contact sensors are rarely used in isolation; their signals are generally integrated with those from tactile arrays and other sensors to produce additional information for identifying objects. For example, *Dario et al.* [19.141] demonstrate an approach in which a thermal contact sensor is used in combination with a tactile pressure sensing array and a dynamic tactile sensor used to characterize surface roughness, for discriminating among different objects. Different exploratory procedures, inspired by those used by humans [19.142] are called upon to resolve ambiguities.

19.3 Integration Challenges

A critical problem that we have not yet addressed is the difficulty of connecting to a large and diverse array of tactile sensors. In 1987 *Jacobsen et al.* [19.143] cited the routing of wires as perhaps the most difficult problem in dexterous hand design and, to a large extent, this remains true today. However, some solutions to this problem have been presented in recent years by either using wireless sensors or by use of clever bussing for power and signal connections. *Shinoda and Oasa* [19.144] embed tiny wireless sensing elements in an elastic skin that uses an inductive base coil to provide power and signal transmission. Each sensing element is a tuned resonator with a distinct resonant frequency whose resonant frequency is stress sensitive.

Yamada et al. [19.148] use wireless sensor chips that use light transmitted through a transparent elastomer both for power and to communicate six stress components to a power-receiver chip positioned safely beneath the skin's surface. *Hakozaki and Shinoda* [19.145] embed tactile sensor chips between two layers of conductive rubber that serve to provide means for power as well as a bussed serial communication, thus eliminating discrete wiring. The shrinking dimensions of microprocessors also make it possible to mount devices for multiplexing, signal conditioning, etc. in the immediate proximity of the sensors, thereby reducing the amount of raw information that must be relayed back to the robot.

19.4 Conclusions and Future Developments

In comparison to computer vision, tactile sensing always seems to be *a few years away* from widespread adoption. As explained in the introduction to this chapter, the reasons include physical problems (placement and robustness of sensors, wiring challenges) and the diversity of sensor types for detecting forces, pressures, local geometries, vibrations, etc. As we have seen, the transduction and interpretation methods are typically different for each of these tactile quantities. However, there are some basic issues that apply to tactile sensing in general; for example, sensors are generally located within or beneath a compliant skin, which affects the quantities that they sense in comparison to pressures, stresses, thermal gradients or displacements applied to the skin surface.

When choosing tactile sensors for a robot arm or hand, it is effective to begin with a consideration of which tactile quantities are most desired and for what purpose; for example, the main concern is to obtain accurate measurements of loads or contact forces at sufficient

data rates for force servoing, then intrinsic tactile sensing may make the most sense. If manipulating objects with soft contacts and with sliding or rolling, curved array sensors for measuring pressure distributions, or perhaps local skin deflections, may be desirable. If exploring objects to learn about their texture and material composition, dynamic tactile sensors and thermal sensors may be effective.

In an ideal world, one would incorporate all these tactile sensors in a robotic end-effector without regard to cost, signal processing or wiring complexity. Fortunately, the cost and size of transducers suitable for tactile sensing are steadily dropping and the ability to perform localized processing is improving with surface-mounted devices on flexible circuits. In the near future it will be increasingly possible to fabricate dense arrays of transducers in situ on contoured surfaces, using material deposition and laser machining techniques. In this way, robots may finally start to approach the tactile sensitivity and responsiveness of the simplest of animals.

Inertial Sensors

Gregory Dudek, Michael Jenkin

Part C | 20

This chapter examines how certain properties of the world can be exploited in order for a robot or other device to develop a model of its own motion or pose (position and orientation) relative to an external frame of reference. Although this is a critical problem for many autonomous robotic systems, the problem of establishing and maintaining an orientation or position estimate of a mobile agent has a long history in terrestrial navigation.

20.1 Odometry

The word *odometry* is a contraction of the Greek words *hodos* meaning *travel* or *journey*, and *metron* meaning *measure*. Given its importance to a wide variety of applications from civil engineering to military conquest, the basic concepts that underly odometry haven been studied for over 2000 years. Perhaps the earliest reference to odometry appears in the *Ten Books on Architecture* by Vitruvius, in which he describes *a useful invention of the greatest ingenuity, transmitted by our predecessors, which enables us, while sitting in a carriage on the road or sailing by sea, to know how many miles of a journey we have accomplished* [20.1]. In the context of autonomous vehicles, odometry usually refers to the use of data from the actuators (wheels, treads, etc.) to estimate the overall motion of the vehicle. The basic concept [20.2] is to develop a mathematical model of how selected motions of the vehicle's wheels, joints, etc. induce motion of the vehicle itself, and then to integrate these specified motions over time in order to develop a model of the pose of the vehicle as a function of time.

The use of odometry information to estimate the pose of the vehicle as a function of time is known as *dead reckoning*.

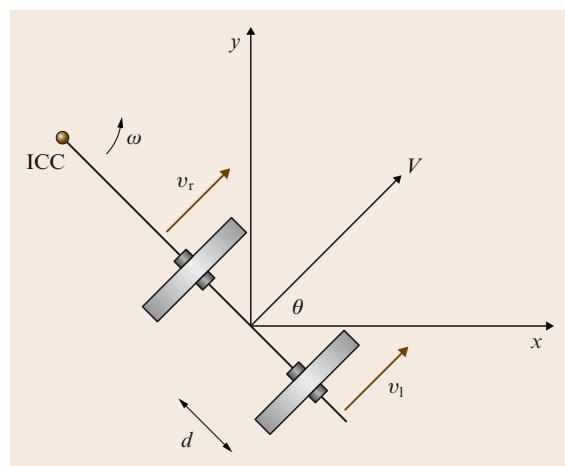

Fig. 20.1 Differential drive kinematics

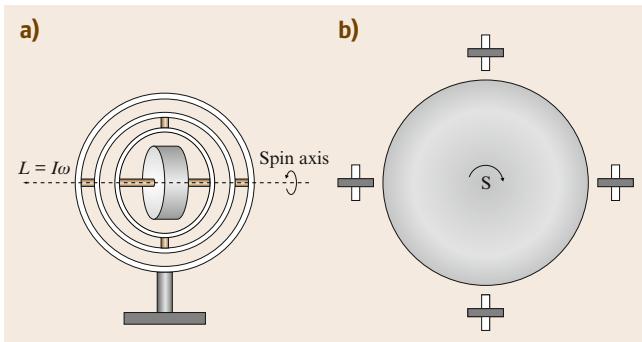

Fig. 20.2a,b Mechanical gyroscope. (a) Traditionally gimballed gyroscope. The gimbals provide the gyroscope the freedom to rotate about its axis as the base of the gyroscope is rotated. (b) A gyroscope as it is rotated around the planet. The wheel of the gyroscope (grey) remains in the same orientation as it revolves with the planet. To an observer on the planet the gyroscope will appear to rotate

onning or deductive reckoning and finds wide application in navigation at sea [20.3].

The details of odometry estimation varies by vehicle design. In the context of mobile robots perhaps the simplest vehicle for odometry estimation is the differential drive vehicle (Fig. 20.1). A differential drive vehicle has two driveable wheels which are independently controllable and which are mounted along a common axis. Assuming that the location of the wheels are fixed on the vehicle, then for the wheels to remain in constant contact with the ground, the two wheels must describe arcs on the plane such that the vehicle rotates around a point

(known as the ICC – instantaneous center of curvature) that lies on the wheels' common axis (Fig. 20.1). If the ground contact speeds of the left and right wheels are v_l and v_r respectively, and the wheels are separated by a distance $2d$, then

$$\begin{aligned}\omega(R + d) &= v_l \\ \omega(R - d) &= v_r.\end{aligned}$$

We can rearrange these two equations to solve for ω the rate of rotation about the ICC and R the distance from the center of the robot to the ICC

$$\begin{aligned}\omega &= \frac{(v_l - v_r)}{(2d)}, \\ R &= d \frac{(v_r + v_l)}{(v_l - v_r)}.\end{aligned}$$

The instantaneous velocity of the point midway between the robot's wheels is given by $V = \omega R$.

Now as v_l and v_r are functions of time we can generate a set of equations of motion for the differential drive robot. Using the point midway between the wheels as the origin of the robot, and writing θ as the orientation of the robot with respect to the x -axis of a global Cartesian coordinate system, one obtains

$$\begin{aligned}x(t) &= \int V(t) \cos(\theta(t)) dt, \\ y(t) &= \int V(t) \sin(\theta(t)) dt, \\ \theta(t) &= \int \omega(t) dt.\end{aligned}$$

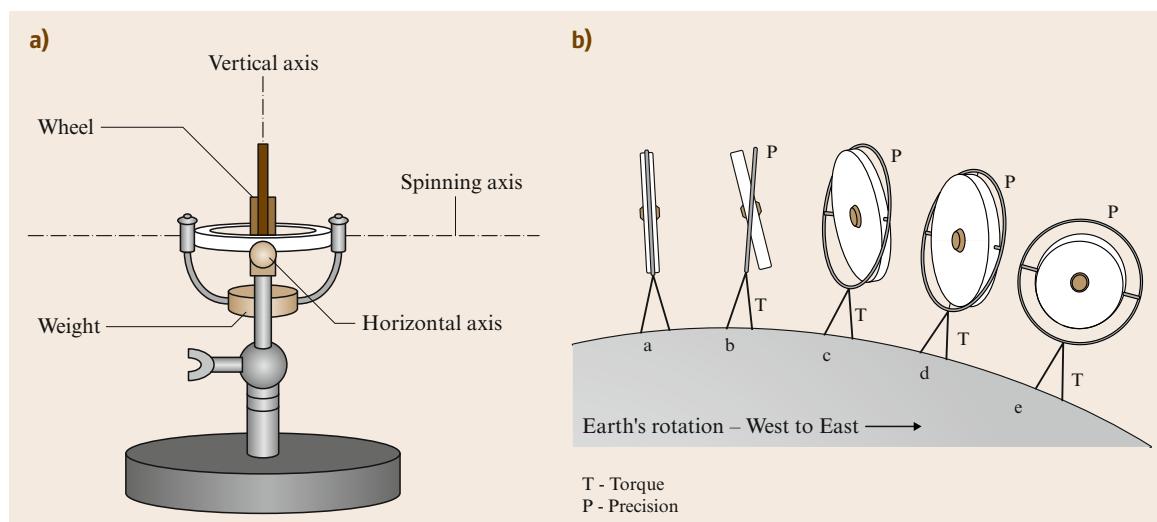

Fig. 20.3a,b Simple gyrocompass. (a) Pendulus gyro. (b) Precessional motion

This is the solution for the odometry of a differential drive vehicle on the plane. Given the control inputs (v_l and v_r) and some initial state estimate, we can estimate the state of an idealized robot using this motion model at any time t .

Given such a model and complete knowledge of the control inputs, we should, in principle, be able to estimate a robot's pose at any time. In a perfect world this would be all that is necessary to estimate accurately the robot's pose at any time in the future. Unfortunately errors in the modeling (incorrect estimations of wheel size, vehicle size), uncertainty about the control inputs, realities of the motor controller (errors between commanded wheel rotation and true rotation), errors in the physical modeling of the robot (wheel compaction, ground

compaction, wheel slippage, nonzero tire width), etc., introduce an error between the dead reckoning estimate of the vehicle motion and its true motion. The problem of correcting for this error is the problem of *pose maintenance* for the vehicle, and requires the integration of the dead reckoning estimate with estimates obtained from other sensor systems.

Other chapters in this handbook (e.g., Chaps. 21–24) examine sensors that rely on external events, visual and otherwise, that can provide information as to the robot's pose or changes in its pose. Here we consider sensors that transduce physical properties of matter under the influence of external forces and properties of matter and the use of a global position system (GPS).

20.2 Gyroscopic Systems

The goal of gyroscopic systems is to measure changes in vehicle orientation by taking advantage of physical laws that produce predictable effects under rotation. A rotating frame is not an inertial frame, and thus many physical systems will appear to behave in an apparently *non-Newtonian* manner. By measuring these deviations from what would be expected in a Newtonian frame the underlying self-rotation can be extracted.

20.2.1 Mechanical Systems

Mechanical gyroscopes and gyrocompasses have a long history in navigation. *Bohnenberger* is generally credited with the first recorded construction of a gyroscope [20.4], and in 1851 Léon Foucault recognized the gyroscope as an inertial frame. The gyrocompass was patented in 1885 by Martinus Gerardus van den Bos. In 1903 Herman Anschütz-Kaempfe constructed a working gyrocompass and obtained a patent on the design. In 1908 Elmer Sperry patented a gyrocompass in the US and then attempted to sell this device to the German Navy. A patent battle followed, and Albert Einstein testified in the case. (See [20.5–8] for more details on the history of the gyrocompass and its inventors.)

Gyroscopes and gyrocompasses rely on the principle of the conservation of angular momentum [20.9]. Angular momentum is the tendency of a rotating object to keep rotating at the same angular speed about the same axis of rotation in the absence of an external torque. The angular momentum \mathbf{L} of an object with moment of

inertia \mathbf{I} rotating at angular speed $\boldsymbol{\omega}$ is given by

$$\mathbf{L} = \mathbf{I} \times \boldsymbol{\omega}.$$

Consider a rapidly spinning wheel mounted on a shaft so that it is free to change its axis of rotation (Fig. 20.2a). Assuming no friction due to air resistance or the bearings, the rotor axis will remain constant regardless of the motion of the external cage. This constancy of orientation can be exploited to maintain a bearing independently of the motion of the vehicle, although it is not usually desirable to use the principle of conservation of angular momentum via a gyroscope directly. To see this, suppose that a gyroscope is set on the equator, with its spinning axis aligned along the equator (Fig. 20.2b). As the Earth spins, the gyroscope will maintain a constant axis of orientation and thus to an Earth-fixed observer will appear to rotate, returning to its original orientation every 24 h. Similarly, if the gyroscope were to be positioned on the equator such that its spinning axis was parallel to the axis of rotation of the earth, the gyroscope's axis of rotation would remain stationary and would appear to remain stationary to an Earth-fixed observer as the planet rotates.

Although this global motion limits the mechanical gyroscope's ability to sense absolute orientation directly, gyroscopes can be used to measure local changes in orientation, and thus are well suited to vehicular robotic applications. Rate gyros (RGs) measure a vehicle's rotation rate (its *angular rate* of rotation). This is the fundamental measurement that is the basis of all gyroscopic systems. Rate-integrating

gyros (RIGs) use embedded processing to internally integrate the angular rotation rate to produce an estimate of the absolute angular displacement of the vehicle.

In order to exploit a gyroscope for navigation with respect to an Earth-stable frame, it is desirable for the rotational axis of the shaft to remain fixed within the Earth frame, rather than remaining fixed with respect to an external frame. A gyrocompass obtains this by relying on precession. When a torque is applied to change the axis of rotation of a spinning object, conservation of angular momentum will cause a change in the spin direction that is perpendicular to the angular momentum and the direction in which the torque is applied. This is the effect that causes gyroscopes suspended at one end to *spin* around the end from which they have been suspended. Consider the *pendulus gyro* sketched in Fig. 20.3a. This is a standard gyroscope with a weight suspended below the rotational axis. As before, imagine this pendulus gyrocompass set spinning on the equator with the axis of rotation aligned with the axis of rotation of the planet, and with the weight hanging directly down. As the planet spins, the gyroscope's axis of rotation remains stationary and would appear to remain stationary as the planet rotates. Now suppose that instead of being aligned with the spin axis of the planet the spin axis is aligned with the equator. As the planet spins, the spin axis is drawn out of the plane as it remains aligned with the original spin axis. As it becomes drawn out of the plane, the mass hanging below the gyrocompass is raised up and generates a torque down due to gravity. The direction perpendicular to the spin axis and the torque rotates the spin axis away from the equator known and towards the true pole. This process is sketched in Fig. 20.3b.

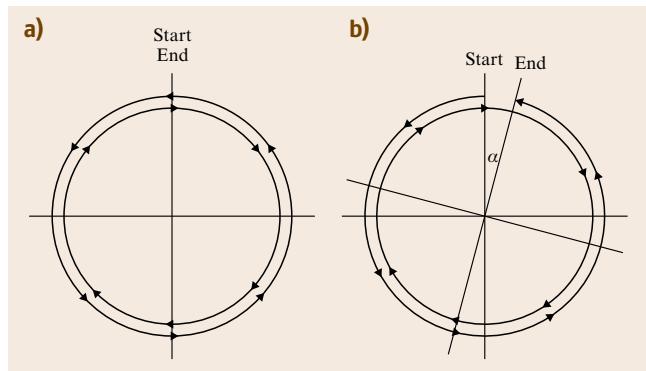

Fig. 20.4a,b Circular light path. (a) Stationary path. (b) Moving path

Unfortunately the pendulus gyro is not an ideal device for navigation. Although its rotation axis will align with the rotation axis of the planet, it does not converge to this value directly but oscillates about it. The solution to this damping problem is to use oil reservoirs, rather than a solid weight, as the counterbalance, and to restrict the motion of the oil in the reservoir [20.10].

The gyrocompass finds true north by controlling the precession of a gyroscope. In practice, the performance of a mechanical gyrocompass is impacted by external forces acting on the compass which also contribute to the precession of the gyroscope. This includes forces generated by motion of the device containing the gyrocompass, as well as any external forces acting on the vehicle. Another issue for mechanical gyrocompasses is that in latitudes away from the equator the stable position of the gyrocompass is not horizontal, and accurate estimates of true north at such latitudes requires corrections to be applied to raw gyrocompass values. Finally, mechanical gyrocompasses require an external force to be applied to maintain the spin of the gyroscope. This process introduces unwanted forces into the system which can further corrupt the measurement process.

Given the complexity, cost, size, the delicate nature of gyrocompasses, and the availability of less expensive and more reliable technologies, mechanical gyrocompasses have given way to optical- and micro-electromechanical systems (MEMS)-based systems.

20.2.2 Optical Systems

Optical gyroscopes rely on the *Sagnac effect* rather than rotational inertia in order to measure (relative) heading. The mechanism is based on the behavior of an optical standing wave in a rotating frame. Historically this was first produced using lasers and an arrangement of mirrors, but it is now typically obtained using fibre-optic technology. The Sagnac effect is named after its discoverer Georges Sagnac [20.11, 12]. The underlying concept can be traced back even earlier to the work of Harriss [20.13], and perhaps finds its most famous application in terms of the measurement of the rotation of the Earth [20.14].

Ignore relativistic effects and consider the circular light path shown in Fig. 20.4a. If two light pulses are sent in opposite directions around a stationary path of perimeter $D = 2\pi R$ they will travel the same distance at the same speed. They will arrive at the starting point simultaneously, taking time $t = D/c$ (where c is the speed of light in the medium). Now let us suppose that instead of being stationary, this circular light path rotates clockwise

about its center at rotational speed ω (Fig. 20.4b). The light traveling clockwise around the path must go *farther* to reach the starting point, while light traveling counterclockwise around the path goes a *shorter* distance. The clockwise path has distance $D_c = 2\pi R + \omega R t_c$, where t_c is the time taken in the clockwise direction, while the counterclockwise path has distance $D_a = 2\pi R - \omega R t_a$, where t_a is the time taken in the counterclockwise direction. But $D_c = c t_c$ and $D_a = c t_a$, so $t_c = 2\pi R / (c - \omega R)$ and $t_a = 2\pi R / (c + \omega R)$. The time difference $\Delta t = t_c - t_a$ is given by

$$\Delta t = 2\pi R \left(\frac{1}{c - \omega R} - \frac{1}{c + \omega R} \right).$$

By measuring Δt , the rotational speed can be computed. Note that, although the above derivation assumes classical mechanics and ignores relativistic effects, the derivation also applies when relativistic speeds are taken into account [20.15]. See [20.16] for an in-depth review of the Sagnac effect and ring lasers.

In optical gyroscopes lasers are typically used as the light source. Optical gyroscopes either employ straight-line light paths with mirror surfaces or prisms at the edges to direct the light beam (a ring laser gyroscope – **RLG**), or a polarization maintaining glass-fiber loop (fiber optic gyro – **FOG**). The glass fiber may actually loop multiple times, thus extending the effective length of the light path. The time delay between the clockwise and counterclockwise directions is detected by examining the phase interference between the clockwise and counterclockwise light signals. Multiple optical gyroscopes with nonparallel axes can be ganged together in order to measure three-dimensional (3-D) rotations.

Various techniques can be used to measure the time difference between the two paths, including examining the Doppler (frequency) shift of the laser light due to the motion of the gyro and an examination of the beat frequency of the interference pattern between the clockwise and counterclockwise paths [20.17]. Ring interferometers typically consist of many windings of fiber-optic lines that conduct light of a fixed frequency in opposite directions around the loop and measure the phase difference. A ring laser consists of a laser cavity in the shape of a ring. Light circulates in both directions around this cavity, producing two standing waves with the same number of nodes in both directions. Since the optical path lengths are different in the two directions, the resonant frequencies differ. The difference between these two frequencies is measured. An unfortunate side-effect of the ring-laser approach is that the two signals will

lock in to each other for small rotations and it is typically necessary to physically rotate the device in a controlled manner in order to ensure that this lock-in effect can be avoided.

20.2.3 MEMS

Almost all micro-electromechanical systems (**MEMS**) gyroscopes are based on vibrating mechanical elements to sense rotation. Vibratory gyroscopes rely on the transfer of energy between vibratory modes based on Coriolis acceleration. Coriolis acceleration is the apparent acceleration that arises in a rotating frame of references. Suppose that an object moves along a straight line in a rotating frame of reference. To an outside observer in an inertial frame the object's path is curved – thus there must be some force acting on the object to maintain the straight line motion as viewed by the rotating observer. An object moving in a straight line with local velocity \mathbf{v} in a frame rotating at rate $\boldsymbol{\Omega}$ relative to an inertial frame will experience a Coriolis acceleration given by

$$\mathbf{a} = 2\mathbf{v} \times \boldsymbol{\Omega}.$$

Transducing acceleration in a **MEMS** gyroscope amounts to inducing some local linear velocity and measuring the resultant Coriolis forces.

Early **MEMS** gyroscopes utilized vibrating quartz crystals to generate the necessary linear motion. More recent designs have replaced the vibrating quartz crystals with silicon-based vibrators. Various **MEMS** structures have been developed including those described below.

Tuning-Fork Gyroscopes

Tuning-fork gyroscopes use a tuning-fork-like structure (Fig. 20.5) as the underlying mechanism. As the tuning forks vibrate within a rotating frame, Coriolis forces cause the tines of the fork to vibrate out of the plane of the fork, which is measured. This is the effect used by the InertiaCube sensor [20.18].

Vibrating Wheel Gyroscopes

Vibrating wheel gyroscopes use a wheel that oscillates about its rotational axis. External rotation of the frame causes the wheel to tilt, which can be sensed.

Wine-Glass Resonator Gyroscopes

Wine-glass resonator gyroscopes use the effect of Coriolis forces on the position of nodal points on a resonating structure to estimate the external rotation.

As **MEMS** gyroscopes have no rotating parts, have low-power consumption requirements, and are very

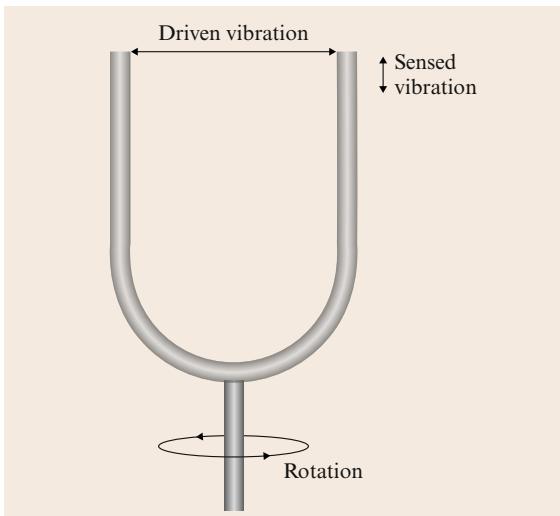

Fig. 20.5 MEMS gyroscope: principle of operation

small, **MEMS** gyros are quickly replacing mechanical and optical gyroscope sensors in robotic applications.

20.2.4 Performance

Inertial measurement units can be evaluated with respect to various factors that determine performance, several of which are enumerated below.

1. Bias repeatability. This is the maximum deviation of the gyroscope under fixed inertial operation conditions with constant temperature, i.e., the drift of the reading under ideal conditions. This is measured over different time scales and leads to *short-term* and *long-term* bias repeatability.
2. Angle random walk. This measures the noise in the angular rate data coming from the gyro.

3. Scale factor ratio. This parameter is not specific to inertial measurement units (**IMUs**) or gyros and is a general measurement of signal amplitude. It measures the ratio of the output analogue voltage to the sensor parameter of interest. For a gyroscope this is typically measured in mV/(deg/sec) whereas for an accelerometer it is typically measured in mV/(m/s²).

20.2.5 Summary

With the exception of gyrocompasses, gyroscopes measure relative rotational motion around a single axis. They accomplish this measurement by exploiting physical properties of rotating frames of reference. Earlier technologies based on mechanical gyroscopes have given way to optical- and **MEMS**-based devices but the underlying principle remains unchanged: that rotating frames of reference show specific physical properties that can be measured to estimate the relative rotation.

A problem common to all gyroscopes is that of drift. Each of the relative motion measurements is corrupted by an error process, and these errors accumulate over time. This, coupled with specific measurement errors associated with the individual gyroscope technologies, means that unless the error is corrected through reference to some alternate (external) measurement, the drift will eventually exceed the required accuracy of the measurement.

As individual gyros only measure rotation about a single axis, it is common to gang multiple gyros together with orthogonal axes of sensitivity in order to measure 3-D rotations. These collections of gyros are often integrated with other sensors (compasses, accelerometers, etc.) in order to construct *inertial measurement units* (or **IMUs**). This is considered in Sect. 20.4.

20.3 Accelerometers

Just as gyroscopes can be used to measure changes in orientation of a robot, other inertial sensors – known as *accelerometers* – can be used to measure external forces acting on the vehicle. One important factor concerning accelerometers is that they are sensitive to all external forces acting upon them – including gravity. Accelerometers use one of a number of different mechanisms

to transduce external forces into a computer-readable signal.

Mechanical Accelerometer

A mechanical accelerometer (Fig. 20.6a) is essentially a spring–mass–damper system with some mechanism for external monitoring. When some force is applied

(e.g., gravity), the force acts on the mass and displaces the spring. Assuming an ideal spring with a force proportional to its displacement, the external forces balance the internal ones

$$\begin{aligned} F_{\text{applied}} &= F_{\text{inertial}} + F_{\text{damping}} + F_{\text{spring}} \\ &= m\ddot{x} + c\dot{x} + kx , \end{aligned}$$

where c is the damping coefficient. This equation can be solved to show that, depending on the size of the damping coefficient relative to the expected external force and the mass, the system can be made to reach a stable final value in a reasonably short period of time whenever a static force is presented. This need to pre-estimate the expected force and the resulting (potentially long) time for the system to converge on a final measurement coupled with nonideal performance of the spring limits the applicability of mechanical accelerometers. Another issue with mechanical accelerometers is that they are particularly sensitive to vibration.

Piezoelectric Accelerometer

Rather than relying on a direct mechanical measurement of external forces, piezoelectric accelerometers are based on a property exhibited by certain crystals, across which a voltage is generated when they are stressed. A small mass can be positioned so that it is only sup-

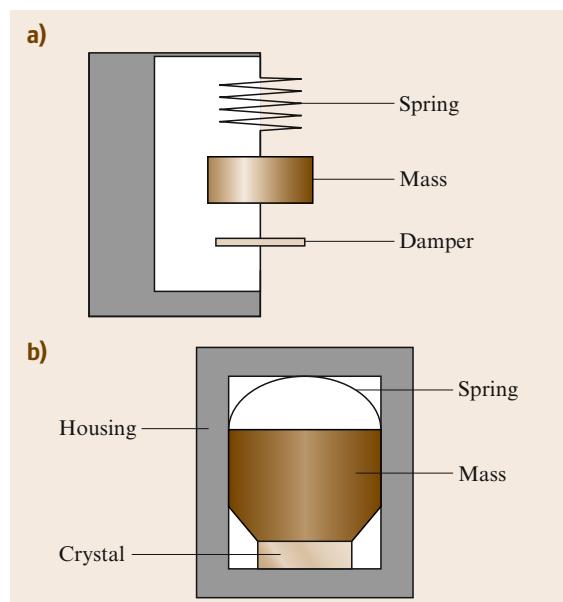

Fig. 20.6a,b Accelerometers. (a) Mechanical accelerometer. (b) Piezoelectric accelerometer

ported by the crystal, and as forces cause the mass to act upon the crystal this induces a voltage that can be measured (Fig. 20.6(b)).

20.4 IMU Packages

An inertial measurement unit (**IMU**) is a device that utilizes measurement systems such as gyroscopes and accelerometers to estimate the relative position, velocity, and acceleration of a vehicle in motion. The resulting navigation system is known as an inertial navigation system or **INS**. First demonstrated in 1949 by C. S. Draper, **IMUs** have become a common navigational component of aircraft and ships. Historically an **IMU** is self-contained and provides this estimate without reference to external references, however the definition has become less precise in recent years and now it is common to apply the term **IMU** also to systems that do include such external references.

IMUs come in two basic flavors, gimbaled systems and strap-down systems. As their name suggests, gimbaled **IMUs** are mounted within complex gimbal structures in order to provide a stable platform from which measurements can be made. Gyroscopes are used to ensure that the gimbal remains aligned with the initial reference frame at power up. The orienta-

tion of the gimbaled platform relative to the vehicle is used to map measurements taken within the **IMU** to the reference frame of the vehicle. Strap-down **IMUs**, on the other hand, have the **IMU** rigidly connected to the vehicle (strapped down), so no such transformation is required. In either case estimating the motion relative to the initial frame requires integrating information from the sensors within the **IMU** (accelerometers, gyroscopes, etc.) in real time. This was a significant computational effort in the early days of **IMUs**, and thus historically (prior to the 1970s) the gimbaled **IMU** was more common. Given the low cost of such computation today, and the costs associated with manufacturing and operating gimbaled **IMUs**, strap-down **IMUs** are much more common today [20.19].

A true **IMU** maintains a 6-degree-of-freedom (**DOF**) estimate of the pose of the vehicle: position (x, y, z) and orientation (roll, pitch, yaw). **IMU**-like systems that (for example) only maintain ongoing estimates of orientation

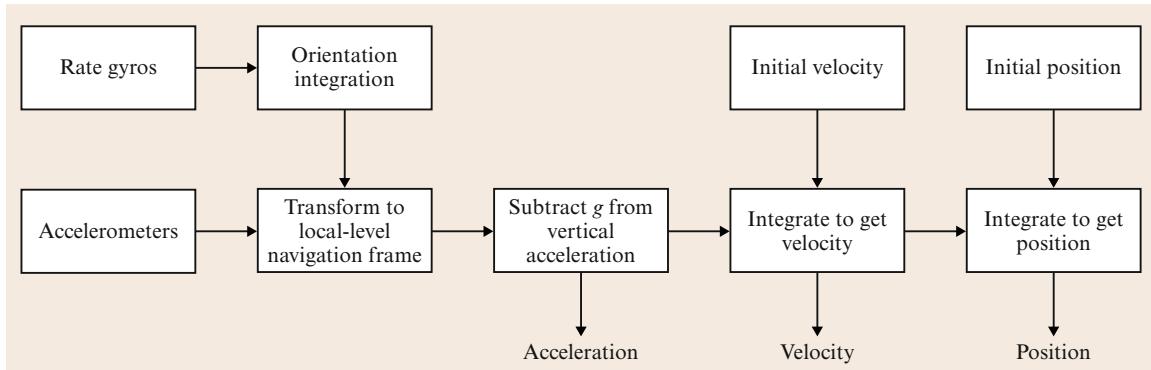

Fig. 20.7 IMU block diagram

are known as *attitude and heading reference systems*, and operate in a similar fashion as IMUs but maintain a less full representation of the vehicle's state. In addition to maintaining a 6-DOF pose of the vehicle, commercial IMUs also typically maintain estimates of velocity and acceleration.

The basic computational task of an IMU is shown in Fig. 20.7. This IMU uses three orthogonal accelerometers and three orthogonal gyroscopes. The gyroscope data ω is integrated to maintain an ongoing estimate of vehicle orientation θ . At the same time, three accelerometers are used to estimate the instantaneous vehicle acceleration a . This data is then transformed via the current estimate of the vehicle orientation relative to gravity, so that the gravity vector can be estimated and extracted from the measurement. The resulting acceler-

ation is then integrated to obtain vehicle velocity v and then integrated again to obtain the position r .

IMUs are extremely sensitive to measurement errors in the underlying gyroscopes and accelerometers. Drift in the gyroscopes leads to misestimates of the vehicle orientation relative to gravity, resulting in incorrect cancellation of the gravity vector. As the accelerometer data is integrated twice, any residual gravity vector will result in a quadratic error in position [20.18]. As it is never possible to eliminate the gravity vector completely, and this and any other error is integrated over time, drift is a fundamental issue for any IMU. Given a sufficiently long period of operation all IMUs eventually drift and reference to some external measurement is required to correct this. For many field robots GPS has become an effective source for these external corrections.

20.5 GPS

The global positioning system (GPS) is the single most commonly used mechanism for location estimation. It provides a three-dimensional position estimate in absolute coordinates as well as current time and date and is available anywhere on the Earth's surface. Standard GPS provides a position estimate in the horizontal plane to within about 20 m. It was originally developed for military applications but has become widely adopted in civilian applications, including automobile navigation systems, recreational orienteering, and inventory tracking for transportation companies.

20.5.1 Overview

The system is based on received radio signals transmitted by an ensemble of satellites orbiting the Earth.

By comparing the time delays from the different satellite signals, a position fix can be computed. The most widely accepted GPS system is based on the NAVSTAR satellite system deployed and maintained by the United States, specifically by the Air Force Space Command. As a US military service, the US government reserves the right to terminate or modify its availability at their discretion. A similar system named *Globalnaya Navigatsionnaya Sputnikovaya Sistema* (GLONASS) is operated by the Russian government, but at the time of writing it is not available for robotic applications. Another alternative system is being deployed by the European Union, named Galileo, which has the explicit expectation that it will not be under military control. It is expected to offer two different classes of service: an open service and an encrypted higher-quality commercial service. Other GPS systems

such as the Chinese *Beidou* or the Japanese *QZSS* are outside the scope of this chapter.

In general the term **GPS** always refers to the NAVSTAR system. Historically NAVSTAR provided two different services: the precise positioning system (**PPS**), reserved primarily for military users, and the standard position system (**SPS**) with lower accuracy. The difference between these was referred to as selective availability (**SA**). This difference in accuracy was artificially induced via pseudorandom noise in the **SPS** signal for strategic reasons, and was eliminated in 2001. Although this accuracy distinction could, in principle, be reinstated this seems unlikely due to the widespread commercial dependence on **GPS** that has arisen in the last decade. Even now, the **GPS** network includes supplementary data in encrypted precision P(Y) code which is not available to civilian users.

The **GPS** satellite network is based on a base constellation of 24 orbiting satellites along with up to six supplementary additional satellites that are also operational. These satellites are in almost-circular medium Earth orbit. As opposed to being geostationary the orbits are semisynchronous, meaning that their position relative to a ground observer is constantly changing, and that their orbital period is exactly half a sidereal day. The orbits are selected so that from almost any point of the Earth's surface there will always be four or more satellites directly visible – a criterion for obtaining a **GPS** position estimate. The satellites are organized into six orbital planes with four satellites in each. The system is designed such that averaged over the entire Earth's surface and over a 24 h interval, the satellites should allow 99.9% coverage at the worst-covered location in any 24 h interval, and the signal should be at least 83.92% available at the worst place on Earth on the worst day over a 30-day measurement interval. Note that this criterion for availability takes into account transmitted operational factors above and beyond simple coverage. Of course, this criterion ignores the reality of topographic features like mountains, as well as other objects such as buildings that can obstruct the line of sight.

Each satellite repeatedly broadcasts a data packet known as the coarse-acquisition (**C/A**) code, which is received by the **GPS** receiver on the L1 channel at 1575.42 MHz. The simple principle is that, if the receiver knows the absolute positions of the observed satellites, the receiver position can be directly determined. If the signal propagation time for the radio signals were known, the receiver position could be computed directly via trilateration (Fig. 20.8). This implies that an abso-

lute timing reference is present on the receiver, which would be prohibitively costly. Instead, only the satellites have highly accurate atomic clocks (accurate to approximately 1 s in 300 000 years). The receiver computes the difference in signal propagation times between the different satellites, and uses this to compute a range estimate referred to as a *pseudorange* (to explicitly indicate that it is corrupted by several sources of measurement noise). The specific geometric problem is referred to as *multilateration* or *hyperbolic positioning* and the solution is computed using a sophisticated Kalman filter within the **GPS** receiver. To avoid retaining an ephemeris (pose) table for the satellites and a very accurate clock in the receiver, each satellite broadcasts its own position and an accurate time signal as part of the data packet that it transmits.

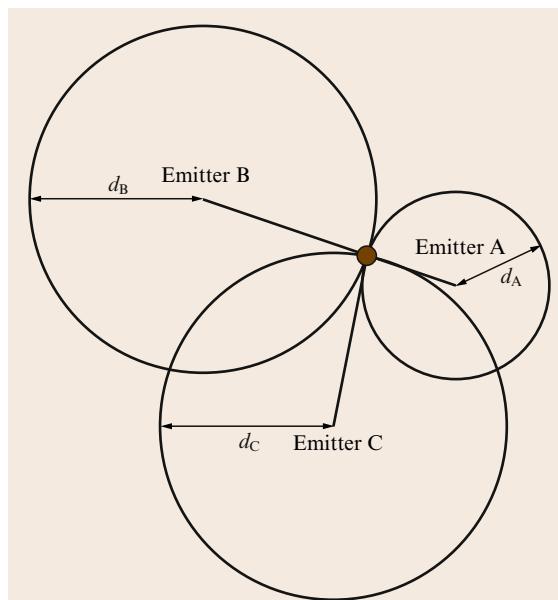

Fig. 20.8 **GPS** trilateration on the plane. Suppose that one receives signals from three transmitters (A, B, and C) with known locations. Knowledge of the signal delay from one emitter (say A) localizes the receiver to lie on a circle of known diameter (d_A) whose center is the emitter. The constraints from two emitters intersect at two points (maximum). A third emitter is required to disambiguate these two solutions. In three dimensions, the signal propagation constraint from a single emitter constrains the receiver to lie on a sphere. The intersection of the constraints from two emitters constrains the receiver to lie on a circle. The intersection of the constraints from three emitters constraints the receiver to one of two points

GPS satellites broadcast at several different frequencies known as L1 through L5; only L1 (1575.42 MHz) and L2 (1227.6 MHz) are used by civilian **GPS** receivers. The standard service offered by NAVSTAR and the performance criteria for it are determined by the L1 signal, which contains two unencrypted components: the acquisition message (coarse-acquisition message **C/A**) and a navigation data message. It is also possible to use the encrypted L2 signal as well, even without the secret decryption keys, to provide augmented error correction (by observing the relative effects of ionospheric distortion as a function of frequency). The restricted-access signal broadcast on both the L1 and L2 channels is the P-code (as well as a fairly recent M-code) which is known as the Y-code or P(Y) or P/Y code once it is encrypted. Both the **C/A** and P(Y) codes include the navigation message stream that specifies clock bias data, orbital information, ionospherical propagation corrections factors, ephemeris data, status information on all the satellites, universal time code, and other information. The satellite performance is coordinated by the master control station located at the Schriever Air Force Base near Colorado Springs, Colorado, USA and is connected to a global network of five additional monitoring stations (Cape Canaveral USA, Ascension Island, Kwajalein Atoll in the Marshall Islands, Diego Garcia Atoll, and Hawaii) which are used to produce the measurements that are uplinked to generate the navigation message stream. Finally, it should be noted that an additional signal is now available on the L2 frequency band. This L2C signal on satellites designated *block IIR-M* promises to provide much improved receiver sensitivity so that position fixes can be obtained in environments, such as in forests, where they are currently not readily available.

20.5.2 Performance Factors

GPS performance depends on several factors: satellite transmission accuracy, environmental conditions, interactions with ground-based obstacles, and receiver properties.

In the context of robotics, factors that affect the performance of the satellites themselves and the atmospheric conditions are essentially uncontrollable. Nevertheless, it should be noted that these can be sources of error and that the **GPS** signal itself may not always be reliable. A *service failure* is defined as a set of circumstances where the positioning service exhibits atypical error behavior (i.e., incorrect signals). Such failures are classified as either minor and major failures. Minor fail-

ures are those that have limited impact on a receiver and lead to ranging errors of under 150 m. Major failures are those that lead either to larger errors or data processing overloads in the receiver. If a single satellite experiences an error that leads to a major failure, then within a 6 h period, approximately 63% of the Earth's surface will have the satellite in view at some point.

The controllable factors in using **GPS** for accurate localization are

1. it requires an unobstructed line of sight to the satellites,
2. it depends on atmospheric conditions, and
3. it depends on the ability to receive (weak) radiofrequency communications.

There is a potential for wildly incorrect estimates. Generally satellites that are directly overhead provide better signals than those near the horizon. In addition, since the basis of **GPS** position is differential signal analysis, it is best if the satellites used in the **GPS** computation are widely spaced in the sky.

GPS signals are in the microwave band and, as such, they can pass through plastic and glass, but are absorbed by water (wood, heavy foliage) and are reflected by many materials. As a consequence, **GPS** is unreliable in heavy forest, deep canyons, inside automobiles and boats, in heavy snowfall or between tall buildings. In some cases, partial obstruction of the sky may not prevent a position estimate from being computed. Assuming the minimum number of satellites operating at any time is 24, then on average across the Earth's surface eight satellites are in view so that even partial occlusion of the sky can often be tolerated. On the other hand, partial occlusion can lead to reduced accuracy since the selection of available satellites used for computing position becomes limited and optimal accuracy is obtained by using as many satellites as possible (weighting them appropriately in the internal Kalman filter).

Secondary factors that differentiate different **GPS** receivers are the rate at which the signals are collected, the receiver sensitivity, the number of satellites used in the final computation, the number of factors taken into account in the estimator, and the exploitation of supplementary positioning schemes such as the wide-area augmentation system (WAAS) (see later). A major factor in determining the rate at which estimates can be produced is the number of independent receiver elements in the **GPS** system. Sequential single-channel receivers are simpler and thus more economical (and potentially smaller), but they must lock sequentially onto each satellite being used. Parallel multichannel receivers can lock

onto to more than one satellite at once, and are generally faster and more costly; some degree of parallelism is the norm in good-quality consumer devices.

GPS computations are based on an estimation of the dilution of precision (**DOP**) and specifically for the dilution of precision of the positional parts of the system, i. e., positional dilution of precision (**PDOP**). These correspond to partial derivatives of the error with respect to position and allow the most accurate ensemble of visible satellites to be determined at any time. The standard implementation for **GPS** systems specifies that **PDOP** values be recomputed every 5 min.

The minimum performance parameters for **GPS** receivers are based upon transforming instantaneous range residuals to a user position estimate using a linearized position solution from a stationary, surveyed location. Most **GPS** receivers use additional techniques such as range residual smoothing, velocity aiding, Kalman filtering, or multiple satellite (*all-in-view satellite*) solutions. That said, formal performance for the system is measured with respect to the minimum. The **GPS** position estimation algorithm is summarized as follows

1. Select the best four satellites based upon the minimum error measured in terms of **PDOP**.
2. Update every five minutes, or whenever a satellite being used in the solution sets.
3. Measure the pseudorange to each satellite. Each of the four measurements must have a reception time tag within 0.5 s of the solution time. The reception time tag is based upon measurement system time, and the transmission time tag is based upon satellite time.
4. Determine the ephemeris for each of the satellites being used, and compute the Earth-centered, Earth-fixed (**ECEF**) coordinates for each. Correct for the Earth's rotation and thus compute an estimated pseudorange measurement that should be obtained for each satellite.
5. Compute the *range residuals* as the differences between the actual and observed measurements.
6. Estimate the matrix G that determines the overall system solution, known as the *position solution geometry matrix*. The matrix can be described in terms of a collection of row vectors, one for each of the satellites being used, each row being made up of the x , y , z and time coordinate direction cosines for the vector between the user and the satellite (with respect to a fixed reference frame for the planet called the World Geodetic System, WGS84).
7. Compute the user's position.

The standard implementation of **GPS** is based upon a position fix rate of once per second, although faster and slower rates are possible. Under typical operating conditions and without specialized enhancements **GPS** accuracy is roughly 20–25 m in the horizontal plane and 43 m in the vertical direction. The restricted **PPS** signal provides an accuracy of at least 22 m (typical values are 7–10 m) in the horizontal plane and 27.7 m in the vertical direction as well as coordinated universal time (UTC) time accuracy within 200 ns based on a reference signal from the **US** Naval Observatory.

GPS signals can be affected by multipath issues, where the radio signals reflect off surrounding terrain – buildings, canyon walls, hard ground, etc. This delay in reaching the receiver causes inaccuracy. A variety of receiver techniques, most notably narrow correlator spacing [20.20], have been developed to mitigate multipath errors. For long delay multipaths, the receiver itself can recognize the wayward signal and discard it. To address shorter delay multipaths due to the signal reflecting off the ground, specialized antennas may be used. This form of multipath is harder to filter out as it is only slightly delayed compared to the direct signal, causing effects that are almost indistinguishable from routine fluctuations in the atmospheric delay.

20.5.3 Enhanced GPS

Wide-Area Augmentation System (WAAS)

The wide-area augmentation system (WAAS) is a supplementary signal that can be received by **GPS** receivers to improve their accuracy. WAAS increases the accuracy of horizontal position estimates from 10–12 m with **GPS** alone, to 1–2 m. The WAAS signal contains corrections for the **GPS** signal that reduce the effects of errors due to timing errors, satellite position corrections, and local perturbations due to variations in the ionosphere. These correction terms are estimated by ground-based stations at fixed and accurately known positions and uplinked to satellites which broadcast them to suitably enabled **GPS** receivers. The WAAS signal is only computed and available for North America, but similar correction signals are becoming available elsewhere as part of the standardization of satellite-based augmentation systems (**SBAS**). This includes Europe, where it is called the Euro Geostationary Navigation Overlay Service (**EGNOS**), and Japan and parts of Asia, where it is called the Multifunctional Satellite Augmentation System (**MSAS**). Further enhancements to **GPS** and WAAS, in the form of the Global Navigation Satellite System Landing System (**GLS**), are slated for completion in 2013.

Differential GPS

Differential GPS is a technique for correcting GPS signals by using a nearby GPS receiver located at a known accurately surveyed position. In fact, several variations on this basic idea exist and are also known under the general rubric of ground-based augmentation systems (GBAS). DGPS uses the same principles as WAAS but on a local scale without resorting to the use of satellite uplinks. The receiver at the known position computes the error in the GPS signal and transmits it to the nearby receiver at the unknown location. Since the error varies as a function of position on the earth, the effectiveness of the correction degrades with distance, typically with a maximum effective range of a couple of hundred miles. The method was especially desirable before the suspension of selective availability and the development of WAAS (which can be viewed as a form of DGPS). In the USA and Canada, a network of ground-based DGPS transmitters are in place, sending signals using radio frequencies between 285 kHz and 325 kHz. Commercial DGPS solutions akin to WAAS also exist.

Receiver Autonomous Integrity Monitor (RAIM)

Receiver autonomous integrity monitoring (RAIM) is a technique by which multiple pseudorange measurements (i.e., pose estimates) are obtained using different combinations of satellites. If inconsistent measurements are obtained, it indicates that a failure of some sort has taken place in the system. A position fix using at least five satellites is needed to detect such an error while at least six satellite are needed to exclude the data from a single bad satellite and still obtain a reliable estimate.

20.5.4 GPS Receivers and Communications

GPS receivers are classified according to their performance and cost. The best receivers are referred to as *geodetic grade* with economical models referred to as *resource grade* or *recreational*. In general the costs of these

different models vary by several orders of magnitude, but the gap in performance is gradually narrowing.

Receivers come in two types: code phase and carrier phase. Code phase receivers use the satellite navigation message part of the data stream to provide the ephemeris data and produce real-time output. There is a delay for them to lock into the satellites, but then they produce output continuously without an initial position estimate. The C/A signal is a 1023 pseudorandom noise (PRN) bit string with a known key. The actual pseudorange data is determined by finding the phase offset of this bit string.

Carrier phase receivers, on the other hand, use the phase of the raw GPS signal rather than the embedded (digital) C/A signal. The L1 and L2 signals have wavelengths of 19 and 24 cm, respectively, and good-quality phase measurements allow horizontal positioning accuracies on the order of millimeters. These measurements, however, only provide relative position information within a neighborhood of some tens of kilometers.

Serial Protocols

Consumer GPS devices almost universally support some variant of the National Marine Electronics Association (NMEA) protocol, a serial protocol often transmitted using RS-232 wiring. Several variants of the protocol exist, but NMEA 0183 is the most commonly supported while NMEA 2000 supports higher data rates. While the protocol is proprietary and the official specification can only be purchased from the National Marine Electronics Association, there are several open-source descriptions of the protocol that have been reverse engineered.

The protocol supports an ASCII mode of communications based on a *talker* (the GPS receiver) and one or more *listeners* (computers) which receive simple protocol strings called sentences. Anecdotal evidence suggests that there are ambiguities in the protocol that can lead to difficulties in assuring compatibility between devices (this suggestion is necessarily made without inspecting the proprietary documentation, which might preclude its description here).

20.6 GPS–IMU Integration

Although GPS offers the promise of high-resolution positioning information on or about the surface of the Earth, it does not solve all of the problems associated with robot pose estimation. First, it does not directly obtain information about vehicle orientation. To determine the orientation of the vehicle yaw, and for many vehicles

pitch and roll, must be estimated by either differentiating the GPS signal or by integration with other sensors such as compasses, gyrocompasses, and IMUs. Second, GPS receivers are generally unable to provide continuous independent estimates of position. Estimates are only available at distinct time instances with (for inex-

pensive receivers at least) considerable delays between measurements. A continuous estimate of pose requires estimation of pose between GPS readings. Finally, it is not always possible to obtain a GPS fix. Local geography (e.g., mountains, buildings, trees) or an overhead cover that is opaque to radio signals (e.g., indoors, underwater) can block the signal entirely. Integration of a GPS receiver with another sensor technology (often an IMU) can be used to deal with these issues, at least for short periods of time.

20.7 Further Reading

Odometry

Many general robotics books, including [20.2] and [20.22], provide considerable information on vehicle odometry and derive odometry equations for standard vehicle designs.

Gyroscopic Systems

Everett's book [20.23] provides a review of various sensor technologies including gyroscopic systems and accelerometers. Interesting historical documentation on the gyrocompass and its inventor can be found in Hughes's book [20.5].

The process of integrating GPS and IMU data is typically expressed as a Kalman filter estimation process (Sect. 25.2.3). Essentially the IMU data is used to bridge between solid GPS measurements and is combined in a least-squares optimal sense with the GPS data when both are available. Given the complementary nature and true independence of the two sensors, a wide range of commercial packages have been developed to integrate GPS and IMU data (see [20.21] for an example).

Accelerometers

Everett's book [20.23] provides a review of various sensor technologies, including gyroscopic systems and accelerometers.

GPS

Considerable details on the theory and implementation of GPS systems can be found in Leick's book [20.24]. See also [20.25]. Details of various approaches to GPS-INS integration can be found in [20.26] and [20.27].

20.8 Currently Available Hardware

Although the specific models listed below are likely to have a short shelf life, the list of contacts may be a good starting point for the identification of specific inertial sensing devices.

Gyroscopic Systems

21. Sonar Sensing

Sonar Sensing

Lindsay Kleeman, Roman Kuc

Part C | 21

Sonar or ultrasonic sensing uses the propagation of acoustic energy at higher frequencies than normal hearing to extract information from the environment. This chapter presents the fundamentals and physics of sonar sensing for object localization, landmark measurement and classification in robotics applications. The source of sonar artifacts is explained and how they can be dealt with. Different ultrasonic transducer technologies are outlined with their main characteristics highlighted.

Sonar systems are described that range in sophistication from low-cost threshold-based ranging modules to multitransducer multipulse configurations with associated signal processing requirements capable of accurate range and bearing measurement, interference rejection, motion compensation, and target classification. Continuous-transmission frequency-modulated (CTFM) systems are introduced and their ability to improve target sensitivity in the presence of noise is discussed. Various sonar ring designs that provide rapid surrounding environmental coverage are described in conjunction with mapping results. Finally the chapter ends with a discussion of biomimetic sonar, which draws inspiration from animals such as bats and dolphins.

21.1 Sonar Principles

Sonar is a popular sensor in robotics that employs acoustic pulses and their echoes to measure the range to an

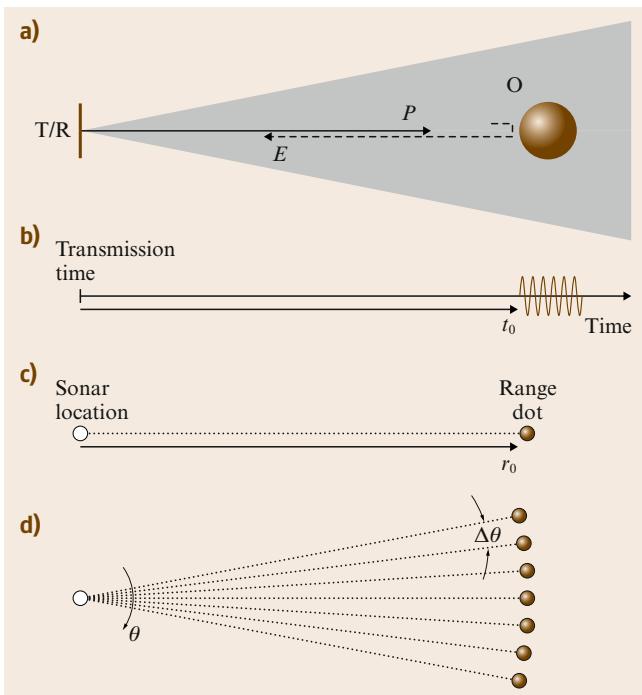

Fig. 21.1a–d Sonar ranging principles: (a) sonar configuration, (b) echo waveform, (c) range dot placement, (d) sonar map

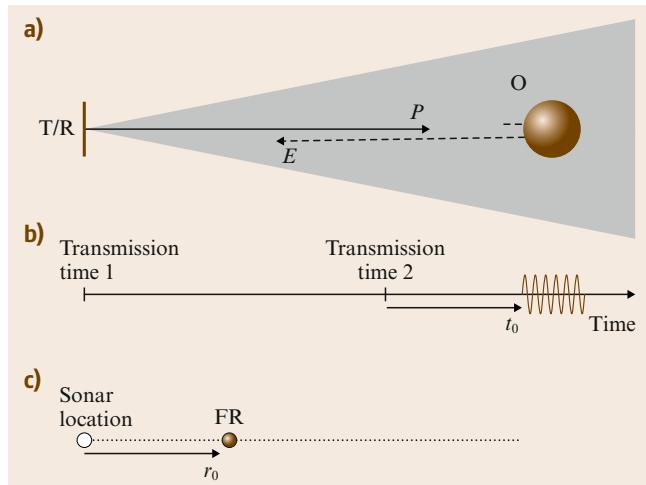

Fig. 21.2a–c False range reading: (a) sonar configuration, (b) probing pulse 2 transmitted before echo from pulse 1 arrives, (c) false range (FR) is measured from transmission time 2

object. Since the sound speed is usually known, the object range is proportional to the echo travel time. At ultrasonic frequencies the sonar energy is concentrated in a beam, providing directional information in addition to range. Its popularity is due to its low cost, light weight, low power consumption, and low computational effort, compared to other ranging sensors. In some applications, such as in underwater and low-visibility environments, sonar is often the only viable sensing modality.

Sonars in robotics have three different, but related, purposes:

1. Obstacle avoidance: the first detected echo is assumed to measure the range to the closest object. Robots use this information to plan paths around obstacles and to prevent collisions.
2. Sonar mapping: a collection of echoes acquired by performing a rotational scan or from a sonar array is used to construct a map of the environment. Similar to a radar display, a range dot is placed at the detected range along the probing pulse direction.
3. Object recognition: a sequence of echoes or sonar maps is processed to classify echo-producing structures composed of one or more physical objects. When successful, this information is useful for robot registration or landmark navigation.

Figure 21.1 shows a simplified sonar system, from its configuration to the resulting sonar map. A sonar transducer, T/R, acts as both the transmitter (T) of a probing acoustic pulse (P) and the receiver of echoes (E). An object O lying within the sonar beam, indicated by the shaded region, reflects the probing pulse. A part of the reflected signal impinges on the transducer as is detected as an echo. The echo travel time t_0 , commonly called the *time-of-flight (TOF)* is measured from the probing pulse transmission time. In this case the echo waveform is a replica of the probing pulse, which usually consists of as many as 16 cycles at the resonant frequency of the transducer. The object range r_0 is computed from t_0 using

$$r_0 = \frac{ct_0}{2}, \quad (21.1)$$

where c is the sound speed (343 m/s at standard temperature and pressure). The factor of 2 converts the round-trip ($P+E$) travel distance to a range measurement. Beam-spreading losses and acoustic absorption limit sonar range.

In forming a sonar map, a range dot is placed along the direction corresponding to the transducer's physical orientation. A sonar map is usually built by rotating the sensor about the vertical axis, indicated by the orientation angle θ , through a series of discrete angles separated by $\Delta\theta$ and placing sonar dots the corresponding ranges. Since the range from the object O to the center of T/R is almost constant as T/R rotates, the range dots typically fall on a circle as long as O lies within the beam. Hence, sonar maps are made up of arcs.

The major limitations of sonar include

1. the wide sonar beam causes poor directional resolution. Objects are located at the middle of isolated arcs, but shorter-range objects shorten the arcs of those at farther ranges, and the arcs produced by a collection of objects are often difficult to interpret. A consequence of this effect is that wide beams occlude small openings, limiting robot navigation,
2. the slow sound speed, relative to an optical sensor, reduces the sonar sensing rate. A new probing pulse should be transmitted after all detectable echoes from the previous pulse have expired, otherwise the false reading shown in Fig. 21.2 can occur. The echo from probing pulse 1 occurs after probing pulse 2 is emitted. Sonar measures the TOF from the most recent probing pulse. Many sonars transmit probing pulses every 50 ms, but encounter false readings in reverberant environments,
3. smooth surfaces at oblique incidence do not produce detectable echoes. Figure 21.3 shows a planar surface (a wall) that acts as a mirror to the sonar beam. The important point is that the nearby wall does not itself produce a detectable echo, and a robot using sonar for obstacle avoidance may collide with the wall,
4. artifacts caused by beam side-lobes and multiple reflections produce range readings in the environment where no objects exist. Figure 21.3 also shows the redirected beam enclosing object O. The echo is also redirected by the wall back to the transducer. From the transducer's reference, the object is at the virtual object location VO, and it would generate the same sonar map as shown in Fig. 21.1. Since there is no physical object corresponding to the sonar dot location, it is an artifact. Also, note that the acoustic energy indicated by the dot-dashed line reflected back to the transducer is not detected because it does not lie within the beam cone. Beam side-lobes often detect these echoes and produce

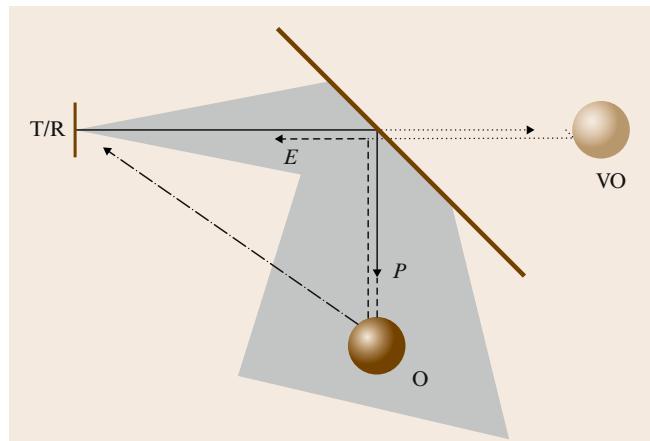

Fig. 21.3 The smooth surface redirects the beam, causing a sonar artifact at virtual object (VO) location. The dot-dashed echo path falls outside the sonar beam and does not produce a detectable echo

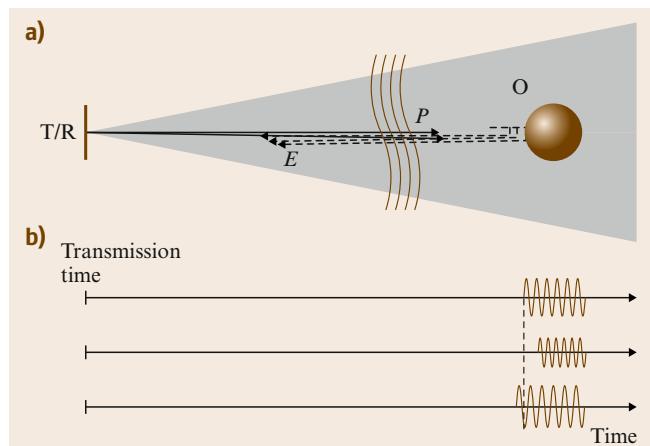

Fig. 21.4a,b Random echo jitter. (a) Sonar configuration; thermal inhomogeneities in the acoustic transmission medium cause refraction effects. (b) Examples of variations in echo travel times and amplitudes in a static environment

- shorter-range readings but placed along the sonar orientation,
5. travel time and amplitude variations in the echoes caused by inhomogeneities in the sound speed. Both effects cause random fluctuations in the detected echo travel time, even in static environments. Figure 21.4 illustrates thermal fluctuations that cause speed up, retardation, and travel redirection by refraction of echoes. These cause temporal and amplitude variations in the echoes and jitter in the

range readings. While these typically introduce minor changes in sonar maps, they often cause havoc with approaches using finer analysis.

This chapter describes the physical and mathematical details that extend this simplified sonar model to practical sonar systems.

21.2 Sonar Beam Pattern

To derive a qualitative description of the sonar transducer, we apply elementary acoustics theory to a simplified model to achieve a simple analytic form [21.1]. A sonar emitter is commonly modeled as a circular piston surface of radius a vibrating with frequency f in an infinite planar baffle. The wavelength λ is

$$\lambda = \frac{c}{f}, \quad (21.2)$$

where c the sound speed in air, 343 m/s at 25 °C [21.2]. When $a > \lambda$ the emitted pressure field forms a beam consisting of a main lobe surrounded by side-lobes. In the far field, or range greater than a^2/λ , the beam is described by its *directivity pattern*, which is the two-dimensional Fourier transform of the aperture function, in this case the circular aperture produces a Bessel function. The emitted pressure amplitude at range r and angle θ relative to the piston axis can be written as

$$P_E(r, \theta) = \frac{\alpha a^2 f}{r} \left(\frac{2 J_1(ka \sin \theta)}{ka \sin \theta} \right), \quad (21.3)$$

where α is a proportionality constant that includes the density of air and the source strength, $k = 2\pi/\lambda$, and J_1 is the Bessel function of the first kind. The term in the brackets evaluates to 1 along the sonar axis, $\theta = 0$. The a^2 term indicates that the emitted pressure increases with the piston area. The frequency f appears in the numerator because the faster-moving piston generates higher pressures. The range r appears in the denominator because the conservation of energy requires the pressure to decrease as the beam widens with range.

The main lobe is defined by its first off-axis null, which occurs at an angle of

$$\theta_0 = \arcsin \left(\frac{0.61\lambda}{a} \right) = 14.7^\circ. \quad (21.4)$$

For example, the popular electrostatic instrument grade transducer, formerly produced by Polaroid [21.3],

had a radius of $a = 1.8$ cm and is conventionally driven at $f = 49.4$ kHz, making $\lambda = 0.7$ cm and $\theta_0 = 14.7^\circ$.

An object that is small compared to λ and located in the emitted pressure field produces an echo with a spherical wavefront whose amplitude decays with the inverse

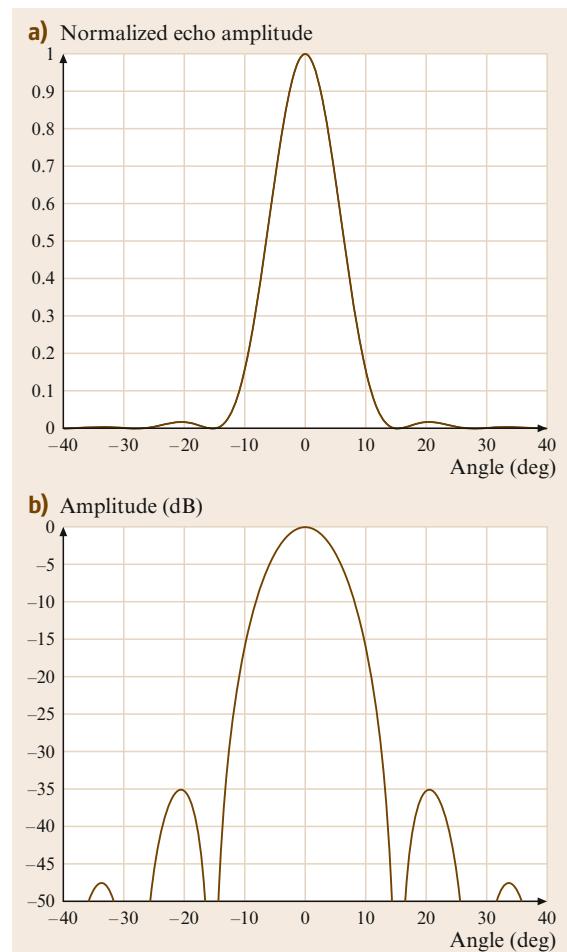

Fig. 21.5a,b Normalized amplitude of echo from small object predicted by the piston model as a function of angle. **(a)** Linear scale. **(b)** Decibel scale

of the distance propagated. In the common pulse-echo single transducer (*monostatic*) ranging sensor, only part of the echo wavefront impinges on the receiving aperture. The *sensitivity pattern* of the circular aperture, now acting as the receiver, has the same beam-like Bessel function form given in (21.3) by the reciprocity theorem [21.1]. If the reflecting object is located at (r, θ) relative to the transducer, the detected echo pressure amplitude, referenced to the receiver output, is given by

$$P_D(r, \theta) = \frac{\beta f a^4}{r^2} \left(\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right)^2, \quad (21.5)$$

where β is a proportionality constant that includes parameters that cannot be controlled in a design, such as the density of air. The additional a^2 in the numerator occurs because larger apertures detect more of the echo wavefront.

Figure 21.5 shows the echo amplitude from a small (point-like) object located in the far field as a function of angle detected by the electrostatic instrument grade transducer. The curve has been normalized by the on-axis echo amplitude.

This model is qualitative in that it provides the following practically useful insights:

- For a small reflector size relative to the wavelength, the echo amplitude decreases inversely with the square of the range because there is a $1/r$ dispersion loss from the transmitter to the object, followed by an additional $1/r$ dispersion loss in the echo back to the receiver. However, larger reflectors can be treated using a Huygens principle approach [21.4] by dividing them into smaller reflectors and coherently adding their echo contributions. When this is done in two dimensions over a normally incident extended plane reflector, the echo amplitude decreases as $1/r$ rather than $1/r^2$. A cylindrical reflector extends over one dimension and results in an amplitude variation with range between $1/r$ and $1/r^2$. A more extreme situation can occur with a concave reflector that acts as an acoustic magnifier, resulting in an amplitude that decreases with a negative power of range of less than one.
- The transducer excited by an approximation to a sinusoid exhibits side-lobes due to null caused by phase cancellation. For example, the 16-cycle excitation employed in the conventional sonar exhibits side-lobes. The peak of the first side-lobe is -35 dB relative to the echo amplitude when a small reflec-

tor lies on the transducer axis. The specification sheet for the 600 series instrument-grade transducer shows the first off-axis null at 15° and a first side-lobe peak magnitude of -26 dB. We presume that these measurements were made using a plane as a reflector.

- This model can be used to compute approximate beam parameter values for other common transducers. For example, the SensComp 7000 Series [21.5] with $a = 1.25$ cm yields $\theta = 20^\circ$, equal to the specified value. However, the specified first side-lobe peak magnitude equals approximately -16 dB, which is substantially different from the expected -35 dB.

The limitations of the qualitative model include:

- Actual transducers only approximate pistons vibrating in an infinite planar baffle. The infinite baffle directs all the radiated sound pressure into the half-space in front of the transducer. Actual transducers radiate in all directions, but most of the acoustic energy is concentrated within the main lobe.
- All pulse-echo ranging sonars operate with finite-duration pulses rather than infinite-duration sinusoids. Several systems described below use pulses that are quite different from a sinusoidal excitation, either in duration or in form. These are commonly analyzed by computing the spectrum of the pulse and decomposing it into several sinusoidal frequencies, each having its own beam pattern. For example, the echo amplitude predictions above are reasonably accurate, including beam width and side-lobes, for the 16-cycle pulses. However, when impulse or swept-frequency excitations are used, the net beam profile becomes the superposition (of linear amplitudes) of the beam patterns produced by each frequency component in the excitation. Such broadband excitations do not exhibit nulls because the nulls formed by one frequency are filled in by main and side-lobes of beams produced by other frequencies.
- Most sonar transducers are encased in protective housings. The electrostatic instrument-grade transducer cover forms a mechanical filter that enhances the acoustic output at 49.4 kHz. The cases of other transducers may distort the transmitted field, but most form some type of directional beam.
- The model does not include frequency-dependent acoustic absorption of the transmission medium. These reduce the echo amplitudes predicted by the model.

The analytic model above is limited to simple configurations. With current computational power, transducers can be extended to those with arbitrary, even multiple, apertures and with various excitations. Waveforms of echoes from objects having arbitrary shapes can be simulated by using Huygens principle [21.4]. The transmitter, receiver, and object surfaces are broken up into two-dimensional surface arrays of emitting, reflecting, and detecting elements, using squares of dimension $< \lambda/5$ (the smaller the better, but taking longer). The impulse response of a given configuration is computed by as-

suming an impulsive emission and superimposing the travel times along all possible paths from all transmitter elements to all object elements and then to all receiver elements. The temporal resolution should be $< (20f_{\max})^{-1}$, where f_{\max} is the maximum frequency in the excitation. A 1 μs resolution is adequate for a 16-cycle 49.4 kHz excitation. A much finer resolution ($< 0.1 \mu\text{s}$) is required for an impulsive excitation. The echo waveform is then computed as the convolution of this impulse response with the actual transmitted pulse waveform [21.4].

21.3 Speed of Sound

The speed of sound c varies significantly with atmospheric temperature, pressure, and humidity and can be critical in determining the accuracy of a sonar system. This section outlines the relationship between c and these variables and is based on [21.6, 7].

The speed of sound in dry air at sea-level air density and one atmosphere pressure is given by

$$c_T = 20.05\sqrt{T_C + 273.16} \text{ ms}^{-1}, \quad (21.6)$$

where T_C is the temperature in degrees Celsius. Under most conditions (21.6) is accurate to within 1%. However, should the relative humidity be known, a better estimate can be made as

$$\begin{aligned} c_H &= c_T + h_r [1.0059 \times 10^{-3} \\ &\quad + 1.7776 \times 10^{-7}(T_C + 17.78)^3] \text{ ms}^{-1}. \end{aligned} \quad (21.7)$$

Equation (21.7) is accurate to within 0.1% for temperatures in the range -30 – 43°C for most pressures at sea level. Should atmospheric pressure, p_s be known then

the following expression can be used

$$c_P = 20.05 \sqrt{\frac{T_C + 273.16}{1 - 3.79 \times 10^{-3}(h_r p_{\text{sat}}/p_s)}} \text{ ms}^{-1}, \quad (21.8)$$

where the saturation pressure of air, p_{sat} is dependent on temperature as follows

$$\begin{aligned} &\log_{10}\left(\frac{p_{\text{sat}}}{p_{s0}}\right) \\ &= 10.796 \left[1 - \left(\frac{T_{01}}{T}\right)\right] - 5.0281 \log_{10}\left(\frac{T_{01}}{T}\right) \\ &\quad + 1.5047 \times 10^{-4}\{1 - 10^{-8.2927[(T/T_{01})-1]}\} \\ &\quad + 0.42873 \times 10^{-3}\{-1 + 10^{4.7696[1-(T_{01}/T)]}\} \\ &\quad - 2.2196, \end{aligned} \quad (21.9)$$

p_{s0} is the reference atmospheric pressure of 101.325 kPa and T_{01} is the triple-point isotherm temperature with the exact value of 273.16 K.

21.4 Waveforms

Sonars employ a variety of waveforms, the most common types of which are shown in Fig. 21.6. Each waveform can be considered the echo from a normally incident plane. Waveforms are classified as being narrow- or wide-band depending on their spectral bandwidth. Narrow-band pulses provide superior detection

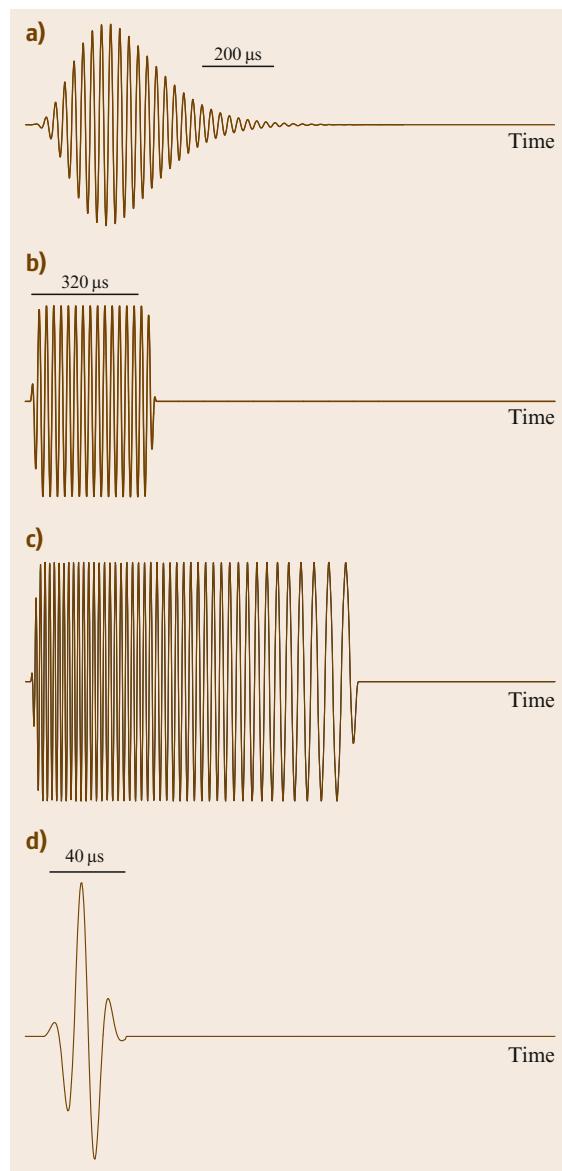

performance in the presence of additive noise, while wide-band pulses provide better range resolution and do not have side-lobes.

Figure 21.6a shows the waveform produced by the Murata 40 kHz piezoelectric transducer excited by an eight-cycle 40 kHz square wave 40 V_{rms}. The Murata

Fig. 21.6a–d Common sonar pulse waveforms. (a) Murata 40 kHz transducer (narrow band). (b) Polaroid 600 electrostatic transducer excited with 16-cycle sinusoid at 49.4 kHz (6500 ranging module – narrow band). (c) Polaroid 600 electrostatic transducer excited with decreasing-frequency excitation signal (wide band). (d) Polaroid 600 electrostatic transducer excited with 10 μ s 300 V pulse (wide band) ▶

sensor is small, lightweight, and efficient, but has an approximately 90° beam width. These transducers are used in monostatic, bistatic, and multiple transducer arrays [21.8, 9].

The next three waveforms were produced by the Polaroid 600 electrostatic transducer. Similar waveforms are generated by the smaller Polaroid 7000 transducer. Figure 21.6b shows the waveform produced by the 6500 ranging module. This ranging module with its 10 m range, low cost, and simple digital interface is a popular choice for implementing sonar arrays and rings. While the electrostatic transducer is inherently wide-band, with a usable frequency range from 10 to 120 kHz [21.10], narrow-band pulses are produced by exciting the transducer with 16 cycles at 49.4 kHz. Figure 21.6c illustrates a means to exploit the wide bandwidth of the Polaroid electrostatic transducer by exciting it with a decreasing-frequency square wave. Such frequency-sweep pulses are processed by a band of band-pass filters to extract the frequency dependence of reflecting objects. A correlation detector, also known as a matched filter, compresses swept-frequency pulses to improve range resolution. Longer-duration (100 ms) pulses are used in CTFM systems. Figure 21.6d shows a wide-band pulse when the excitation is a 10 μ s-duration 300 V pulse. The metal protective mesh, which also acts as a mechanical filter resonant at 50 kHz, was removed by machining to achieve a usable bandwidth from 10 kHz to 120 kHz, with the peak occurring at 60 kHz. Such wide-band pulses are useful for object classification [21.10, 11]. These pulses have small amplitudes, limiting their range to 1 m or less.

21.5 Transducer Technologies

Electrostatic and piezoelectric transducers are the two major types available that operate in air and can in principle operate both as a transmitter and receiver – some samples are shown in Fig. 21.7. In general electrostatic devices have a higher sensitivity and bandwidth but typ-

ically require a bias voltage above 100 V. Piezoelectric devices operate at lower voltages, making their electronic interfacing simpler, but have a high- Q resonant ceramic crystal and this results in a narrow frequency response compared to electrostatic transducers.

Fig. 21.7 Left to right: Series 9000, instrument-grade, and Series 7000 transducers; front and back views are shown (Photo courtesy Acroname, Inc., Boulder; www.acroname.com)

respectively. A piezoelectric resonant crystal mechanically vibrates when a voltage is applied across the crystal, and in reverse generates a voltage when mechanically vibrated. Often a conical concave horn is mounted on the crystal to acoustically match the crystal acoustic impedance to that of air. An example is the Murata MA40A5R/S receiver and sender transducers, which operate at 40 kHz. This device has a diameter of 16 mm and a 60° beam angle for transmitter combined with receiver for -20 dB loss compared to the maximum sensitivity. The effective bandwidth of transmitter and receiver is only a few kHz due to the resonant nature of the crystals. This limits the envelope rise time of pulses to around 0.5 ms. An advantage is the ability to drive piezoelectric devices with low voltages, for example by connecting each terminal to complementary CMOS logic outputs. There is a wide range of resonant frequencies for piezoelectric transducers from 20 kHz to megahertz. Also available is piezoelectric film called polarized fluoropolymer, polyvinylidene fluoride (**PVDF**) from www.msiusa.com. This flexible film can be cut to shape and custom ultrasonic transmitters and receivers can be formed. The sensitivities of the transmitters and receivers made from **PVDF** is generally lower than that of ceramic crystal transducers and most applications are short range where the broadband nature of **PVDF** allows short pulses to be formed, allowing pulse-echo ranging to as little as 30 mm.

21.5.3 MEMS

Microelectromechanical system (**MEMS**) ultrasonic transducers can be fabricated on a silicon chip and integrated with electronics. The sensors offer a low-cost mass-produced alternative to standard transducers. **MEMS** ultrasonic transducers operate as electrostatic capacitive transducers where the membrane can be made from thin nitride. Devices operate at frequencies up to several megahertz and offer advantages in signal-to-noise ratio over piezoelectric devices due to their better matching to air acoustic impedance [21.13]. Two-dimensional arrays of devices can be deployed on a chip that are well matched and steerable.

21.5.1 Electrostatic

An example of an electrostatic transducer is the Polaroid instrument-grade transducer (now available from SensComp.com) constructed from a gold-coated plastic foil membrane stretched across a round grooved aluminium back plate. The conductive foil is charged via a bias voltage of 150 V with respect to the back plate. Incoming sound waves vibrate the foil and change the average distance between the foil and back plate and thereby changing the capacitance of the foil. Assuming that the charge q is constant, the voltage $v(t)$ is generated proportional to this varying capacitance $C(t)$ as $v(t) = qC(t)$. As a transmitter, the transducer membrane is vibrated by applying 0–300 V pulses across this capacitor, typically using a pulse transformer. The charge induced by the 300 V on the capacitor causes an electrostatic attraction force between the membrane and the back plate. The grooves on the back plate allow stretching of the membrane and by creating randomness in the back plate roughness a broad resonance can be achieved in the frequency response. For example the bandwidth of the 7000 series Polaroid transducer is 20 kHz. A front grille is mounted on the transducer and removing this grille reduces losses and reverberation between the grill and the membrane. Another electrostatic transducer was designed by Kay and details of its design can be found in [21.12].

21.5.2 Piezoelectric

Piezoelectric ceramic transducers can be used as both transmitters and receivers, however some manufacturers sell transmitters and receivers separately in order to optimize the transmitted power and receiver sensitivity,

21.6 Reflecting Object Models

Modeling the reflection processes helps in interpreting echo information. In this section we consider three simple reflector models: planes, corners, and edges, shown in Fig. 21.8. These models apply to both single transducers and arrays.

A plane is a smooth surface that acts as an acoustic mirror. Smooth walls and door surfaces act as planar reflectors. The plane must be sufficiently wide to produce the two reflections whose path is shown in dotted line. The plane reflector is then slightly larger than the intersection area of the beam with a plane of infinite extent. Smaller planes produce weaker echoes because of a smaller reflecting surface and negative interference by echoes diffracted from the edges of the plane. An acoustic mirror allows the analysis using a virtual transducer, indicated by primes in the figure.

A corner is the concave right-angle intersection of two surfaces. Corners formed by intersecting walls, the sides of file cabinets, and door jambs are commonly observed corner reflectors in indoor environments. The novel feature of the corner, and its three-dimensional (3-D) counterpart the corner cube, is that waves reflect back in the same direction from which they originate. This is caused by planar reflections at each of the two surfaces defining the corner. The virtual transducer is then obtained by reflecting the transducer about one plane of the corner and then the other plane. This gives rise to a reflection through the intersection point of the corner as shown in Fig. 21.8b. The virtual transducer analysis indicates that, for a monostatic sonar, echoes from a plane and corner are identical and that planes and corners can generate identical sonar maps [21.4]. The difference in the virtual transducer orientation between planes and corners has been exploited using transducer arrays to differentiate these reflectors [21.11, 14].

The edge shown in Fig. 21.8c models physical objects such as convex corners and high-curvature surfaces (posts), where the point of reflection is approximately independent of transducer position. Edges are encountered in hallways. While planes and corners generate strong echoes, edges generate weak echoes that are detected only a short range [21.4], making them difficult objects to detect. Early robot sonar researchers placed bubble wrap material on edge surfaces to make them reliably detectable.

Many environmental objects can be configured as a collection of planes, corners, and edges. Models for echo production [21.15, 16] indicate that normally in-

cident surface patches and locations at which sharp changes in the surface function and its derivatives generate echoes. Objects with rough surfaces or a collection of many objects generate echoes from a variety of ranges and bearings, as illustrated in Fig. 21.9. If $p(t)$ repre-

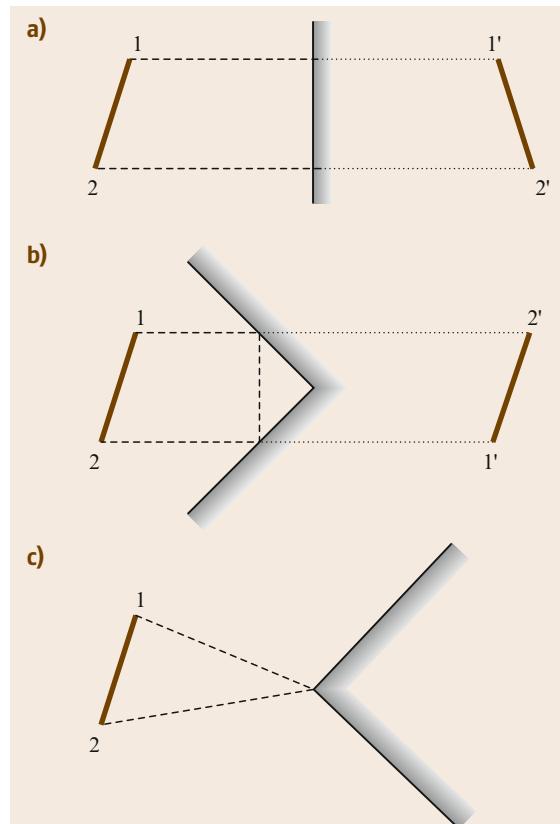

Fig. 21.8a–c Reflector models: (a) plane, (b) corner, and (c) edge

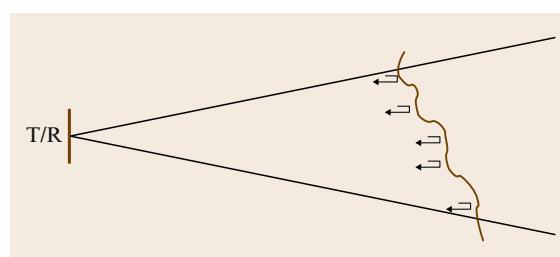

Fig. 21.9 Random reflector model. Echoes reflect back from normally incident surface sections within the beam

sents a single echo waveform, often a replica of the probing waveform, the total echo waveform $p_T(t)$ is the sum of individual echoes $p_i(t)$ from N normally incident patches at range r_i and bearing θ_i , scaled by amplitude a_i , or

$$p_T(t) = \sum_{i=1}^N a_i(\theta_i) p_i \left(t - \frac{2r_i}{c} \right), \quad (21.10)$$

where $a_i(\theta_i)$ is an amplitude factor related to the surface patch size and its bearing in the beam. Widebandwidth echoes are more complicated because their

waveform changes in a deterministic fashion due to diffraction [21.11].

Sonars that analyze $p_T(t)$ employ analog-to-digital converters to obtain waveform samples [21.11, 17]. Reflecting patches separated in range produce isolated patches [21.11], but more often the incremental travel time is less than the pulse duration, causing pulse overlap. Rough surfaces and volume scatterers, such as indoor foliage, have large N , allowing $p_T(t)$ to be treated as a random process [21.18, 19]. Conventional **TOF** sonars output the first time that $p_T(t)$ exceeds a threshold [21.11].

21.7 Artifacts

Sonars usually work well in simple environments, while complex environments often produce mysterious readings, artifacts, that foil attempts to build reliable sonar maps. Artifacts have given sonar a bad reputation as being a noisy, or low-quality, sensing modality. Sonar stalwarts believe sonar would open up many new applications, *if only* we understood echoes at a level that approximates that employed by bats and dolphins [21.20]. Sonar stalwarts divide into two categories in terms of how they treat artifacts. The first attempts to build *intelligent sensors* that identify and suppresses artifacts before transmitting data to a higher-level reasoning program. Previous approaches [21.21, 22] required custom electronics, which other researchers have been reluctant to adopt because of expense or lack of experience. An alternate approach is to control conventional sonar in a novel fashion to produce a series of spikes and requires only software changes [21.23]. Sonar arrays have been used to find consistent data [21.24–26]. Echoes from specular reflectors, such as planes, corners, or posts, exhibit detectable features, which can be obscured by artifacts.

The second category of sonar users attempts to eliminate artifacts produced by conventional sensors by using higher-level postprocessing. These include proponents of occupancy (or certainty) grids [21.27, 28], including those that apply simplified physical models, such as sonar arcs [21.29, 30]. In simple environments postprocessing usually eliminates artifacts that are inconsistent with a feature [21.31] or with a physical map [21.30]. More-sophisticated methods handle artifacts by treating them as noise and applying hidden Markov models (**HMM**) [21.32]. However, multiple passes are needed to successfully teach the system about relatively simple environments, mostly because artifacts are not amenable

to being treated as independent additive noise. Eliminating troublesome artifacts would replace **HMM** with simpler Markov chains [21.33, 34], and sufficient sonar data can be obtained in a single pass. What frustrates this second category, and mildly amuses the first, is that this postprocessing works well *in simple environments*, but fails in real-world environments. This second category eventually abandons sonar and joins the camera and laser ranging crowd.

There are two important classes of artifacts: axial multiple reflection (**MR**) artifacts and dynamic artifacts. These artifacts are important in sonar mapping when they indicate the presence of a static object at a location where none exists. Troublesome **MR** artifacts are caused by delayed echoes produced by a previous probing pulse exceeding the detection threshold after the current probing pulse has been transmitted. Such artifacts then appear as close-range objects and obscure actual farther-range objects in conventional sonars. Most sonars employ probing pulse emission periods longer than 50 ms to avoid **MR** artifacts, although some reverberant environments can still produce artifacts [21.35].

Dynamic artifacts are produced by moving objects, such as individuals passing through the sonar beam. Even though these are actual objects and echoes indicate their true range, their presence should not be part of a sonar map that describes the static environment. Such dynamic artifacts make quantitative matchings between stored and generated sonar maps error-prone.

Another common artifact is a nonaxial **MR** artifact [21.4] caused by an obliquely incident smooth surface that redirects the sonar beam to some other echo-producing object. The **TOF** produces a range reading that is positioned along the sonar axis. While the object is

not at the location indicated on a sonar map, its location in the sonar map is a stable element and can be useful for navigation.

One may argue that, if the locations of all objects are known, the echoes can be determined and should not be treated as random processes. However, the presence of speed fluctuations in the medium due to thermal gradients and ever-present electronic noise cause random fluctuations in the times that thresholds are exceeded. Even a stationary sonar in a static environment exhibits random fluctuations [21.36], similar to the visual experience of fading when viewing objects beyond a heated surface.

Sonar can identify artifacts by applying three physical criteria that are met by echoes from static environmental objects. Artifact features include [21.35]

1. echo amplitude – echoes with amplitudes less than a specified threshold;
2. coherence – echoes forming constant-range azimuthal intervals less than a specified threshold; and
3. coincidence – echoes detected with a sonar array at different times (lacking temporal coherence) or corresponding to different locations (lacking spatial coherence).

21.8 TOF Ranging

Most conventional sonars employ Polaroid 6500 ranging modules [21.37] connected to the Polaroid 600 series electrostatic ultrasound transducer. The module is controlled with digital signals on two input lines (*INIT* for initialization and probing pulse transmission and *BLNK* for clearing the indication and resetting the detector) and the *TOF* reading occurs on its output line (*ECHO*). A logic transition on *INIT* causes the transducer to emit a pulse lasting for 16 cycles at 49.4 kHz. The same transducer detects echoes after a short delay to allow transmission transients to decay. Another interrogation pulse is typically emitted only after all the

echoes produced by the previous pulse have decayed below a detection threshold.

The module processes echoes by performing rectification and lossy integration. Figure 21.10 illustrates a simulation of the processed waveform applied to the threshold detector. While the echo arrives at time t_0 after the emission, *ECHO* exhibits a transition at the measured *TOF* time t_m , the first time the processed echo signal exceeds a detection threshold τ . By convention, the range r of the reflecting object is calculated by

$$r = \frac{ct_m}{2}, \quad (21.11)$$

where c is the speed of sound in air, usually taken as 343 m/s.

Figure 21.10b shows details around the threshold detection point including the residual high-frequency ripple after full-wave rectification and integration. Two effects can be noticed. First, t_m will always occur after t_0 , making threshold detection a biased estimate of the true echo arrival time. Moreover, this bias is related to the echo amplitude: stronger echoes will produce an integrator output having a greater slope, which exceeds τ sooner than t_0 . Second, as the echo amplitude decreases, for example, when the object moves away from the transducer axis, the threshold level occurs later in the integrator output and t_m will experience small jumps in time approximately equal to half the period [21.38].

The first step in developing a model of the detection process is to develop a model for the echo amplitude as a function of bearing. The Polaroid transducer is often modeled as a vibrating piston to yield the transmitter/receiver beam pattern shown in Fig. 21.11. To

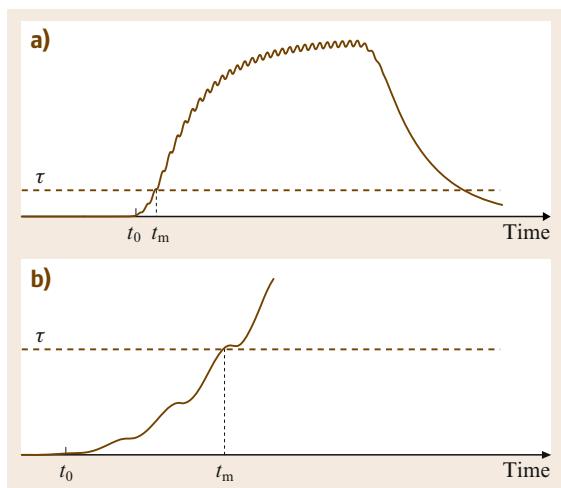

Fig. 21.10a,b Simulation of Polaroid ranging module operation. (a) Processed echo waveform. (b) Expanded time and amplitude scale around threshold crossing point

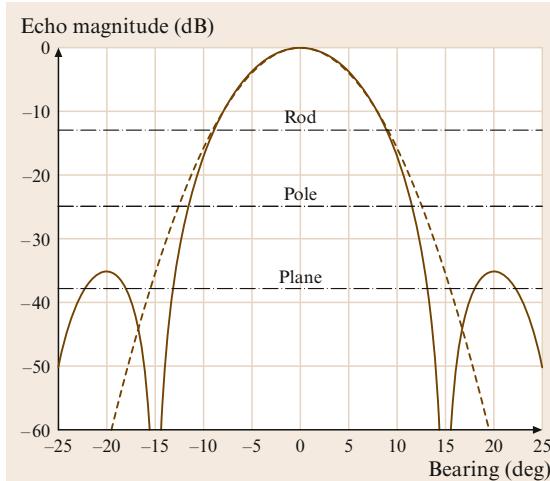

Fig. 21.11 Piston model transmitter/receiver pattern for the Polaroid 600 series transducer. A Gaussian approximation with $\text{SD} = 5.25^\circ$ is shown in dashed line. Equivalent threshold levels for plane, pole, and rod objects at 1.5 m range are shown as dot-dashed lines

(a) 1 m wide plane ($\tau/A = 0.15 \mu\text{s}$). (b) 8.9 cm diam pole ($\tau/A = 0.67 \mu\text{s}$). (c) 8 mm diam rod ($\tau/A = 2.68 \mu\text{s}$) ▶

simplify the analysis, the peak of the beam profile is approximated with a Gaussian function, a parabola in logarithmic units in Fig. 21.11, to determine the echo amplitude as a function of object bearing θ , or

$$A_\theta = A_0 \exp \left(-\frac{\theta^2}{2\sigma^2} \right), \quad (21.12)$$

where A_0 is the on-axis amplitude and σ is a measure of the beam width. The value $\sigma = 5.25^\circ$ provides a good fit around the peak of the beam pattern. The

Gaussian model is reasonable only over the central section of the main lobe that produces detectable echoes.

We assume that the echo arrival time t_0 does not change significantly with transducer orientation (object bearing); this effect was investigated and found to be minor [21.4]. In contrast, measured TOFs, denoted by t_m and t'_m in Fig. 21.12, are amplitude dependent and a function of object bearing, which affects echo amplitude as shown in Fig. 21.11.

The module processes the detected echo waveform by rectification and lossy integration, as discussed above. To derive a useful analytic model, assume that the integration is lossless and the rectified echo is a unit step function with amplitude A . This approximates the processed waveform shown in Fig. 21.10b by a linear function around time t_m , shown in Fig. 21.12. The model ignores the residual ripple and the decreasing slope of the waveform as the lossy rectification approaches a constant value, shown in Fig. 21.10. The linear function with a slope proportional to the echo amplitude is given by $A_\theta(t - t_0)$, for $t \geq t_0$. This function exceeds the threshold τ at

$$t_m = t_0 + \frac{\tau}{A_\theta} = t_0 + \frac{\tau}{A_0} \exp\left(\frac{\theta^2}{2\sigma^2}\right). \quad (21.13)$$

For fixed τ , the incremental delay in t_m is a function of the bearing θ and inversely proportional to the echo amplitude. When a constant echo amplitude A (in volts) is applied to the integrator, the slope of the linear output is A V/s, with typical values on the order of $A_\theta = 10^5$ V/s. If $\tau = 0.10$ V, $\tau/A_\theta = 10^{-6}$ s = 1 μ s.

Experiments were conducted with a Polaroid 600 series transducer connected to a model 6500 ranging module [21.38]. The Polaroid module was operated conventionally to generate t_m values as a rotational scan was performed. Objects include a 1 m-wide plane, a 8.9 cm-diameter pole, and an 8 mm-diameter rod, all located at 1.5 m range. A rotational scan was performed from -40° to $+40^\circ$ in 0.3° steps. At each angle, 100 t_m values were recorded. The mean deviations from the t_m when the object is on the sonar axis ($\theta = 0$) were determined

and the standard deviation (SD) values were computed. There were no other objects in proximity to the object being scanned. Echoes from objects beyond 2 m were eliminated by a range gate.

Figure 21.13a shows the data for the plane, Fig. 21.13b for the pole, and Fig. 21.13c for the rod. The values are shown relative to the t_m value observed at 0° bearing. Dashed lines indicate the values predicted by the model. The t_m values showed a variation with $SD = 5 \mu$ s (0.9 mm) at zero bearing, which is about nine times greater than that predicted by sampling jitter alone. This random time jitter is caused by dynamic thermal inhomogeneities in the air transmission medium, which change the local sound speed and cause refraction [21.36, 39]. The SD increases with deviation from zero bearing because smaller echoes exceed the threshold later in the processed waveform. The smaller slope of the latter part of the processed echo waveform shown in Fig. 21.10 causes greater t_m differences for a given variation in echo amplitude, thus increasing the SD.

One feature in the data not described by the model is due to residual ripple in the integrator output, which causes jumps in TOF readings equal to half periods (10 μ s) added to the value predicted by (21.13). These jumps are clearly evident in the mean values of Fig. 21.13.

The angular extent over which echoes were detected was 45° for the plane, 22.8° for the pole, and 18.6° for the rod. Side-lobes produced by the plane are visible and have small echo amplitudes, which cause their t_m values to be retarded in time. These angular extents can be related to the echo amplitudes that would have produced the respective arcs according to the piston model; these are indicated in Fig. 21.11. For the plane, the threshold level relative to the maximum echo amplitude is -38 dB, for the pole -25 dB, and for the rod -13 dB. Since the ranging module threshold at 1.5 m range is the same for each object, the difference in levels indicates the relative echo strength from each object, i.e., the plane echo is 13 dB (a factor of 4.5) greater than the pole echo, and the pole echo is 12 dB (a factor of 4) greater than the rod echo.

21.9 Echo Waveform Coding

Systems that display echo information beyond the first echo have been investigated [21.11, 17, 24, 40–42], but typically employ custom electronics. One motivation for examining the entire echo waveform is the success of

diagnostic medical ultrasound imaging systems, which adopt this method [21.43, 44].

As a less expensive alternative to analog-to-digital conversion, the Polaroid ranging module can detect

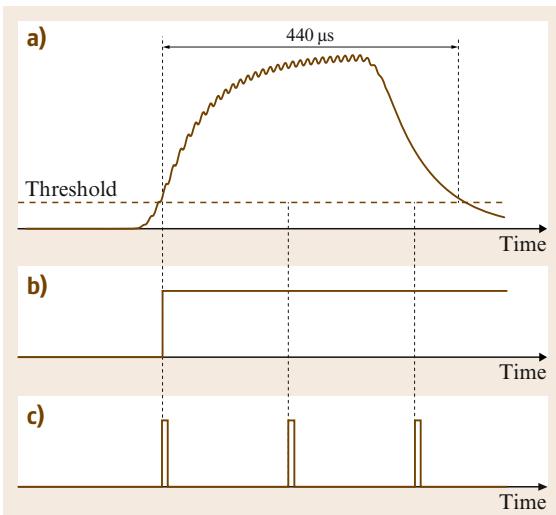

Fig. 21.14a–c Polaroid ranging module operation modes. (a) Processed echo waveform. (b) *ECHO* output produced in conventional time-of-flight mode. (c) *ECHO* output produced in *PAS* mode

echoes beyond the initial echo by repeatedly resetting the detection circuit. The 6500 module specification suggests a delay before resetting to prevent the current echo from retriggering the detection circuit [21.3]. Let us ignore this suggestion and control the Polaroid module in nonstandard way to provide information about the entire echo waveform. Since the echo amplitude is estimated from the digital output produced by the Polaroid module, this operation has been called *pseudo-amplitude scan (PAS)* sonar [21.23].

The conventional ranging module processes detected echoes by performing rectification and forming a lossy integration, as illustrated in Fig. 21.14a.

The *BLNK* input is typically kept at zero logic level, which enables the *ECHO* output. *ECHO* exhibits a transition at the time when the processed echo signal exceeds a threshold, as shown in Fig. 21.14b. By convention, the time interval between the *INIT* and *ECHO* transitions indicates the time of flight (*TOF*), from which the range r of the reflecting object is calculated by

$$r = \frac{c \times \text{TOF}}{2} . \quad (21.14)$$

Echoes occurring after the initial echo can be detected by resetting *ECHO* by pulsing the *BLNK* input. The specification suggests that the *BLNK* pulse should be delayed after the *ECHO* indication by at least 440 μs to account for all 16 returning cycles in the echo and to

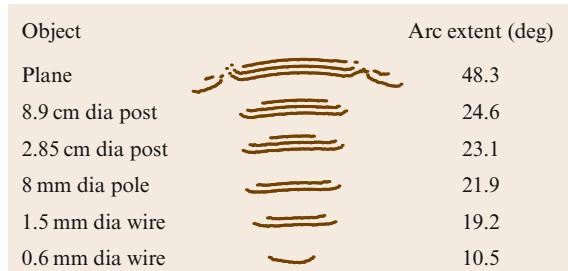

Fig. 21.15 *PAS* sonar maps of six objects located at 1 m range. The sonar is located below the objects in the figure

allow it to decay below the threshold for the largest observable echo. The largest echoes typically saturate the detection circuit, providing a predetermined maximum value. This duration corresponds to the time interval over which the processed signal is above the threshold, as shown in Fig. 21.14a.

When an *ECHO* event is observed, the *PAS* system issues a short 3 μs (corresponding to a software query period) pulse on the *BLNK* input line, which clears the *ECHO* signal as shown in Fig. 21.14c. Upon being cleared, the Polaroid module exhibits a delay inversely related to the echo amplitude, lasting at least 140 μs for large-amplitude echoes, and then produces another *ECHO* event if the processed echo signal still exceeds the threshold. The *PAS* system repeatedly issues a *BLNK* pulse whenever an *ECHO* event is observed. Hence, a strong echo is represented by three pulses on the *ECHO* line, the first corresponding to the conventional *TOF*, followed by two more pulses. Because lower amplitude echoes spend less time above the threshold, a weaker echo produces two pulses spaced farther apart, and a very weak echo may produce only one pulse.

A *PAS* sonar map is generated by placing a range dot along the transducer axis as a rotational scan is executed. With multiple readings per interrogation pulse, a *PAS* sonar map contains multiple dots at each interrogation angle. Rotational scans then form arcs, with isolated arcs indicating weak echoes, arc pairs moderate echoes, and arc triplets large echoes. To illustrate, Fig. 21.15 shows arcs formed by a large plane (2.3 m width by 0.6 m height) and five cylinders with different diameters, all placed at 1 m range. Examining objects at the same range eliminates effects caused by the range-dependent gain of the module.

A conventional *TOF* sonar map by comparison would display only the nearest arc in the *PAS* map for each object. Qualitatively, the arc length increases and the number of arcs increase with the echo amplitude,

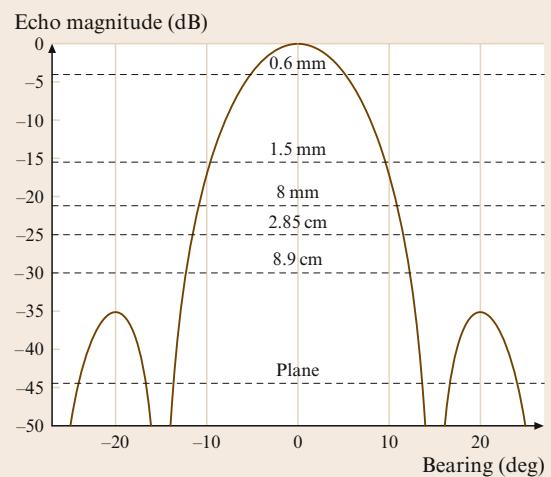

Fig. 21.16 Transmitter–receiver beam pattern. Dashed lines indicate the equivalent threshold level for each object

which is bearing dependent. The strongest reflectors produce concave arcs [21.4, 45]. This occurs because, with echo amplitudes much greater than the threshold, the threshold is exceeded near the beginning of the echo, yielding a nearly constant range reading over a significant extent over bearing. In contrast, the weakest reflectors produce convex arcs, caused by echoes whose amplitudes are comparable to the threshold. As the echo amplitude decreases the threshold is exceeded at later points along the processed waveform, producing greater range readings. This effect also appears at the edges of the arcs produced by strong reflectors.

Computing the beam pattern of the vibrating piston model [21.1], which is a reasonable approximation to the Polaroid transducer, yields the curve shown in Fig. 21.16. This figure describes the detected echo magnitude normalized to have a maximum of 0 dB, which occurs along the beam axis. The larger echoes are much greater than the threshold, such as those produced by the plane, whose maximum amplitudes can be 44 dB relative to the threshold. The –44 dB threshold agrees with the PAS map for a plane: strong echoes (three stripes) occur within 10° of normal incidence, range readings increase due to echo amplitude reduction at $\pm 15.6^\circ$, approximating the predicted nulls at $\pm 14.7^\circ$, and smaller-amplitude echoes from the side-lobes are present. Weaker reflectors correspond to larger thresholds when their on-axis echoes normalize to 0 dB. The beam pattern model explains how arc length varies with object reflecting strength. The indicated thresholds were found by matching the angular beam width to the arc extent.

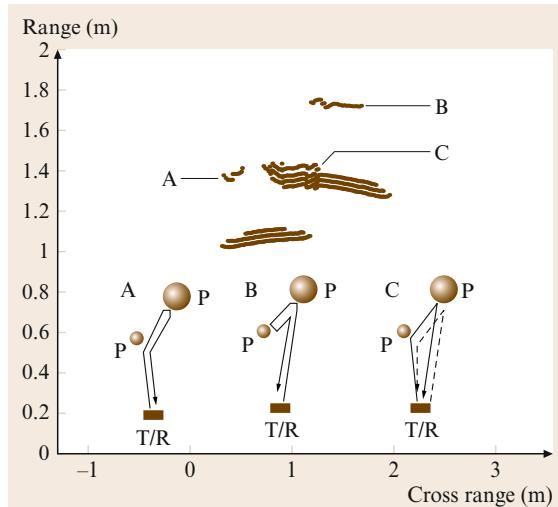

Fig. 21.17 PAS sonar map of 2.85 cm-diameter post (p) and 8.9 cm-diameter post (P). The transducer is located at (0,0). A: Artifact caused by echo originating at transmitter T, reflected by p, bouncing off P back to p, and directed toward receiver R. (T \rightarrow p \rightarrow P \rightarrow p \rightarrow R). B: T \rightarrow P \rightarrow p \rightarrow P \rightarrow R. C: T \rightarrow p \rightarrow P \rightarrow R and T \rightarrow P \rightarrow p \rightarrow R

It is apparent that PAS maps provide information useful for solving the inverse problem, that of determining the identity of the object from the echoes. Figure 21.15 shows that PAS maps contain information about the echo amplitude. While it is true that the conventional TOF sonar maps, represented by the closest arc, can determine the object location from the arc center and can infer the echo amplitude from the arc extent, it is also true that this information is presented in a more robust way in the PAS maps. For this simple case of isolated objects, the posts can be clearly differentiated from the pole, while the corresponding conventional TOF arcs are comparable. A tenfold increase in post diameter yields only a modest increase in the conventional TOF arc length, while increasing the number of arcs from two to three in the PAS maps.

When examining the entire echo waveform, one must account for artifacts that are produced when objects interact acoustically. Some artifacts occur after the first detected echo, so these are not a problem in TOF sonar maps [21.4], but must be addressed in interpreting PAS maps. Consider a simple environment consisting of two posts: a 2.85 cm-diameter post (p), located at $r = 1$ m and bearing 12° , and an 8.9 cm-diameter post (P), at $r = 1.3$ m and bearing -10° . The corresponding

PAS map shown in Fig. 21.17 displays the echoes from the two objects plus additional echoes that illustrate two types of multiple reflection artifacts. The first type, indicated by A and B, results when only one object is within the transducer beam. An interrogation pulse that is redirected by a reflected object must be directed back to the receiver within its beam pattern in order to be detected. The paths that do this are shown in the figure. The single-arc convex shape of A indicates that the echo has a small amplitude. This is reasonable since both reflectors are nonplanar, and hence weak.

The second type of artifact (C) shown in Fig. 21.17 occurs when both objects are within the beam pattern.

This allows two distinct paths for the echoes to return to the receiver, occurring in opposite directions and doubling the artifact amplitude. With both objects lying near the beam edges, the echo amplitude is small. Since the distance traveled by these echoes is slightly greater than the range to the farther object, this artifact shows a range slightly beyond the more distant object. The superposition of these two components makes the echo from the farther object appear spread out in time. This pulse stretching explains why four arcs are observed, and at one angle five arcs. If the bearing angle between p and P was increased to exceed the beam width, this artifact would disappear.

21.10 Echo Waveform Processing

In this section pulse-echo sonar that processes sampled digitized receiver waveforms is described. These systems offer superior performance over the simple Polaroid ranging module systems described above, which report the **TOF** based on a threshold. Echo waveform processing does however incur the overhead of more-complex electronics and signal processing and is not readily available commercially.

21.10.1 Ranging and Wide-Bandwidth Pulses

It is shown in [21.11, 46] that the maximum-likelihood estimator (**MLE**) for the **TOF** is obtained by maximizing the correlation $\text{cor}(\tau)$ between the received pulse $p(t)$ (containing Gaussian white noise) and the known pulse shape shifted by τ , $\text{rec}(t - \tau)$

$$\text{cor}(\tau) = \frac{\int_a^b p(t)\text{rec}(t - \tau)dt}{\sqrt{\int_a^b p^2(t)dt \int_a^b \text{rec}^2(t)dt}}, \quad (21.15)$$

where the pulse extends from time a to b . The known pulse shape at the receiver depends on the angle of transmission and reception with respect to the normals of the respective transducers. The pulse shape can be obtained by collecting a good signal to noise pulse at 1 m range at normal incidence to the receiver and transmitter and using elliptical impulse response models to obtain template pulses at angles different to normal incidence. Pulse shape also changes with range due to the dispersive properties of absorption due losses in air transmission. These can be modeled using an estimate of the impulse

response due to one meter path through air as is done in [21.11].

The correlation, $\text{cor}(\tau)$ is normalized in (21.15) to be between -1 and $+1$. The correlation at the maximum thus gives a good indication of the match between the expected and actual pulse shapes and can be used to assess the quality of the **TOF** estimate. In practice (21.15) is used in discrete time form, where the integrals are replaced by sums of products and digital signal processors are an ideal implementation since they are highly optimized to perform this calculation [21.47, 48]. To achieve an arrival time estimator with resolution smaller than the discrete time sample rate, parabolic interpolation can be used on the maximum three correlations [21.11]. Of interest is the jitter standard deviation σ_R in the **TOF** estimator due to receiver noise. From [21.11, 46]

$$\sigma_R = \frac{\sigma_n}{B\sqrt{\sum_k \text{rec}(kT_s)^2}}, \quad (21.16)$$

where the summation index k is over the entire receiver pulse sampled every T_s seconds (1 μ s in [21.11, 47]), B is the bandwidth of the receiver pulse, and σ_n is the standard deviation of the receiver noise. Equation (21.16) shows that broadband high-energy pulses achieve low errors in the **TOF** estimator. In [21.11] this is achieved by using a 300 V pulse to excite the transmitter and achieve close to the impulse response from the device with a pulse shape similar to that shown in Fig. 21.6d.

21.10.2 Bearing Estimation

There are many proposed methods for bearing estimation. A single transducer [21.49] can be used by

exploiting the dependency of the received pulse shape on the angle of reception. This approach works for angles within one half of the beam width since the pulse shape is symmetric with respect to the transducer normal angle. Differences in zero-crossing times either side of the maximum amplitude of the pulse are used to obtain an accuracy of the order of 1° . Other single-receiver techniques rely on repeated measurements from a scan across the scene [21.50, 51] and achieve a similar level of accuracy but at much slower sensing speed since multiple readings are necessary.

Other single measurement approaches rely on two or more receivers [21.11, 12, 24]. This gives rise to a correspondence problem where data must be associated between the receivers. The closer the spacing between receivers, the simpler and more reliable the correspondence procedure. The misconception that bearing accuracy improves with larger receiver spacing ignores the correlation between measurement errors that can arise due to the measurements sharing an overlapping space of air in the propagation of the ultrasound. Due to the high accuracy of TOF estimation in [21.11] the receivers could be spaced as close as physically feasible (35 mm) and still bearing accuracies lower than any other systems are reported. Standard deviations of bearing errors are reported to be below 0.2° for a plane at a range of 4 m within a -10° to $+10^\circ$ beam width.

There are two common approaches to bearing estimation – interaural amplitude difference (IAD) [21.52] and interaural time difference (ITD) [21.11, 24, 47–49, 52]. IAD uses two receivers pointing away from each other so that an echo has a different amplitude response in each receiver's beam width. In ITD both receivers usually point in the same direction and the TOF is measured on each receiver and triangulation is applied to determine the angle of arrival. The bearing calculation is dependent on the target type, such as a plane, corner or edge; these geometries are analyzed in [21.11]. A simple arrangement with a transceiver and receiver is shown in Fig. 21.18, where T/R1 is the transceiver and R2 is the second receiver, spaced a distance d from each other. The virtual image of the transmitter is shown as T'. The two TOFs measured on the two receivers are t_1 and t_2 , and these are used to estimate the bearing angle, θ , to the plane which is the angle to the plane normal. Applying the cosine rule to the triangle R2 R1 T' in Fig. 21.18 gives

$$\cos(90 - \theta) = \sin \theta = \frac{d^2 + c^2 t_1^2 - c^2 t_2^2}{2dct_1}. \quad (21.17)$$

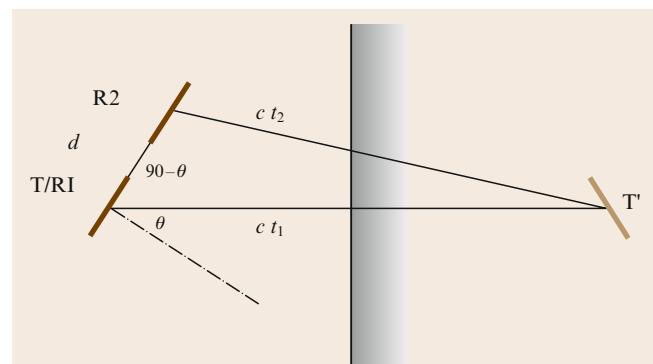

Fig. 21.18 Bearing (θ) calculation for a plane using a transceiver T/R1 and a receiver R2. T' is the virtual image of T

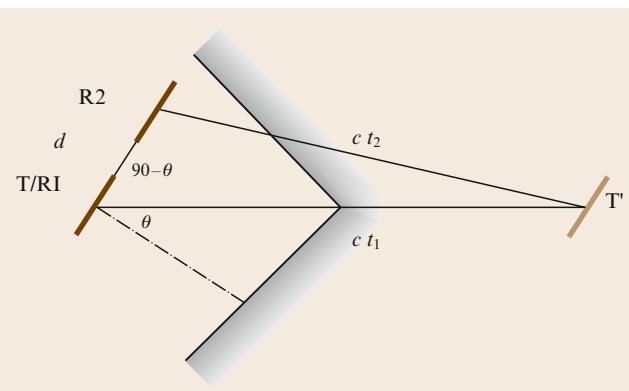

Fig. 21.19 Bearing (θ) calculation for a corner using a transceiver T/R1 and a receiver R2. T' is the virtual image of T

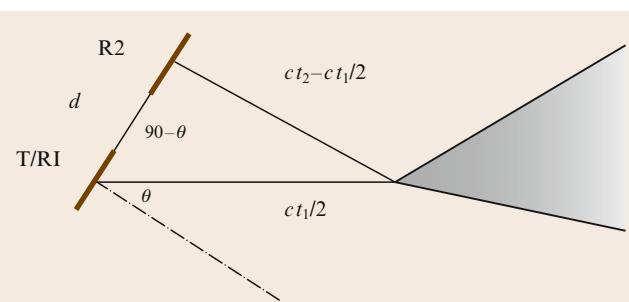

Fig. 21.20 Bearing (θ) calculation for an edge using a transceiver T/R1 and a receiver R2. No virtual image is present since the edge radiates from a point source at the edge

When $d \ll ct_1$, (21.17) can be approximated by

$$\sin \theta \approx \frac{c(t_1 - t_2)}{d}. \quad (21.18)$$

Note that any common (i.e., correlated) noise in t_1 and t_2 is removed by the difference in (21.18) and hence the correlation in noise components of the TOF cannot be overlooked in bearing estimation as described above.

The situation for a corner is shown in Fig. 21.19 and the same result applies as in (21.17). For an edge the situation is shown in Fig. 21.20, where R1 has a TOF from T to the edge and back to R1, whilst R2 has a TOF from T to the edge and back to R2. From the geometry,

we use the same approach as in (21.17) to give

$$\begin{aligned}\sin \theta &= \frac{d^2 + c^2 t_1^2 / 4 - c^2(t_2 - t_1/2)^2}{2dc t_1 / 2} \\ &= \frac{d^2 + c^2 t_2(t_1 - t_2)}{dc t_1}.\end{aligned}\quad (21.19)$$

Note that (21.19) can be approximated by (21.18) when $d \ll t_1$.

21.11 CTMF Sonar

Continuous-transmission frequency-modulated (CTMF) sonar differs from the more common pulse-echo sonar discussed in previous sections in the transmission coding and the processing required to extract information from the receiver signal.

21.11.1 CTMF Transmission Coding

The CTMF transmitter continuously emits a varying-frequency signal, usually based on a sawtooth pattern as shown in Fig. 21.21, where the frequency is often swept through an octave every sweep cycle T . The transmitted signal with a linearly changing frequency can be expressed as

$$S(t) = \cos[2\pi(f_{ht} - bt^2)] \quad (21.20)$$

for $0 \leq t < T$. The sweep cycle is repeated every T seconds as shown in Fig. 21.21. Frequency is $1/2\pi$ times the time derivative of the phase in (21.20). Note that the highest frequency is f_h and the lowest transmitted frequency is $f_h - 2bT$, where b is a constant that de-

termines the sweep rate. We can then define the swept frequency ΔF as

$$\Delta F = 2bT. \quad (21.21)$$

21.11.2 CTMF TOF Estimation

Echoes are generated when the transmitted wavefront encounters reflectors and are an attenuated, delayed version of the transmitted signal

$$E(t) = AS\left(t - \frac{2R}{c}\right), \quad (21.22)$$

where R is the range to the reflector, c is the speed of sound and A is the amplitude that may in the case of curved objects depend on the frequency of the sound at reflection.

The TOF is estimated by the two step process of demodulation and spectral analysis. Demodulation is achieved by multiplying the received signal by a copy of the transmitted signal and low pass filtering. This can best be understood in the simple case of one echo. The signal $D(t)$ is obtained using (21.20) and (21.22)

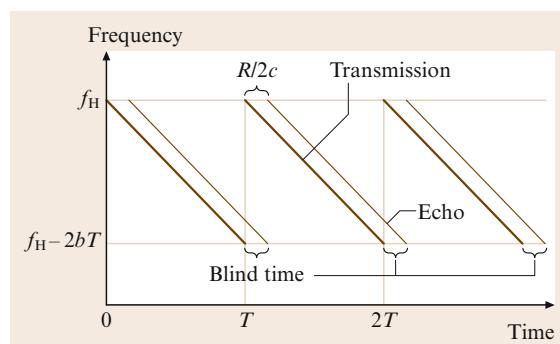

Fig. 21.21 Plot of frequency versus time for CTMF. The blind time applies if the shown echo corresponds to a maximum range target at R_m

$$\begin{aligned}D(t) &= E(t)S(t) \\ &= \frac{A}{2} [\cos(2\pi f_e t - \phi) \\ &\quad + \cos(2\pi f_u t - 2bt^2 - \phi)] \\ \text{for } f_e &= \frac{4Rb}{c}, \\ f_u &= \left(2f_h + \frac{4Rb}{c}\right), \\ \phi &= f_h \frac{2R}{c} + \frac{4bR^2}{c^2},\end{aligned}\quad (21.23)$$

where the following trigonometric identity has been used in (21.23)

$$\cos(x)\cos(y) = \frac{1}{2}[\cos(x-y) + \cos(x+y)]. \quad (21.24)$$

A low-pass filter removes frequency components above f_H and this results in the base-band signal:

$$D_b(t) = \frac{A}{2} \left[\cos \left(2\pi \frac{4Rb}{c} t - \phi \right) \right] \quad (21.25)$$

which has a frequency proportional to the range R . The ranges of echoes can be extracted by examining the spectrum of D_b using, for example, a discrete Fourier transform (DFT) or the fast Fourier transform (FFT) if the number of samples is a power of 2. From (21.25) for a frequency peak of f_r Hz the corresponding range R is given by

$$R = f_r \frac{c}{4b}. \quad (21.26)$$

Note that the above analysis relies on excluding the receiver waveform at the start of each sweep for a *blind time* (Fig. 21.21) of $R_m/2c$, where R_m is the maximum target range. During this blind time the receiver signal is dependent on the previous sweep rather than the current sweep as assumed in the analysis above. The sweep time T needs to be much larger than this blind time for the sonar to operate effectively. The blind time can be eliminated at the expense of introducing complexity in the demodulation process as described in [21.53], where an interlaced double demodulation scheme is described.

21.11.3 CTFM Range Discrimination and Resolution

We define range discrimination as the separation in range of two targets that can be simultaneously detected as distinct. The range resolution is defined as the smallest increment in range that can be measured by the sonar.

Suppose that, in order to extract ranges of targets, $D_b(t)$ from (21.25) is sampled at ΔT intervals and k samples are collected before a DFT (or FFT if k is a power of 2) is performed. The frequency samples of the DFT will be $\Delta f = 1/(k\Delta T)$ apart. From (21.26), this represents a range resolution ΔR of

$$\Delta R = \frac{c\Delta f}{4b} = \frac{c}{4bk\Delta T}. \quad (21.27)$$

We can relate this to the swept frequency ΔF from (21.21) as

$$\Delta R = \frac{c}{2\Delta F} \times \frac{T}{k\Delta T}, \quad (21.28)$$

where the second term is the ratio of the sweep time to the spectral sample time. In order to discriminate two peaks in the DFT, they must be at least two samples apart and hence

$$\text{range discrimination} = \frac{c}{\Delta F} \times \frac{T}{k\Delta T}. \quad (21.29)$$

Note that (21.28, 21.29) show that, subject to signal-to-noise constraints, CTFM can lengthen the *data integration time* $k\Delta T$ in order to improve the range discrimination and resolution of the sonar. Also it is possible, subject to signal noise, to use interpolation techniques (e.g. parabolic interpolation) on the DFT peaks to resolve to a smaller than Δf frequency and hence improve range resolution (but not range discrimination).

21.11.4 Comparison of CTFM and Pulse-Echo Sonar

- The range resolution of pulse-echo sonar and CTFM sonar is theoretically the same given the same signal-to-noise ratios and bandwidths [21.53]. The range discrimination in pulse-echo sonar is limited by the pulse length, where shorter pulse lengths require higher bandwidth. However in CTFM, range discrimination can be improved by increasing the data integration time, allowing more design flexibility.
- CTFM also allows for the energy of the transmitted signal to be spread evenly over time, resulting in lower peak acoustic power emission compared to pulse-echo systems with the same receiver signal-to-noise ratio. CTFM can provide a greater average power in a practical context and consequently a greater sensitivity to weak reflectors is possible.
- CTFM requires more-complex transmitter circuitry and the requirement for FFT processing on the receiver side.
- Separate transmitter and receiver transducers are necessary with CTFM, whilst pulse-echo systems can use a single transducer for both transmission and reception, resulting in restriction on the minimum range of pulse-echo sonar due to the blanking of the receiver during transmission. CTFM has no inherent restriction on minimum range.
- CTFM sonar can continuously derive range information from targets every $k\Delta T$ seconds at a delay of $R/c + k\Delta T$ compared to every $2R_m/c$ with a delay of $2R/c$ in pulse-echo sonar (ignoring processing

delays in both), which may be important in real-time tracking applications.

- Other benefits of **CTFM** are that the number of range measurements per cycle is limited only by the range discrimination constraint of (21.28) and the signal-to-noise ratio.
- In terms of bearing estimation and classification of targets from a moving platform, short pulse-echo sonar systems like [21.26, 47] do not suffer from the **CTFM** data integration time required to estimate accurately the frequencies corresponding to ranges (and hence bearing). During the data integration time, the target can move with respect to the sensor and blur the measurements, making bearing estimation and classification less accurate. In short pulse-echo systems, the target is effectively sampled with a pulse of less than $100\ \mu\text{s}$, resulting in a consistent snapshot of the target.

21.11.5 Applications of CTFM

Kay [21.54, 55] developed a mobility aid for blind people using a **CTFM** sonar system based on a sweep of $f_H = 100\ \text{kHz}$ down to $50\ \text{kHz}$ with a sweep period of $T = 102.4\ \text{ms}$. After demodulation, ranges are heard as audible tones with frequencies up to $5\ \text{kHz}$ corresponding to ranges of up to $1.75\ \text{m}$. The system uses one transmitter and three receivers as shown in Fig. 21.22. Users of the system can listen to the demodulated signal in stereo headphones corresponding to the left and right receivers, each mixed with the large central oval receiver. Higher frequencies correspond to more-distant ranges. To illustrate the sensitivity, a $1.5\ \text{mm}$ -diameter wire is easily detectable at $1\ \text{m}$ range – the echo produced is $35\ \text{dB}$ above the noise floor in the system.

CTFM sonar has been used to recognize isolated plants [21.40, 56]. The advantage gained from **CTFM** is that extensive range and echo amplitude information is obtained from the whole plant given the spectrum of the demodulated received signal, and these echoes are obtained from an excitation across an octave of frequencies from 100 down to $50\ \text{kHz}$ with a high signal-to-noise ratio that allows weak reflections from leaves to be sensed. This information is called the *acoustic density profile* and 19 different features are found to be useful in classifying the plants, such as the number of range cells above a threshold in amplitude, the sum of all range cells, the variation about the centroid, the distance from the first to the highest amplitude cell, and the range over which reflections are detected. With

Fig. 21.22 Aid for blind people – the small oval transducer is the transmitter and the other three components are receivers. The large oval receiver provides high resolution, enabling fixation by users' fine neck control (Photo courtesy [21.54])

a population of 100 plants, an average of 90.6% correct pairwise classification was obtained using a statistical classifier.

Scanning **CTFM** with a single transmitter and single receiver has been successfully applied to mapping of indoor environments that include smooth and rough surfaces [21.51] with bearing errors on the order of 0.5° for smooth surfaces and higher for edges. The classification uses amplitude information that is normalized with range using a fixed attenuation constant of sound. In practice this attenuation constant varies with temperature and humidity and needs to be calibrated before each experiment for consistent results. Greater robustness, speed, and accuracy has been demonstrated with **TOF** methods of classification that require at least two transmitter positions and two receivers as described in [21.11, 47]. **CTFM** could be applied to array systems to achieve higher sensitivity to weak targets than the existing pulse-echo systems.

CTFM has been employed in three binaural systems [21.12] where a rigorous theoretical and experimental comparison of these ultrasonic sensing systems based on different range and bearing estimators is made. *Stanley* [21.12] also contains detailed engineer-

ing design information of **CTFM** sonar systems. The conclusion is that **CTFM** can insonify large areas due to its higher average power transmissions and consequently good signal to noise performance. The use of autoregressive estimators for spectral lines in the demodulated signal were found to provide better res-

olution than the **DFT**. The interaural distance and power difference **CTFM** approaches provided state-of-the-art performance except that the pulse-echo approach in [21.11] using a high-energy short pulse was found to be a *factor of six to eight times* superior in bearing precision.

21.12 Multipulse Sonar

This section examines sonar systems that employ more than one pulse in the transmitter(s). The main motivations are interference rejection and on-the-fly classification. Multipulse sonar has also been used to generate a better signal-to-noise ratio by creating longer transmitted pulse sequence using Barker codes [21.57]. The autocorrelation of a Barker code gives a narrow peak with low autocorrelation away from the central lobe. The matched filter then gives rise to pulse compression that averages noise over a longer time period.

21.12.1 Interference Rejection

External acoustic noise, such as compressed air, is a source of sonar interference. Sonar systems attempt to reduce the effects of external interference by filtering the signal and the optimal filter is the matched filter where the impulse response is the time reversal of the pulse shape that is expected. Since a time-reversed convolution is a correlation, the matched filter then acts as a correlation with the expected pulse shape as discussed in Sect. 21.10. Approximations to matched filtering can be designed based on a bandpass filter with a frequency response that is similar to the spectrum of the expected receiver pulse. **CTFM** systems allow robust suppression of external interference by employing a matched filter across a broad range of frequencies contained in the continuous chirp transmission.

When more than one sonar system operates in the same environment, the transmitted signal from one sonar system can be received by another, causing crosstalk errors. This is particularly evident in classical sonar rings constructed from Polaroid ranging modules. Error-eliminating rapid ultrasonic firing strategies have been developed [21.58] and are claimed to remove most of this interference and allow faster operation of these sonar rings.

More-sophisticate coding of transmitted pulse(s) has been employed [21.22, 59–62] to allow rejection of external interference and crosstalk. One difficulty with

multiple transmitted pulses over an greater time period than a single pulse is that target clutter can produce many overlapping pulses at the receivers that are difficult to unravel and interpret, and the sonar range discrimination can be compromised.

21.12.2 On-the-Fly Target Classification

Target classification into planes, cylinders, and edges has been achieved by deploying a single transmitter and three receivers [21.24] using a single measurement cycle. At least two transmitters are required to differentiate planes from concave right-angled corners [21.11] where a two transmitter arrangement is used to classify targets into planes, corners, and edges in two successive measurement cycles. The method of classification can be understood with virtual images and mirrors, since specular sonar reflections occur. Looking into a plane mirror gives an image that is left-right reversed compared to looking into a right-angled mirror. An edge is analogous to observing a high-curvature specular surface, such as a polished chair leg, where the whole image is compressed to a point. Sonar classification exploits the difference in bearing angles to a target from two transmitters to classify as follows: a positive difference δ indicates a plane, a negative δ value indicates a corner, and zero difference an edge, where the angle δ depends on the sensor geometry and target range. More sophistication can be added by using range measurements in addition to bearing, with maximum-likelihood estimation.

This arrangement [21.11] was refined to work with just one measurement cycle of around 35 ms to 5 m range: hence the term *on-the-fly* in [21.47]. This on-the-fly approach uses pulses fired at a precise time difference ΔT and 40 mm apart from two transmitters with two further receivers completing a square. ΔT is usually around 200 μ s but can vary randomly from cycle to cycle to achieve interference rejection (both crosstalk and environmental) with identical sonar systems. Classification is performed simultaneously in one measurement cycle.

The sensor achieves high accuracy in range and bearing with robust classification by exploiting the tight correlation between TOF jitter in the different transmitter to

receiver paths due to the close temporal and spatial arrangement. The sensor has been deployed for large-scale mapping in [21.63].

21.13 Sonar Rings

21.13.1 Simple Ranging Module Rings

Since sonar only detects objects lying within its beam, a common means to scan the entire environment outside the robot is to use an array of sonars, or a *ring* [21.64]. The most common is the Denning ring that contains 24 sonars equally spaced around the robot periphery. This 15° spacing allows some overlap in the sonar beams so at least one of the sonars will detect a strong reflecting object. The sonars in the ring are typically employed sequentially one at a time. Using a 50 ms probing pulse period to reduce false readings a complete environmental scan is accomplished every 1.2 s. This sample time is adequate for a translate-and-stop operation in research settings, but may be too slow for a continually moving robot. A robot moving at 1 m/s may not detect an object with sufficient warning to prevent a collision. Some researchers propose simultaneously employing sonars on opposite ends of the

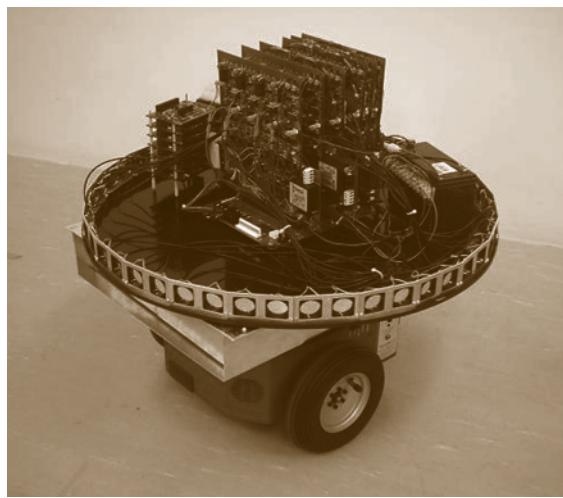

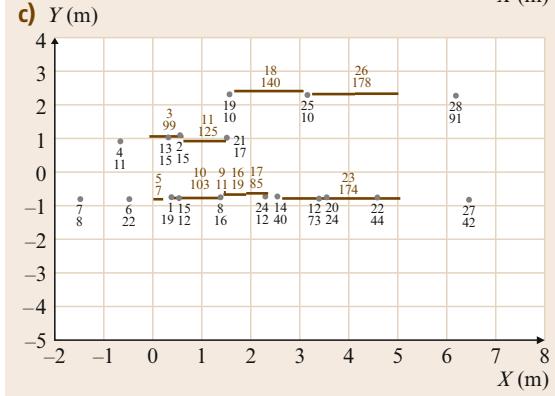

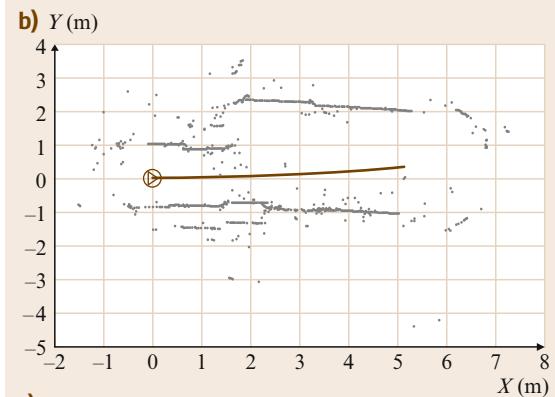

Fig. 21.23 DSP sonar ring hardware

Fig. 21.24a–c DSP sonar ring mapping an indoor environment (a), raw data (b) and SLAM feature map with feature number and number of associations shown as numbers (c). The sonar ring is moving at 10 cm/s with a 11.5 Hz sampling rate ►

ring to speed up acquisition times, while others also reduce the probing pulse period and attempt to identify artifacts.

21.13.2 Advanced Rings

Yata et al. [21.49] developed a 32 cm-diameter sonar ring with 30 transmitters and 30 receivers placed alternately. Murata piezoelectric MA40S4R wide-angle transducers are used to enable overlapping reception of echoes produced by firing all the transmitters simultaneously. An axial symmetrical exponential horn structure is used to narrow the beam shape of the transmitters vertically to avoid reflections from the floor. Received signals are compared with a decaying threshold to produce a 1 bit digitized sampled signal without rectification. Bearing is estimated from the leading edge of echoes and an error standard deviation of 0.4° is reported for ranges up to 1.5 m.

A sonar ring with seven digital signal processors (DSPs) [21.48, 65, 66] that uses 24 pairs of 7000 series Polaroid transducers consisting of a transceiver and receiver has been developed (Fig. 21.23). Each

pair can derive range and accurate bearing information using template-matching digital signal processing (Sect. 21.10) on each of the two receiver channels, which are sampled at 250 kHz with 12 bit analog to digital converters. In total eight receiver channels are processed per DSP. All transceivers are fired simultaneous to enable full surrounding sensing of the environment approximately 11 times a second to a 6 m range with experimentally validated range and bearing accuracies to smooth targets of 0.6 mm and 0.2°, respectively. To suppress interference between neighboring pairs, two different transmitted pulse shapes are employed in an interleaved fashion around the perimeter of the ring. The pulse shapes are derived from two and three cycles of 65 kHz excitation. The DSP sonar ring allows rapid and accurate wall following, map building, and obstacle avoidance due to the high repetition and accurate range and bearing sensing. The beam width of the transducer pairs allows full 360° coverage with respect to smooth specular targets to a range of 3 m. An example of the DSP sonar ring producing a feature for a simultaneous localization and mapping (SLAM) map is shown in Fig. 21.24.

21.14 Motion Effects

When a sensor moves with respect to its targets, sonar measurements are effected. For example, a sonar sensor moving at a speed of 1% of the speed of sound (around 3.4 m/s) will experience errors of the order of 0.6° for some bearing measurements. The effects of linear velocity on the TOF and reception angle are dependent on the target type and hence for motion compensation to be meaningful a target classification sensor is needed. We consider the classical plane, edge, and corner target types in this section. Rotational motion effects are discussed in [21.26] where it is shown that very high speeds of rotation are necessary to give rise to a small bearing error (e.g., 0.1° error for approximately 1700 deg/s). Narrowing of the effective beam width is another effect of high rotation speeds of a sonar sensor.

The sensor is assumed to transmit from a point labeled T and receiver measurements are referenced to this position on the sensor. However, due to the motion of the sensor, the ground referenced position R at the time of reception of the echo moves from T over the course of the TOF. For a linear velocity, the distance between T and R is $\text{TOF} \times v$, where v is the magnitude of the sensor velocity vector relative to the ground, with com-

ponents v_x and v_y parallel to their respective coordinate axes. The expressions derived for linear motion apply to any sonar sensor, since only the physics of sound propagation and reflection are used. All targets are assumed to be stationary.

This section is based on [21.26], where further experimental work not included here can be found.

21.14.1 Moving Observation of a Plane

A plane target reflects the transmission from position T to R as shown in Fig. 21.25a. The TOF is broken up into two parts: t_1 is the time of propagation to the plane and t_2 from the plane to the receiver R. Here we derive the effect of linear motion on the $\text{TOF} = t_1 + t_2$ and the angle of reception θ all taken from the view of a *stationary observer*. A moving observer is discussed below.

From the right-angle triangle on the left of Fig. 21.25a, we have

$$\sin \theta = \frac{v_x}{c} \quad \text{and} \quad \cos \theta = \sqrt{1 - \left(\frac{v_x}{c}\right)^2} \quad (21.30)$$

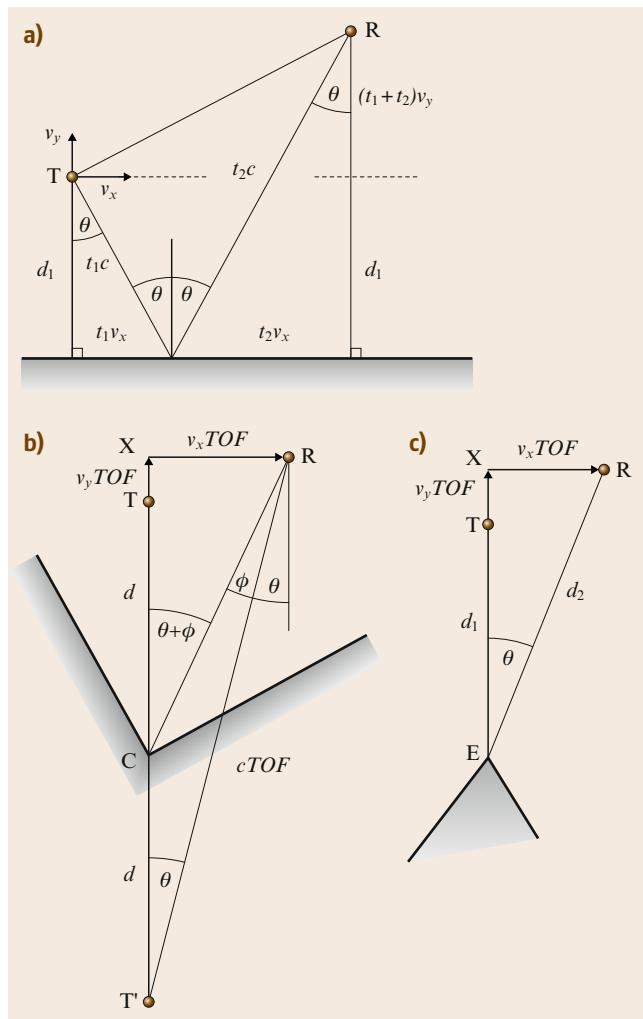

Fig. 21.25a–c Observing a target from a moving sensor. T is the position of the transmitter and R is where the echo is received at the end of the TOF. The target is a plane in (a), a corner in (b), and an edge in (c)

and also

$$\cos \theta = \frac{d_1}{t_1 c} \implies t_1 = \frac{d_1}{c \cos \theta}. \quad (21.31)$$

From the right-angled triangle on the right of Fig. 21.25a, we have

$$\cos \theta = \frac{(t_1 + t_2)v_y + d_1}{t_2 c} \implies t_2 = \frac{(t_1 + t_2)v_y + d_1}{c \cos \theta}. \quad (21.32)$$

The TOF is obtained by adding (21.31) and (21.32) and then substituting (21.31) giving

$$\text{TOF} = \left(\frac{2d_1}{c} \right) \frac{1}{\sqrt{1 - \frac{v_x^2}{c^2} - \frac{v_y}{c}}}. \quad (21.33)$$

The first factor in (21.33) represents the stationary TOF. The second factor approaches unity as the velocity approaches zero.

21.14.2 Moving Observation of a Corner

Figure 21.25b shows the situation for a corner with the virtual image of T is shown as T'. From the right-angled triangle T'XR

$$c^2 \text{TOF}^2 = (2d_1 + v_y \text{TOF})^2 + v_x^2 \text{TOF}^2 \quad (21.34)$$

which gives

$$\text{TOF} = \frac{2d_1}{c} \left[\frac{\sqrt{1 - \left(\frac{v_x}{c}\right)^2} + \frac{v_y}{c}}{1 - \left(\frac{v_y}{c}\right)^2} \right], \quad (21.35)$$

where $v^2 = v_x^2 + v_y^2$. The left-hand term of (21.35) is the stationary TOF and the right-hand term approaches unity for small velocities. The angle ϕ in Fig. 21.25b is the angle deviation due to motion as reference by a stationary observer. From the triangles T'XR and CXR

$$\begin{aligned} \tan \theta &= \frac{v_x \text{TOF}}{2d_1 + v_y \text{TOF}} \quad \text{and} \\ \tan(\theta + \phi) &= \frac{v_x \text{TOF}}{d_1 + v_y \text{TOF}}. \end{aligned} \quad (21.36)$$

From (21.36), we have

$$\tan(\theta + \phi) = \left(2 - \frac{v_y \text{TOF}}{d_1 + v_y \text{TOF}} \right) \tan \theta \quad (21.37)$$

and solving for $\tan \phi$ yields

$$\begin{aligned} \tan \phi &= \tan \theta \left(\frac{1 - \sin^2 \theta}{\frac{v_y \text{TOF}}{d_1} + 1 + \sin^2 \theta} \right) \\ &= \left(\frac{v_x}{\frac{2d_1}{\text{TOF}} + v_y} \right) \left(\frac{1 - \sin^2 \theta}{\frac{v_y \text{TOF}}{d_1} + 1 + \sin^2 \theta} \right). \end{aligned} \quad (21.38)$$

For $v_x, v_y \ll c$, $\sin \theta \ll 1$ and $2d_1/\text{TOF} \approx c$ we can approximate (21.38) as

$$\phi \approx \frac{v_x}{c}. \quad (21.39)$$

21.14.3 Moving Observation of a Edge

Since an edge reradiates the incoming ultrasound from an effective point source, the reception angle with respect to a stationary observer is unaffected by motion as shown in Fig. 21.25c. The TOF is affected due to the motion moving the receiving position. From the right-angled triangle XER, $d_2^2 = (d_1 + v_y)^2 + v_x^2 \text{TOF}^2$ and $d_1 + d_2 = c \text{TOF}$ leads to

$$\text{TOF} = \frac{2d_1}{c} \left(\frac{1 + \frac{v_y}{c}}{1 - \frac{v_y^2}{c^2}} \right) \approx \frac{2d_1}{c} \left(1 + \frac{v_y}{c} \right), \quad (21.40)$$

where the approximate holds in (21.40) for $v \ll c$.

21.14.4 The Effect of a Moving Observation on the Angle of Reception

The expressions for the reception angle in the previous sections are based on an observer that is stationary with respect to the propagating medium air. In practice the observer is the sensor, and is moving with a velocity v . Suppose that the sonar wave arrives at an angle α relative to the air, as shown in Fig. 21.26. The velocity components of the wavefront relative to the observer, w_x and w_y , are as follows

$$w_x = c \sin \alpha - v_x \text{ and } w_y = c \cos \alpha - v_y. \quad (21.41)$$

From (21.41) the observed angle of arrival, β is

$$\tan \beta = \frac{c \sin \alpha - v_x}{c \cos \alpha - v_y} = \frac{\sin \alpha - \frac{v_x}{c}}{\cos \alpha - \frac{v_y}{c}}. \quad (21.42)$$

21.14.5 Plane, Corner, and Edge Moving Observation Arrival Angles

In this section the arrival angles (in radians) for each target type are summarized and approximated for speeds expected of a mobile robot. The speed is assumed

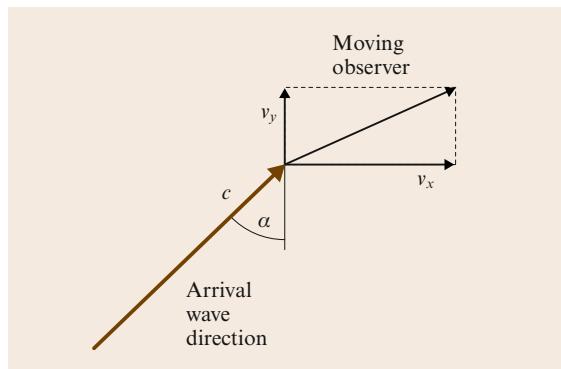

Fig. 21.26 Observation of arriving wave from a moving observer

to be less than a few percent of the speed of sound (typically 340 m/s at room temperature). These effects have been observed experimentally at speeds of up to 1 m/s [21.26].

Equations (21.41) and (21.30) cancel exactly, and for a plane the arrival angle relative to the sensor is exactly zero

$$\beta_{\text{plane}} = 0. \quad (21.43)$$

This can be explained by noting that the forward wave velocity component is always the same as the sensor's as reflection preserves this component.

For a corner the angle ϕ results in a wavefront that appears to be displaced in the same direction as the sensor motion from the real corner direction, as can be seen in Fig. 21.25b. The effect of the moving observer doubles this effect as seen by (21.41) and (21.39)

$$\beta_{\text{corner}} \approx -\frac{2v_x}{c}. \quad (21.44)$$

For an edge the result is due to the observer only

$$\beta_{\text{edge}} \approx \tan^{-1} \left(\frac{0 - \frac{v_x}{c}}{\cos \alpha - \frac{v_y}{c}} \right) \approx -\frac{v_x}{c}. \quad (21.45)$$

21.15 Biomimetic Sonars

The success of biosonars, bats and dolphins [21.67], has led researchers to implement sonars based on biosonar morphology, strategy, and nonlinear processing. The capabilities exhibited by biosonars have caused researchers to examine biomimicking (*biomimetic*) systems.

Biosonar morphology typically has a single transmitter and a pair of receivers. Bats transmit sound pulses through the mouth or nose, while dolphins transmit through a melon. The two receivers correspond to ears that permit binaural processing. Mimicking binaural hearing has led to small arrays that localize objects [21.8]

Fig. 21.27 Biomimetic configuration sonar with center transmitter flanked by receivers that rotate

and scanning strategies [21.68]. Movable pinnae observed in bats have motivated research in receivers that rotate [21.69, 70]. Figure 21.27 shows one such example.

Rotating the receivers so their axes fall onto the reflecting object not only increases the detected echo amplitude, but also its bandwidth, both effects improving the ability to classify an object.

Biosonar strategy provides clues for successful object localization. It is well known that the object location within the transducer beam affects the echo waveform and complicates the inverse problem of object classification [21.10, 71]. Dolphin movies show that they maneuver to position an object at a repeatable location and range, guided by binaural echo processing. This has motivated a dolphin-mimicking movable sonar positioned at the end of a robot arm for object classification [21.10, 71], as shown in Fig. 21.28. This system was able to differentiate reliably the head and tail side of a coin, but only after introducing a scan in elevation to accommodate for the lack of such positioning afforded by binaural hearing. The idea for a scan over elevation was motivated by the nodding motion that dolphins exhibit when searching for prey lying under the sand.

Another useful strategy, suggested by probing pulses emitted by bats, is processing echo sequences. As an

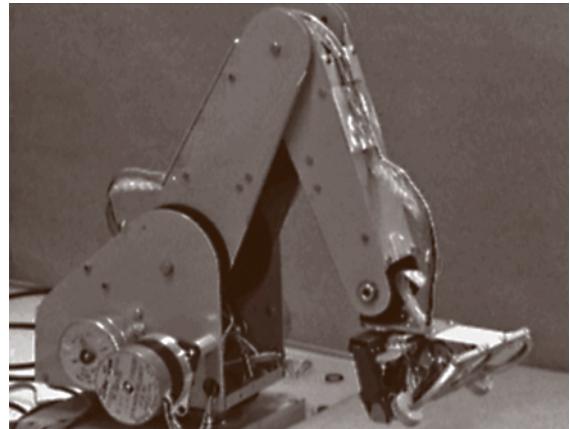

Fig. 21.28 Biomimetic sonar mounted on the end of a robot arm

extension to the conventional stop-and-scan operation of most sonars, sonar data were acquired while the sonar was moving along piecewise linear paths to reveal hyperbolic trends, similar to acoustic flow [21.72]. Matching data to hyperbolic trends permits the estimation of the passing range, which is useful for collision avoidance and passing through narrow openings [21.72].

Most sonar systems use classical estimation procedures involving correlation detection and spectrum analysis. The cochlear model has led to multiple band-pass filters to process wide-band pulses for environmental landmark classification [21.73]. The action potential spikes observed in the biological nervous system also suggest neuromorphic processing based on coincidence detection. The sparse information provided by conventional TOF measurements motivated sonar detectors that provided complete echo waveform information from multiple detections that result in spike-like data [21.23, 74]. Applying temporal and spatial coincidence to spike data has led to reverberation artifact recognition [21.35] and passing-range estimation [21.75].

Such biomimetic techniques provide insights into the information content present in echoes and the type of sensing tasks for which sonar is best suited.

21.16 Conclusions

Sonar is a useful, inexpensive, low-power, light-weight and simple ranging sensor for robotics applications

that can provide accurate object localisation. For sonar to be effectively employed, understanding its physical

principles and implementation is important and these topics are covered in the early sections of this chapter. Various approaches to sonar sensing are highlighted from simple single-transducer ranging to more sophisticated multi-transducer and multi-pulse configurations with associated signal processing requirements. Sophisticated sonars are capable of measuring target range and angle accurately as well as classifying targets, reject-

ing interference, and compensating for motion. Sonar rings provide surrounding environmental coverage, and CTFM systems improve the sensitivity for detecting small reflectors. Research is ongoing in areas such as signal and data processing, sonar map building, sonar configurations, transducer technology and biomimetic sonar that draw inspiration from biological sonar systems, such as used by bats and dolphins.

22. Range Sensors

Range Sensors

Robert B. Fisher, Kurt Konolige

Range sensors are devices that capture the three-dimensional (3-D) structure of the world from the viewpoint of the sensor, usually measuring the depth to the nearest surfaces. These measurements could be at a single point, across a scanning plane, or a full image with depth measurements at every point. The benefit of this range data is that a robot can be reasonably certain where the real world is, relative to the sensor, thus allowing the robot to more reliably find navigable routes, avoid obstacles, grasp objects, act on industrial parts, etc.

This chapter introduces the main representations for range data (point sets, triangulated surfaces, voxels), the main methods for extracting usable features from the range data (planes, lines, triangulated surfaces), the main sensors for acquiring it (Sect. 22.1 – stereo and laser triangulation and ranging systems), how multiple observations of the scene, e.g., as if from a moving robot, can be registered (Sect. 22.2), and several indoor and outdoor robot applications where range data greatly simplifies the task (Sect. 22.3).

22.1 Range Sensing Basics

Here we present: (1) the basic representations used for range image data, (2) a brief introduction to the main 3-D sensors that are less commonly used in robotics applications, and (3) a detailed presentation of the commoner laser-based range image sensors.

22.1.1 Range Images and Point Sets

Range data is a $2\frac{1}{2}$ -D or 3-D representation of the scene around the robot. The 3-D aspect arises because we are measuring the (X, Y, Z) coordinates of one or more points in the scene. Often only a sin-

gle range image is used at each time instance. This means that we only observe the front sides of objects – the portion of the scene visible from the robot. In other words, we do not have a full 3-D observation of all sides of a scene. This is the origin of the term $2\frac{1}{2}$ -D. Figure 22.1a shows a sample range image and Fig. 22.1b shows a registered reflectance image, where each pixel records the level of reflected infrared light.

There are two standard formats for representing range data. The first is an image $d(i, j)$, which records the distance d to the corresponding scene point (X, Y, Z)

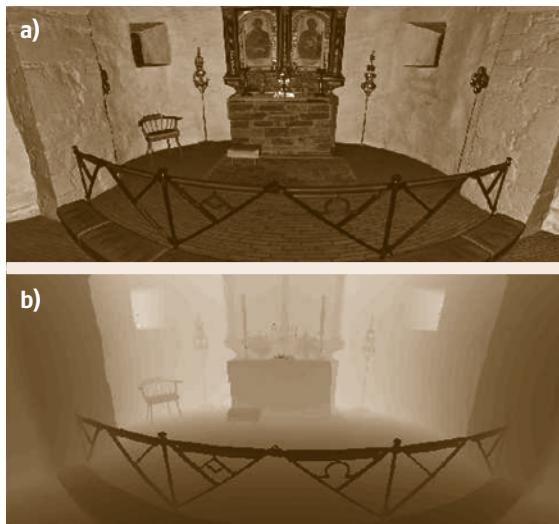

Fig. 22.1 (a) Registered infrared reflectance image. (b) Range image where closer is darker

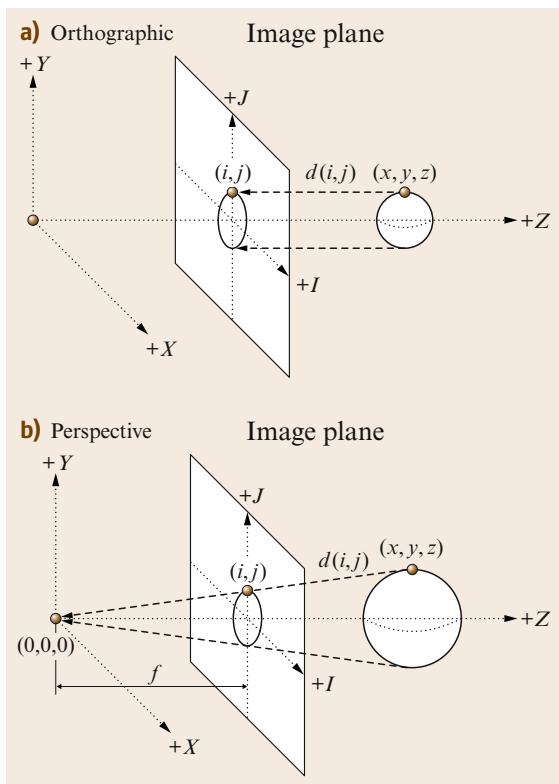

Fig. 22.2a,b Different range image mappings: (a) orthographic and (b) perspective

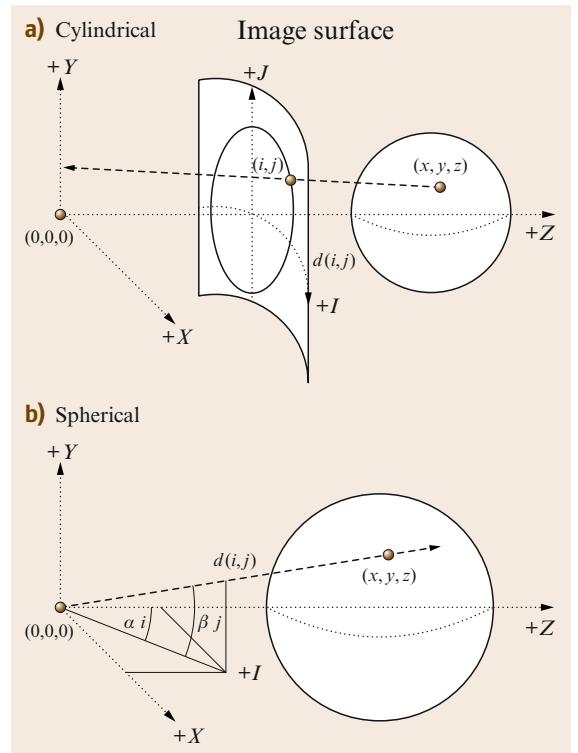

Fig. 22.3a,b Different range image mappings: (a) cylindrical and (b) spherical

for each image pixel (i, j) . There are several common mappings from $(i, j, d(i, j))$ to (X, Y, Z) , usually arising from the geometry of the range sensor. The most common image mappings are illustrated in Figs. 22.2 and 22.3. In the formulas given here, α and β are calibrated values specific to the sensor.

1. *Orthographic.* Here $(X, Y, Z) = (\alpha i, \beta j, d(i, j))$. These images often arise from range sensors that scan by translating in the x and y directions. (Fig. 22.2a.)
2. *Perspective.* Here $d(i, j)$ is the distance along the line of sight of the ray through pixel (i, j) to point (x, y, z) . Treating the range sensor focus as the origin $(0, 0, 0)$ and assuming that its optical axis is the Z axis and that the (X, Y) axes are parallel to the image (i, j) axes, then $(X, Y, Z) = d(i, j)/\sqrt{\alpha^2 i^2 + \beta^2 j^2 + f^2}(\alpha i, \beta j, f)$, where f is the *focal length* of the system. These images often arise from sensor equipment that incorporates a normal intensity camera. (Fig. 22.2b.)

3. *Cylindrical*. Here, $d(i, j)$ is the distance along the line of sight of the ray through pixel (i, j) to point (X, Y, Z) . In this case, the sensor usually rotates to scan in the x direction, and translates to scan in the y direction. Thus, $(X, Y, Z) = (d(i, j) \sin(\alpha i), \beta j, d(i, j) \cos(\alpha i))$ is the usual conversion. (Fig. 22.3a.)
4. *Spherical*. Here, $d(i, j)$ is the distance along the line of sight of the ray through pixel (i, j) to point (X, Y, Z) . In this case, the sensor usually rotates to scan in the x direction, and, once each x scan, also rotates in the y direction. Thus (i, j) are the azimuth and elevation of the line of sight. Here $(X, Y, Z) = d(i, j)(\cos(\beta j) \sin(\alpha i), \sin(\beta j), \cos(\beta j) \cos(\alpha i))$. (Fig. 22.3b.)

Some sensors only record distances in a plane, so the scene (x, z) is represented by the linear image $d(i)$ for each pixel i . The orthographic, perspective, and cylindrical projection options listed above still apply in simplified form.

The second format is as a list $\{(X_i, Y_i, Z_i)\}$ of 3-D data points, but this format can be used with all of the mappings listed above. Given the conversions from image data $d(i, j)$ to (X, Y, Z) the range data is only supplied as a list. Details of the precise mapping and data format are supplied with commercial range sensors.

22.1.2 Stereo Vision

It is possible to acquire range information from many different sensors, but only a few have the reliability needed for most robotics applications. The more reliable ones, laser-based triangulation and laser radar (**LIDAR**), are discussed in the next section.

Real-time stereo analysis uses two or more input images to estimate the distance to points in a scene. The basic concept is *triangulation*: a scene point and the two camera points form a triangle, and knowing the baseline between the two cameras, and the angle formed by the camera rays, the distance to the object can be determined.

In practice, there are many difficulties in making a stereo imaging system that is useful for robotics applications. Most of these difficulties arise in finding reliable matches for pixels in the two images that correspond to the same point in the scene. A further consideration is that stereo analysis for robotics has a real-time constraint, and the processing power needed for some algorithms can be very high. However, in recent years much progress has been made, and the advantage of

stereo imaging is that it can provide full 3-D range images, registered with visual information, potentially out to an infinite distance, at high frame rates – something which no other range sensor can match.

In this subsection we will review the basic algorithms of stereo analysis, and highlight the problems and potential of the method. For simplicity, we use binocular stereo.

Stereo Image Geometry

This subsection gives some more detail of the fundamental geometry of stereo, and in particular the relationship of the images to the 3-D world via projection and re-projection. A more in-depth discussion of the geometry, and the rectification process, can be found in [22.2].

The input images are *rectified*, which means that the original images are modified to correspond to ideal pinhole cameras with a particular geometry, illustrated in Fig. 22.4. Any 3-D point S projects to a point in the images along a ray through the focal point. If the principal rays of the cameras are parallel, and the images are

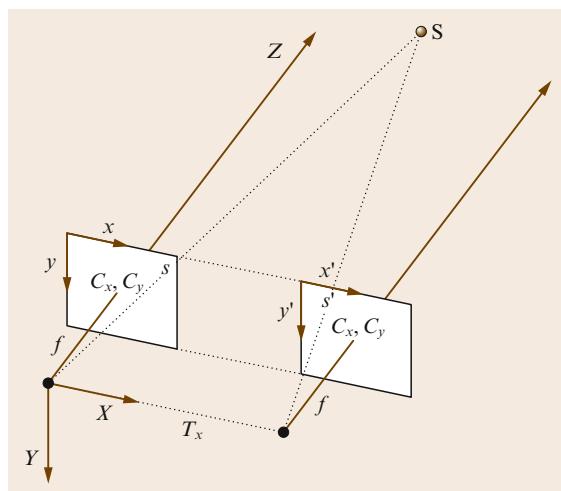

Fig. 22.4 Ideal stereo geometry. The global coordinate system is centered on the focal point (camera center) of the left camera. It is a right-handed system, with positive Z in front of the camera, and positive X to the right. The camera principal ray pierces the image plane at C_x, C_y , which is the same in both cameras (a variation for *verged* cameras allows C_x to differ between the images). The focal length is also the same. The images are lined up, with $y = y'$ for the coordinates of any scene point projected into the images. The difference between the x coordinates is called the *disparity*. The vector between the focal points is aligned with the X -axis [22.1]

embedded in a common plane and have collinear scan lines, then the search geometry takes a simple form. The *epipolar line* of a point s in the left image, defined as the possible positions of s' in the right image, is always a scan line with the same y coordinate as s . Thus, the search for a stereo match is linear. The process of finding a rectification of the original images that puts them into standard form is called *calibration*, and is discussed in [22.2].

The difference in the x coordinates of s and s' is the *disparity* of the 3-D point, which is related to its distance from the focal point, and the baseline T_x that separates the focal points.

A 3-D point can be projected into either the left or right image by a matrix multiplication in homogenous coordinates, using the *projection matrix*. The 3-D coordinates are in the frame of the left camera (Fig. 22.4).

$$\mathbf{P} = \begin{pmatrix} F_x & 0 & C_x & -F_x T_x \\ 0 & F_y & C_y & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}. \quad (22.1)$$

This is the projection matrix for a single camera. F_x and F_y are the focal lengths of the rectified images, and C_x, C_y is the optical center. T_x is the translation of the camera relative to the left (reference) camera. For the left camera, it is 0; for the right camera, it is the baseline times the x focal length.

A point in three dimensions is represented by homogeneous coordinates and the projection is performed using a matrix multiplication

$$\begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \mathbf{P} \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix}, \quad (22.2)$$

where $(x/w, y/w)$ are the idealized image coordinates.

If points in the left and right images correspond to the same scene feature, the depth of the feature can be calculated from the image coordinates using the *reprojection matrix*

$$\mathbf{Q} = \begin{pmatrix} 1 & 0 & 0 & -C_x \\ 0 & 1 & 0 & -C_y \\ 0 & 0 & 0 & F_x \\ 0 & 0 & -1/T_x & (C_x - C_{x'})/T_x \end{pmatrix}. \quad (22.3)$$

The primed parameters are from the left projection matrix, the unprimed from the right. The last term is zero except for verged cameras. If x, y and x', y are the two

matched image points, with $d = x - x'$, then

$$\begin{pmatrix} X \\ Y \\ Z \\ W \end{pmatrix} = \mathbf{Q} \begin{pmatrix} x \\ y \\ d \\ 1 \end{pmatrix}, \quad (22.4)$$

where $(X/W, Y/W, Z/W)$ are the coordinates of the scene feature, and $d = x' - x$ is the disparity. Assuming $C_x = C'_x$, the Z distance assumes the familiar inverse form of triangulation

$$Z = \frac{F - xT_x}{d}. \quad (22.5)$$

Reprojection is valid only for rectified images – for the general case, the projected lines do not intersect. The disparity d is an *inverse depth* measure, and the vector (x, y, d) is a perspective representation range image (see Sect. 22.1.1), sometimes called the *disparity space* representation. The disparity space is often used in applications instead of 3-D space, as a more efficient representation for determining obstacles or other features (see Sect. 22.3.3).

Equation (22.4) is a homography between disparity space and 3-D Euclidean space. Disparity space is also useful in translating between 3-D frames. Let $p_0 = (x_0, y_0, d_0, 1)$ in frame 0, with frame 1 related by the rigid motion R, t . From the reprojeciton (22.4) the 3-D position is $\mathbf{Q}p_0$. Under the rigid motion this becomes $\begin{pmatrix} R & t \\ 0 & 1 \end{pmatrix} \mathbf{Q}p_0$, and finally applying \mathbf{Q}^{-1} yields the disparity representation in frame 1. The concatenation of these operations is the homography

$$H(R, t) = \mathbf{Q}^{-1} \begin{pmatrix} R & t \\ 0 & 1 \end{pmatrix} \mathbf{Q}. \quad (22.6)$$

Using the homography allows the points in the reference frame to be directly projected onto another frame, without translating to 3-D points.

Stereo Methods

The fundamental problem in stereo analysis is matching image elements that represent the same object or object part in the scene. Once the match is made, the range to the object can be computed using the image geometry.

Matching methods can be characterized as local or global. Local methods attempt to match small regions of one image to another based on intrinsic features of the region. Global methods supplement local methods by considering physical constraints such as surface continuity or base of support. Local methods can be further

classified by whether they match discrete features among images, or correlate a small area patch [22.3]. Features are usually chosen to be lighting and viewpoint independent, e.g., corners are a natural feature to use because they remain corners in almost all projections. Feature-based algorithms compensate for viewpoint changes and camera differences, and can produce rapid, robust matching, but they have the disadvantage of requiring perhaps expensive feature extraction, and yielding only sparse range results.

In the next section we present local area correlation in more detail, since it is one of the most efficient and practical algorithms for real-time stereo. A survey and results of recent stereo matching methods is in [22.5], and the authors maintain a web page listing up-to-date information [22.6].

Area Correlation Stereo

Area correlation compares small patches among images using correlation. The area size is a compromise, since small areas are more likely to be similar in images with different viewpoints, while larger areas increase the signal-to-noise ratio. In contrast to the feature-based method, area-based correlation produces dense results. Because area methods need not compute features, and have an extremely regular algorithmic structure, they can have optimized implementations.

The typical area correlation method has five steps (Fig. 22.5).

1. Geometry correction. In this step, distortions in the input images are corrected by warping into a *standard form*.
2. Image transform. A local operator transforms each pixel in the grayscale image into a more appropriate form, e.g., normalizes it based on average local intensity.
3. Area correlation. This is the correlation step, where each small area is compared with other areas in its search window.
4. Extrema extraction. The extreme value of the correlation at each pixel is determined, yielding a disparity image: each pixel value is the disparity between left and right image patches at the best match.
5. Postfiltering. One or more filters clean up noise in the disparity image result.

Correlation of image areas is disturbed by illumination, perspective, and imaging differences among images. Area correlation methods usually attempt to compensate by correlating not the raw intensity images, but some transform of the intensities. Let u, v be

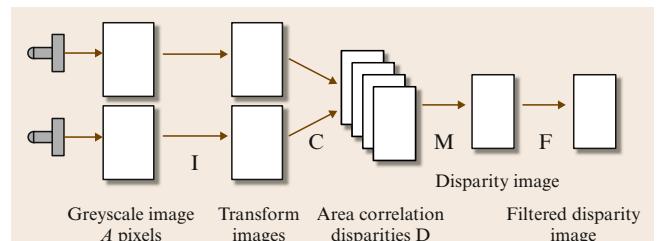

Fig. 22.5 Basic stereo processing. See text for details [22.4]

the center pixel of the correlation, x, y be pixels in the neighborhood about u, v the disparity, and $I_{x,y}, I'_{x,y}$ the intensities of the left and right images.

1. Normalized cross-correlation.

$$\frac{\sum_{x,y} [I_{x,y} - \hat{I}_{x,y}] [I'_{x-d,y} - \hat{I}'_{x-d,y}]}{\sqrt{\sum_{x,y} [I_{x,y} - \hat{I}_{x,y}]^2 \sum_{x,y} [I'_{x,y} - \hat{I}'_{x-d,y}]^2}}$$

2. High-pass filter such as Laplacian of Gaussian (LOG). The Laplacian measures directed edge intensities over some area smoothed by the Gaussian. Typically the standard deviation of the Gaussian is 1–2 pixels.

$$\sum_{x,y} s(\log_{x,y} - \log_{x-d,y}).$$

Where $s(x)$ is x^2 or $\|x\|$ and $\log_{x,y}$ is the Laplacian of Gaussian at pixel x, y .

3. Nonparametric. These transforms are an attempt to deal with the problem of outliers, which tend to overwhelm the correlation measure, especially using a square difference. The census method [22.7] computes a bit vector describing the local environment of a pixel, and the correlation measure is the Hamming distance between two vectors

$$\sum_{x,y} (I_{x,y} > I_{u,v}) \oplus (I'_{x-d,y} > I'_{u,v}).$$

Results on the different transforms and their error rates for some standard images are compiled in [22.6].

Another technique for increasing the signal-to-noise ratio of matches is to use more than two images [22.8]. This technique can also overcome the problem of viewpoint occlusion, where the matching part of an object does not appear in the other image. The simple technique of adding the correlations between images at the same disparity seems to work well [22.9]. Obviously, the computational expenditure for multiple images is greater than for two.

Dense range images usually contain false matches that must be filtered, although this is less of a prob-

Table 22.1 Post-filtering techniques for eliminating false matches in area correlation

| Correlation surface | [22.10] |
|------------------------------|----------------------------------------------------|
| Peak width | Wide peak indicates poor feature localization |
| Peak height | Small peak indicates poor match |
| Number of peaks | Multiple peaks indicate ambiguity |
| Mode filter | Lack of supporting disparities violates smoothness |
| Left/right check [22.11, 12] | Nonsymmetric match indicates occlusion |
| Texture [22.13] | Low texture energy yields poor matches |

lem with multiple-image methods. Table 22.1 lists some of the postfilters that have been discussed in the literature.

Disparity images can be processed to give subpixel accuracy, by trying to locate the correlation peak between pixels. This increases the available range resolution without much additional work. Typical accuracies are a tenth of a pixel.

Stereo Range Quality

Various artifacts and problems affect stereo range images.

Smearing. Area correlation introduces expansion in foreground objects, e.g., the woman's head in Fig. 22.6. The cause is the dominance of strong edges on the object. Nonparametric measures are less subject to this phenomenon. Other approaches include multiple correlation windows and shaped windows.

Dropouts. These are areas where no good matches can be found because of low texture energy. Dropouts are a problem for indoor and outdoor manmade surfaces. Projecting an infrared random texture can help [22.14].

Range resolution. Unlike laser radar (**LADAR**) devices, stereo range accuracy is a quadratic function of distance, found by differentiating (22.5) with respect to disparity:

$$\delta Z = -\frac{F_x T_x}{d^2}. \quad (22.7)$$

The degradation of stereo range with distance can be clearly seen in the 3-D reconstruction of Fig. 22.6.

Processing. Area correlation is processor intensive, requiring Awd operations, where A is the image area, w the correlation window size, and d the number of disparities. Clever optimizations take advantage of redundant calculations to reduce this to Ad (independent of window size), at the expense of some

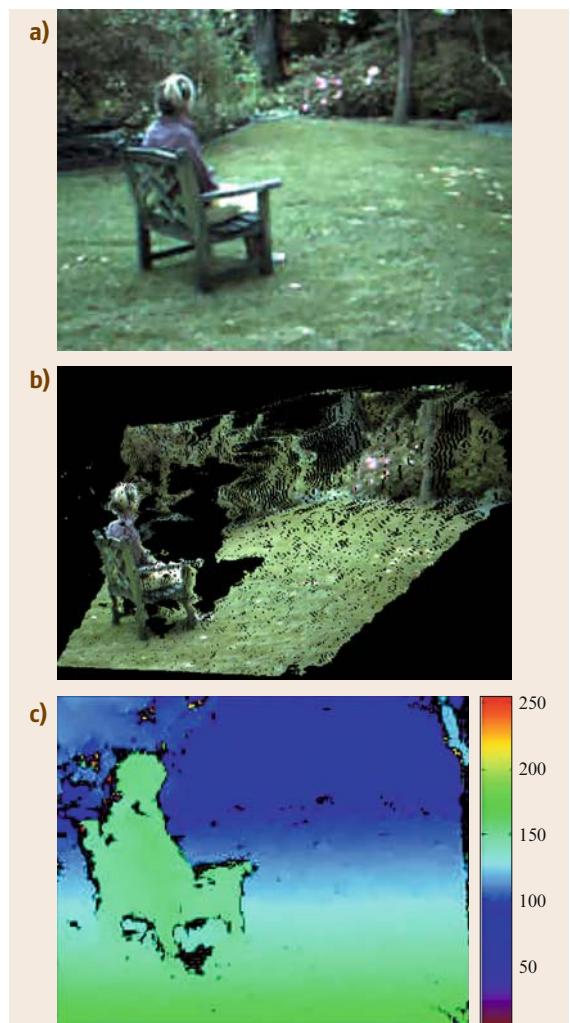

Fig. 22.6a–c Sample stereo results from an outdoor garden scene; baseline is 9 cm. (a) Original left image. (b) Computed 3-D points from a different angle. (c) Disparity in pseudo-color [22.1]

storage. Real-time implementations exist for standard personal computers (**PCs**) [22.1, 15], graphics accelerators [22.16, 17], digital signal processors (**DSPs**) [22.4], field-programmable gate arrays (**FPGAs**) [22.1, 18], and specialized application-specific integrated circuits (**ASICs**) [22.19].

Other Visual Sources of Range Information

Here we briefly list the most popular, but less reliable sources of range information. These sources can potentially supplement other sensors.

- *Focus/defocus.* Knowledge of the camera parameters and the amount of blur of image features allows estimation of how far the corresponding scene features are from the perfect focus distance [22.20]. Sensors may be passive (using a precaptured image) or active (capturing several images with different focus settings).
- *Structure and motion.* Structure and motion algorithms compute 3-D scene structure and the sensor positions simultaneously [22.21]. These is essentially a binocular stereo process (see discussion before), except that only a single moving camera is used. Thus the images needed by the stereo process are acquired by the same camera in several different positions. Video camcorders are also used, but have lower resolution. One important advantage of this approach over the normal algorithm is that features can be tracked easily if the time between frames or the motion is small enough. This simplifies the *correspondence problem*, however it can lead to another problem. If the pair of images used for the stereo calculation are taken close together in time, then the separation between the cameras images will not be much, that is, there will be a *short baseline*. Triangulation calculations are then more inaccurate, as small errors in estimating the position of image features results in large errors in the estimated 3-D position (particularly the depth estimate). This problem can be partly avoided by tracking for longer periods. A second problem that can arise is that not all motions are suitable for estimating the full 3-D scene structure, for example, if the video recorder only rotates about its optical axis or about its focus point, then no 3-D information can be recovered. A little care can avoid this problem.
- *Shading.* The pattern of shading on a surface is related to the orientation of the surface relative to the observer and light sources. This relationship can be used to estimate the surface orientation across the surface. The surface normals can then be integrated to give an estimate of the relative surface depth.
- *Photometric stereo.* Photometric stereo [22.22] is a combination of shading and stereo processes. The key concept is that the shading of an object varies with the position of the light sources. Hence, if you had several aligned pictures of an object or scene with the light source in different positions (e.g., the sun moved), then you can calculate the scene's surface normals. From these, the relative surface depth can be estimated. The restriction of a stationary observer and changing light sources makes this approach less likely to be useful to most robotics applications.
- *Texture.* The way uniform or statistical textures vary on a surface is related to the orientation of the surface relative to the observer. As with shading, the texture gradients can be used to estimate the surface orientation across the surface [22.23]. The surface normals can then be integrated to give an estimate of the relative surface depth.

22.1.3 Laser-Based Range Sensors

There are three types of laser-based range sensors in common use:

1. triangulation sensors
2. phase-modulation sensors
3. time-of-flight sensors

These are discussed in more detail below. There are also Doppler and interference laser-based range sensors, but these seem to not be in general use at the moment so we skip them here. An excellent recent review of range sensors is by *Blais* [22.24].

The physical principles behind the three types of sensors discussed below do not intrinsically depend on the use of a laser – for the most part any light source would work. However, lasers are traditional because: (1) they can easily generate bright beams with lightweight sources, (2) infrared beams can be used unobtrusively, (3) they focus well to give narrow beams, (4) single-frequency sources allow easier rejection filtering of unwanted frequencies, (5) single-frequency sources do not disperse from refraction as much as full-spectrum sources, (6) semiconductor devices can more easily generate short pulses, etc.

One advantage of all three sensor types is that it is often possible to acquire a reflectance image registered with the range image. By measuring the amount that the laser beam strength has reduced after reflection from the target, one can estimate the reflectance of the surface. This is only the reflectance at the single spectral frequency of the laser, but, nonetheless, this gives useful information about the appearance of the surface (as well as the shape as given by the range measurement); Three-color laser systems [22.25] similarly give registered red–green–blue (RGB) color images. Figure 22.1 shows registered range and reflectance images from the same scene.

One disadvantage of all three sensor types is specular reflections. The normal assumption is that the observed light is a diffuse reflection from the surface. If the ob-

served surface is specular, such as polished metal or water, then the source illumination may be reflected in unpredictable directions. If any light eventually is detected by the receiver, then it is likely to cause incorrect range measurements. Specular reflections are also likely at the fold edges of surfaces.

A second problem is the laser *footprint*. Because the laser beam has a finite width, when it strikes the edge of a surface, part of the beam may be actually lie on a more distant surface. The consequences of this will depend on the actual sensor, but it commonly results in range measurements that lie between the closer and more distant surfaces. These measurements thus suggest that there is surface where there really is empty space. Some noise removal is possible in obvious empty space, but there may be erroneous measurements that are so close to the true surface that they are difficult to eliminate.

22.1.4 Time-of-Flight Range Sensors

Time-of-flight range sensors are exactly that: they compute distance by measuring the time that a pulse of light takes to travel from the source to the observed target and then to the detector (usually collocated with the source). In a sense, they are radar sensors that are based on light. The travel time multiplied by the speed of light (in the given medium – space, air or water – and adjusted for the density and temperature of the medium) gives the distance. Laser-based time-of-flight range sensors are also called light detection and ranging (**LIDAR**) or laser radar (**LADAR**) sensors.

Limitations on the accuracy of these sensors are based on the minimum observation time (and thus the minimum distance observable), the temporal accuracy (or quantization) of the receiver, and the temporal width of the laser pulse.

Many time-of-flight sensors used for local measurements have what is called an *ambiguity interval*, for example, 20 m. The sensor emits pulses of light periodically, and computes an average target distance from the time of the returning pulses. To limit noise from reflections and simplify the detection electronics, many sensors only accept signals that arrive within time Δt , but this time window might also observe previous pulses reflected by more distant surfaces. This means that a measurement Z is ambiguous to the multiple of $1/2c\Delta t$ because surfaces that are further away (e.g., z) than $1/2c\Delta t$ are recorded as $z \bmod 1/2c\Delta t$. Thus distances on smooth surfaces can increase until they reach $c\Delta t/2$ and then they become 0. Typical values for $c\Delta t/2$ are 20–40 m. On smooth surfaces, such as a ground

plane or road, an unwinding algorithm can recover the true depth by assuming that the distances should be changing smoothly.

Most time-of-flight sensors transmit only a single beam, thus range measurements are only obtained from a single surface point. Robotics applications usually need more information, so the range data is usually supplied as a vector of range to surfaces lying in a plane (Fig. 22.7) or as an image (Fig. 22.1). To obtain these denser representations, the laser beam is swept across the scene. Normally the beam is swept by a set of mirrors rather than moving the laser and detector themselves (mirrors are lighter and less prone to motion damage). The most common technologies for this are using a stepper motor (for program-based range sensing) or rotating or oscillating mirrors for automatic scanning.

Typical ground-based time-of-flight sensors suitable for robotics applications have a range of 10–100 m, and an accuracy of 5–10 mm. The amount of the scene scanned will depend on the sweep rate of the mirrors and the pulse rate, but 1–25 K points per second are typical. Manufacturers of these sensors include Acuity, SICK, Mensi, DeltaSphere, and Cyrax.

Recently, a type of time-of-flight range sensor called the *flash LADAR* has been developed. The key innovation has been the inclusion of timing circuits at each pixel of the sensor chip. Thus, each pixel can measure the time at which a light pulse is observed from the line of sight viewed by that pixel. This allows simultaneous calculation of the range values at each pixel. The light pulse now has to cover to whole portion of the scene that is observed, so sensors typically use an array of infrared laser light-emitting diodes (LEDs). While spatial resolution is smaller than current cameras (e.g., 64×64 , 160×124 , 128×128), the data can be acquired at video rates (30–50 fps), which provides considerable informa-

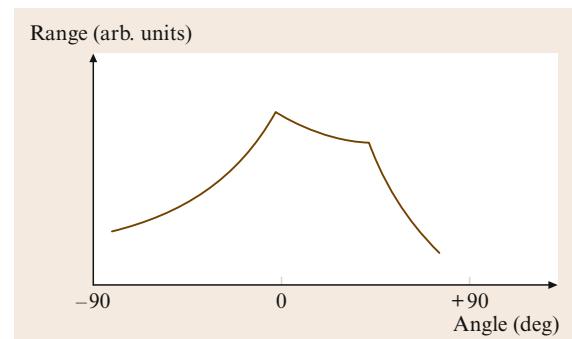

Fig. 22.7 Plot of ideal one-dimensional range image of sample distance versus angle of measurement

tion usable for robot feedback. Different sensor ranges have been reported, such as up to 5 m [22.26] (with on the order of 5–50 cm standard deviation depending on target distance and orientation) or at 1.1 km [22.27] (no standard deviation reported).

22.1.5 Modulation Range Sensors

Modulation-based range sensors are commonly of two types, where a continuous laser signal is either amplitude or frequency modulated. By observing the phase shift between the outgoing and return signals, the signal transit time is estimated and from this the target distance. As the signal phase repeats every 2π , these sensors also have an ambiguity interval.

These sensors also produce a single beam that must be swept. Scan ranges are typically 20–40 m and the accuracy is 5 mm. Figure 22.1 was captured with a modulation sensor.

22.1.6 Triangulation Range Sensors

Triangulation range sensors [22.28] are based on principles similar to the stereo sensors discussed previously. The key concept is illustrated in Fig. 22.8: a laser beam is projected from one position onto the observed surface. The light spot that this creates is observed by a sensor from a second position. Knowing the relative positions and orientations of the laser and sensor plus some simple trigonometry allows calculation of the 3-D position of the illuminated surface point. The triangulation process is more accurate when the laser spot's position is accurately estimated. About 0.1 pixel accuracy can be normally achieved [22.29].

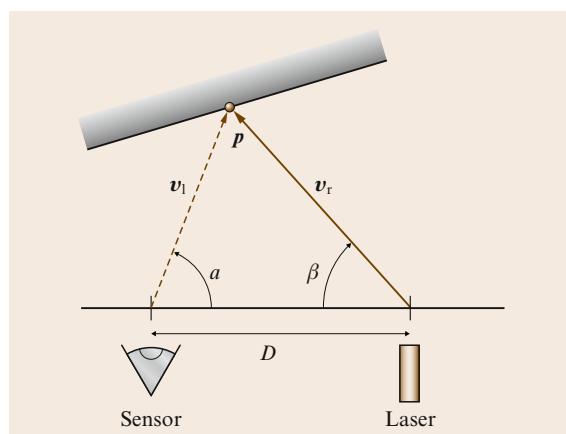

Fig. 22.8 Triangulation using a laser spot

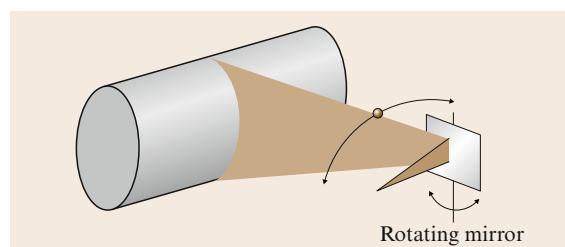

Fig. 22.9 A swept laser plane covers a larger scene

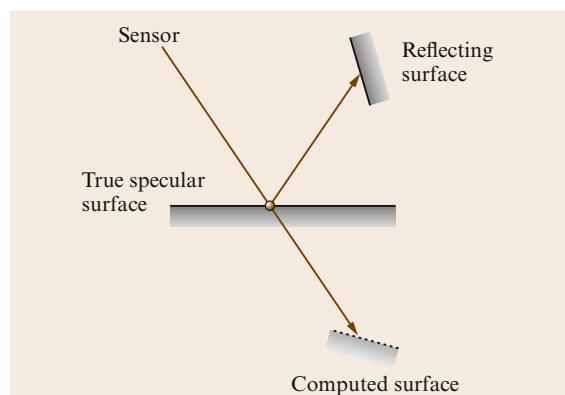

Fig. 22.10 Incorrect estimated depths on specular surfaces

Because the laser illumination can be controlled, this gives a number of practical advantages.

1. A laser of known frequency (e.g., 733 nm) can be matched with a very selective spectral filter of the same frequency (e.g., 5 nm half-width). This normally allows unique identification of the light spot as the filtering virtually eliminates all other bright light, leaving the laser spot as the brightest spot in the image.
2. The laser spot can be reshaped with lenses or mirrors to create multiple spots or stripes, thus allowing the measurement of multiple 3-D points simultaneously. Stripes are commonly used because these can be swept across the scene (see Fig. 22.9 for an example) to observe a full scene. Other illumination patterns are also commonly used, such as parallel lines, concentric circles, cross hairs, and dot grids. Commercial structured light pattern generators are available from, e.g., Lasiris or Edmunds Optics.
3. The laser light ray can be positioned by mirrors under computer control to selectively observe a given area, such as around a doorway or potential obstacle, or an object that might be grasped.

Disadvantages include

1. potential eye safety risks from the power of lasers, particularly when invisible laser frequencies are used (commonly infrared),
2. specular reflections from metallic and polished objects, which may cause incorrect calculation of where the laser spot is illuminating, as in Fig. 22.10, where the hypothesized surface lies behind the true surface.

22.1.7 Example Sensors

A typical phase-modulation-based range sensor is the Zohler and Frohlich 25200. This is an expensive spherical scan sensor, observing a full 360° horizontally and 155° vertically. Each scan can acquire up to 20 000 3-D points horizontally and 8000 points vertically in about 100 s. The accuracy of the scan depends on the distance to the target, but 4 mm is typical, with samples every 0.01° (samples every 1.7 mm at 10 m distance). The densely sensed data is typically used for 3-D scene survey, modeling, and virtual-reality reconstruction.

An example of a laser sensor that has been commonly used for robot navigation is the SICK LMS 200.

This sensor sweeps a laser ray in a horizontal plane through an arc of 180° , acquiring 720 range measurements in a plane in 0.05 s. While a plane might seem limiting, the observed 3-D data can be easily matched to a stored (or previously learned) model of the environment at the height of the scan. This allows accurate estimation of the sensor's position in the scene (and thus a mobile vehicle that carries the sensor). Of course, this requires an environment without overhanging structures that are not detectable at the scan height. Another common configuration is to mount the sensor high on the vehicle with the scan plane tilted downwards. In this configuration the ground in front of the vehicle is progressively scanned as the vehicle moves forward, thus allowing detection of potential obstacles.

The Minolta 910 is a small triangulation scanner with an accuracy of about 0.01 mm in a range of up to 2 m, for about 500^2 points in 2.5 s. It has commonly been used for small-region scanning, such as for inspection or part modeling, but can also be mounted in a fixed location to scan a robot workcell. Observation of the workcell allows a variety of actions, such as inspection of parts, location of dropped or bin delivered components, or accurate part position determination.

More examples and details of range sensors for robot navigation are presented in Sect. 22.3.

22.2 Registration

This section introduces techniques for 3-D localization of parts for robot manipulation, self-localization of robot vehicles, and scene understanding for robot navigation. All of these are based on the ability to register 3-D shapes, e.g., range images to range images, triangulated surfaces or geometric models. Before we introduce these applications in Sect. 22.2.7, we first look at some basic techniques for manipulating 3-D data.

22.2.1 3-D Feature Representations

There are many representations available for encoding 3-D scene structure and model representations, but the following representations are the ones most commonly encountered in robotics applications. Some scene models or descriptions may use more than one of these simultaneously to describe different aspects of the scene or object models.

3-D Point Sets

This is a set $\{\mathbf{p}_i = (X_i, Y_i, Z_i)\}$ of 3-D points that describe some salient and identifiable points in the scene. They might be the centers of spheres (often used as markers), corners where three planes intersect, or the extrema of some protrusion or indentation on a surface. They may be a subset of an initially acquired 3-D full scene point set, they might be extracted from a range image, or they might be computed theoretical points based on extracted data features.

Planes

This is a set of planar surfaces observed in a scene or bounding part or all of an object model. There are several ways to represent a plane, but one common representation is by the equation of the plane $ax + by + cz + d = 0$ that passes through corresponding scene or model surface points $\{\mathbf{p}_i = (X_i, Y_i, Z_i)\}$. A plane only needs three parameters, so there are usually

some additional constraints on the plane representation (a, b, c, d) , such as $d = 1$ or $a^2 + b^2 + c^2 = 1$. The vector $\mathbf{n} = (a, b, c)/\sqrt{a^2 + b^2 + c^2}$ is the surface normal.

A planar surface may only be described by the infinite surface as given by the equation, but it may also include a description of the boundary of the surface patch. Again there are many possible representations for curves, either in three or two dimensions lying in the plane of the surface. Convenient representations for robotics applications are lists of the 3-D points $\{(X_i, Y_i, Z_i)\}$ that form the patch boundary, or polylines, which represent the boundary by a set of connected line segments. A polyline can be represented by the sequence of 3-D points $\{(X_i, Y_i, Z_i)\}$ that form the vertices that join the line segments.

Triangulated Surfaces

This representation describes an object or scene by a set of triangular patches. More general polygonal surface patches or even various smooth surface representations are also used, but triangles are most commonly used because they are simpler and there are inexpensive PC graphics cards that display triangles at high speed.

The triangles can be large (e.g., when representing planar surfaces) or small (e.g., when representing curved surfaces). The size chosen for the triangles reflects the accuracy desired for representing the object or scene sur-

faces. The triangulated surface might be complete in the sense that all observable scene or objects surfaces are represented by triangles, or there might be disconnected surface patches with or without internal holes. For grasping or navigation, you do not want any unrepresented scene surface to lie in front of the represented portion of the surface where a gripper or vehicle might collide with it. Hence, we assume that the triangulation algorithms produce patch sets that, if completely connected at the edges, implicitly bound all real scene surfaces. Figure 22.11 shows an example of a triangulated surface over the original underlying smooth surface.

There are many slightly different schemes for representing the triangles [22.30], but the main features are a list $\{\mathbf{v}_i = (X_i, Y_i, Z_i)\}$ indexed by i of the 3-D vertices at the corners of the triangles, and a list of the triangles $\{t_n = (i_n, j_n, k_n)\}$ specifying the indices of the corner vertices.

From the triangular surface patches, one can compute potential grasping positions, potential navigable surfaces or obstacles, or match observed surface shapes to previously stored shapes.

3-D Lines

The 3-D lines where planar surfaces meet are features that can be easily detected by both stereo and range sensors. These features occur commonly in built environments (e.g., where walls, floors, ceilings, and doorways meet, around the edges of wall structures like notice boards, at the edges of office and warehouse furniture, etc.). They are also common on manmade objects. In the case of stereo imaging, changes of surface shape or coloring are detected as edges, which can be matched in the stereo process to directly produce the 3-D edge. In the case of a range sensor, planar surfaces can be easily extracted from the range data (see next section) and adjacent planar surfaces can be intersected to give the edges.

The most straightforward representation for 3-D lines is the set of points $\mathbf{x} = \mathbf{p} + \lambda\mathbf{v}$ for all λ , where \mathbf{v} is a unit vector. This has five degrees of freedom; more complex representations, e.g., with four degrees of freedom exist [22.2].

Voxels

The voxel (volume pixel) approach represents the 3-D world by 3-D boxes/cells that indicate where there is scene structure and where there is free space. The simplest representation is a 3-D binary array, encoded as 1 for having structure and 0 for free space. This can be quite memory intensive, and also requires a lot of

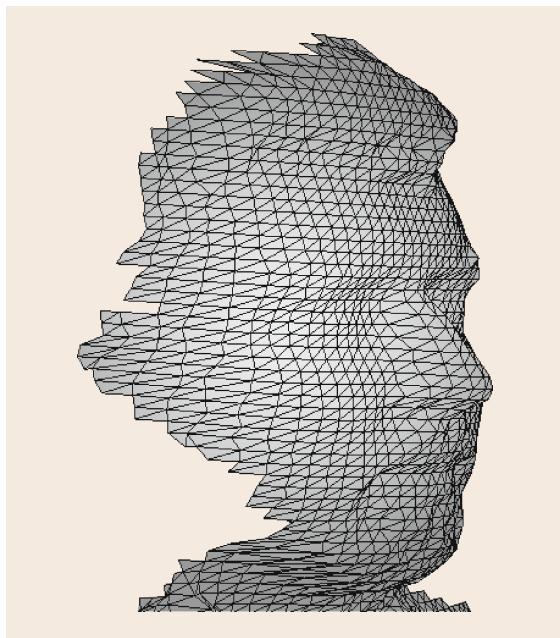

Fig. 22.11 Triangulated surface (thanks to T. Breckon)

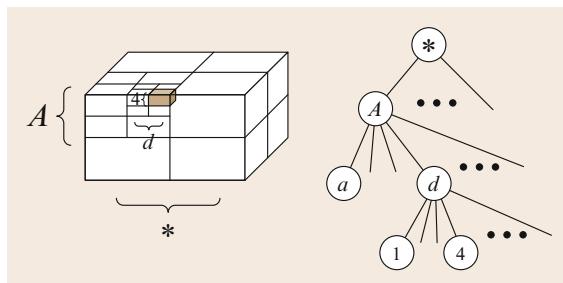

Fig. 22.12 Recursive space decomposition and a portion of the corresponding octree

computation to check many voxels for content. A more complex but more compact representation is the hierarchical representation called the octree [22.30]. This divides the entire (bounded) rectangular space into eight rectangular subspaces called octants (Fig. 22.12). A tree data structure encodes the content of each octant as empty, full or mixed. Mixed octants are then subdivided into eight smaller rectangular octants, encoded as subtrees of the larger tree. Subdivision continues until some minimum octant size is reached. Determining whether a voxel is empty, full or mixed depends on the sensor used, however, if no 3-D data points are located in the volume of a voxel, then it is likely to be empty. Similarly, if many 3-D points are present, then the voxel is likely to be full. The remaining voxels can be considered to be mixed. More details of a voxelization algorithm can be found in [22.31].

For the purpose of robot navigation, localization or grasping, only the surface and free-space voxels need to be marked accurately. The interior of objects and scene structure are largely irrelevant.

22.2.2 3-D Feature Extraction

Three types of structured 3-D features are of particular interest for robot applications: straight lines, planes, and triangulated surfaces. How these are extracted from range data sets is summarized here:

Planes

Planes are generally found by some region-growing process, based on a seed patch. When the scene largely consists of planes, a particularly simple approach is based on selecting a previously unused point and the set of points $\{v_i = (X_i, Y_i, Z_i)\}$ in its neighborhood. A plane is fit to these points using a least-squares method: create a $4 \times N$ matrix D of the N points in the set, each point augmented with a 1. Call these ex-

tended points $\{v_i\}$. As each point lies in the same plane $ax + by + cz + d = 0$, we can easily estimate the plane parameter vector $p = (a, b, c, d)'$ as follows. We know that a perfect plane fit to perfect data would satisfy $Dp = 0$. Since there is noise, we instead create the error vector $e = Dp$ and find the vector p that minimizes its length (squared) $e \cdot e = p'D'Dp$. This vector is the eigenvector with the smallest eigenvalue of the matrix $D'D$. This initial hypothesized plane then needs to be tested for reasonableness by (1) examining the smallest eigenvalue, which should be small and on the order of the square of the expected noise level, and (2) ensuring that most of the 3-D points in the fitted set lie on the plane (i.e., $|v_i \cdot p| < \tau$).

Larger planar regions are *grown* by locating new adjacent points v_i that lie on the plane (i.e., $|v_i \cdot p| < \tau$). When enough of these are found, the parameters p of the plane are re-estimated. Points on the detected plane are removed and the process is repeated with a new seed patch. This process continues until no more points can be added. More complete descriptions of planar feature extraction can be found in [22.32].

When the planes are more sparsely found in the scene, then another approach is the random sample consensus (RANSAC) feature detection algorithm [22.33]. When adapted for plane finding, this algorithm selects three 3-D points at random (although exploiting some locality to the point selection algorithm can improve the efficiency of the algorithm). These three points determine a plane with parameter vector p . All points $\{v\}$ in the set are testing for belonging to the plane (i.e., $|v_i \cdot p| < \tau$). If enough points are close to the plane, then potentially a plane has been found. These points should also be processed to find a connected set, from which a more accurate set of plane parameters can be estimated using the least-squares algorithm given above. If a planar patch is successfully found, the points that lie in that plane are removed from the dataset. The random selection of three points then continues until no more planes are found (a bound on how many tries to make can be estimated).

Straight Lines

While straight lines are common in manmade scenes, direct extraction from 3-D datasets is not easy. The main source of the difficulty is that 3-D sensors often do not acquire good responses at edges of surfaces as (1) the sensor beam will be sampling from two different surfaces and 2) laser-based sensors produce somewhat unpredictable effects. For this reason, most 3-D line detection algorithms are indirect, whereby planes are first

detected, e.g., using the method of the previous section, and then adjacent planes are intersected. Adjacency can be tested by finding paths of connected pixels that lead from one plane to the other. If planes 1 and 2 contains points p_1 and p_2 and have surface normals n_1 and n_2 , respectively, then the resulting intersection line has equation $x = a + \lambda d$, where a is a point on the line and $d = n_1 \times n_2 / \|n_1 \times n_2\|$ is the line direction. There are an infinite number of possible points a , which can be found by solving the equations $a' n_1 = p'_1 n_1$ and $a' n_2 = p'_2 n_2$. A reasonable third constraint that obtains a point near to p_2 is the equation $a' d = p'_2 d$. This gives us an infinite line. Most practical applications require a finite segment. The endpoints can be estimated by (1) finding the points on the line that lie close to observed points in both planes and then (2) finding the two extremes of those points. On the other hand, finding straight 3-D lines can be easier with a stereo sensor, as these result from matching two straight two-dimensional (2-D) image lines.

Triangulated Surfaces

The goal of the process is to estimate a triangulated mesh from a set of 3-D data points. If the points are sampled on a regular grid (e.g., from a $2\frac{1}{2}$ -D range image), then the triangles can be formed naturally from the sampling (Fig. 22.13). If the points are part of a 3-D point set, then triangulation is harder. We do not give details here because of the complexity of this task, but some of the issues that have to be considered are: (1) how to find a surface that lies close to all data points (as it is unlikely to actually pass through all because of noise), (2) how to avoid holes and wild triangles in the

mesh, (3) how to choose the threshold of closeness so that only one surface passes through sections of a point cloud, (4) how to choose the triangle size, (5) what to do about outlying points, and (6) how to maintain observable scene features, such as surface edges. Popular early approaches for triangulation are the marching cube and triangle [22.34, 35] algorithms. These algorithms can give meshes with many triangles. The triangle size and thus the computational complexity of using the mesh can be reduced by mesh decimation, for which many algorithms exist [22.36, 37].

22.2.3 Model Matching and Multiple-View Registration

Model matching is the process of matching some stored representation to some observed data. In the case discussed here, we assume that both are 3-D representations. Furthermore, we assume that the representations being matched are both of the same type, e.g., 3-D model and scene lines. (While different types of data can also be matched, we ignore these more specialized algorithms here.)

A special case of matching is when the two structures being matched are both scene or model surfaces. This commonly occurs when attempting to produce a larger representation of the scene by fusing multiple partial views of the scene. These partial views can be acquired as a mobile vehicle navigates around the scene, observing it from different places. The mobile robotics simultaneous localization and mapping (SLAM) algorithm [22.38] (discussed in Chap. 37) incrementally fuses newly observed scene structure to its growing scene map model, while also matching portions of that newly observed data to previously observed data to estimate its current location. One SLAM project [22.39] used scale invariant feature transform (SIFT) feature points for 3-D modeling and map construction.

The algorithm used for matching depends on the complexity of the structures being matched. If the structures being matched are extended geometric entities such as planes or 3-D lines, then a discrete matching algorithm like the interpretation tree algorithm [22.40] can be used. Alternatively, if the structures are low level, such as 3-D points or triangles, then a point set alignment algorithm like the iterated closest point (ICP) algorithm [22.41] can be used. Both of these are described in more detail below.

After structures have been matched, the commonest next step is to estimate the transformation (rotation plus translation) linking the two datasets. This process is described in the next section. With the transforma-

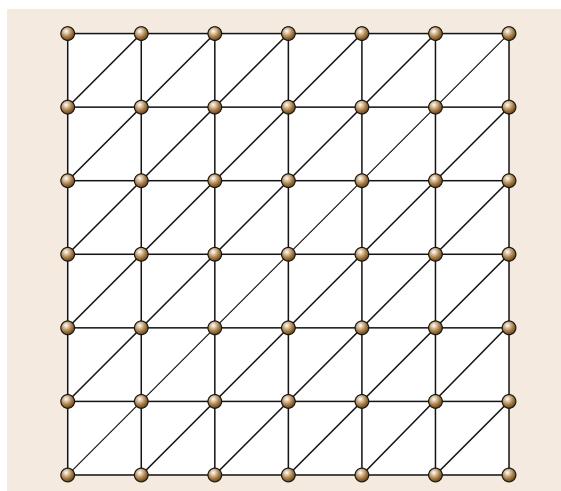

Fig. 22.13 Triangulation of a regular grid of points

tion, we can then transform the data into the same coordinate system and fuse (combine) the datasets. If the structures being fused are points, then the result is a larger point set formed from the combination of the two (or more) original datasets. Sets of planes and lines can also be simply added together, subject to representing the matched members of the two datasets only once. Triangulated surfaces require a more complex merging, in that we require a topologically correct triangulated mesh to be the result. The zipper algorithm [22.42] is a well-known triangulated mesh merging algorithm.

The interpretation tree algorithm [22.40] (see Table 22.2) is suitable for matching small numbers (e.g., less than about 20–30) of discrete objects, such as vertical edges seen in 2-D or 3-D. If there are M model and D data objects, then potentially there are M^D different matches. The key to efficient matching is to identify pairwise constraints that eliminate unsuitable matches. Constraints between pairs of model features and pairs of data features also greatly reduce the matching space. If the constraints eliminate enough features, a polynomial-time algorithm results. The core of the algorithm is defined as follows. Let $\{m_i\}$ and $\{d_j\}$ be the sets of model and data features to be matched, $u(m_i, d_j)$ is true if m_i and d_j are compatible features, $b(m_i, m_j, d_k, d_l)$ is true if the four model and data features are compatible, and T is the minimum number of matched features before a successful match is declared. Pairs is the set of successfully matched features. The function `truesizeof` counts the number of actual matches in the set, disregarding

matches with the wildcard '*' which matches anything.

When the data being matched are sets of points or triangles, then the ICP algorithm [22.41] is more commonly used. This algorithm estimates the pose transformation that aligns the two sets to a minimum distance. With this transformation, the two sets can be represented in the same coordinate system and treated as a larger single set (perhaps with some merging of overlapping data).

Here we give the algorithm for point matching, but this can be easily adapted for other sets of features. This algorithm is iterative, so may not always converge quickly, but often several iterations is sufficient. However, ICP can produce a bad alignment of the data sets. Best results arise with a good initial alignment, such as from odometry or previous positions. The ICP algorithm can be extended to include other properties when matching, such as color or local neighborhood structure. A good spatial indexing algorithm (e.g., k-d trees) is necessary for efficient matching in the closest point function (`CP`) below.

Let \mathcal{S} be a set of N_s points $\{s_1, \dots, s_{N_s}\}$ and \mathcal{M} be the model. Let $\|s - m\|$ be the Euclidean distance between point $s \in \mathcal{S}$ and $m \in \mathcal{M}$. Let $\text{CP}(s, \mathcal{M})$ be the closest point (Euclidean distance) in \mathcal{M} to the scene point s .

1. Let $\mathbf{T}^{[0]}$ be an initial estimate of the rigid transformation aligning the two sets.
2. Repeat for $k = 1 \dots k_{\max}$ or until convergence:
 - a) Compute the set of correspondences $\mathcal{C} = \bigcup_{i=1}^{N_s} \{(s_i, \text{CP}(\mathbf{T}^{[k-1]}(s_i), \mathcal{M}))\}$.

- b) Compute the new Euclidean transformation $T^{[k]}$ that minimizes the mean square error between point pairs in \mathcal{C} .

22.2.4 Maximum-Likelihood Registration

One popular technique for range scan matching, especially in the 2-D case, uses maximum likelihood as the criterion for match goodness. This technique also takes into account a probabilistic model of the range readings. Let r be a range reading of a sensor scan at position s , and \bar{r} the distance to the nearest object along the path of r (which depends on s). Then a model of the sensor reading is the probability $p(r|\bar{r})$. Typically the model has a Gaussian shape around the correct range, with an earlier false-positive region and a missed-reading region at the end (Fig. 22.14).

A scan is matched when its position produces a maximum-likelihood result for all the readings, based on a reference scan. Assuming independence of the readings, from Bayes' rule we get

$$\max_s p(s|r) = \max_s \prod_i p(r_i|\bar{r}_i).$$

The maximum likelihood scan location can be found by hill-climbing or exhaustive search from a good starting point. Figure 22.15 shows the results of maximum likelihood for aligning a scan against several reference scans. In this 2-D case, the reference scans are put into an occupancy grid for computing \bar{r} [22.44]. A widespread modification for efficiency is to compute \bar{r} by a smearing operation on the occupancy grid, ignoring line-of-sight

Fig. 22.15 Scan match by maximum likelihood against several reference scans in an occupancy grid [22.44]

information [22.45]. In the 3-D case, triangulated surfaces are more appropriate than voxels [22.46].

22.2.5 Multiple-Scan Registration

In the previous subsection, multiple reference scans could be used to form an occupancy grid or surface triangles for matching. In general, scan matching between sets of scans produces a network of constraints among the scans, for example, in going around a loop, successive scans form a chain of constraints, and the first and last scans form a closed loop of constraints. Globally consistent registration of scans is a part of SLAM (Chap. 37).

If the individual constraints have covariance estimates, then maximum-likelihood techniques can be used to find a globally consistent estimate for all the scans [22.47]. This global registration is among the scan *poses*, and does not involve the scans themselves – all information has been abstracted to constraints among the poses. Let \bar{s}_{ij} be the scan-matched pose difference between scans s_i and s_j , with covariance Γ_{ij} . The maximum-likelihood estimate for all s is given by the nonlinear least-squares system

$$\min_s \sum_{ij} (s_{ij} - \bar{s}_{ij})^\top \Gamma_{ij} (s_{ij} - \bar{s}_{ij}), \quad (22.8)$$

which can be solved efficiently using iterative least-squares techniques, e.g., Levenberg–Marquadt or conjugate gradient methods [22.48, 49].

A complication is that the system of constraints is calculated based on an initial set of poses s . Given a repositioning of s from (22.8), redoing the scan matching will give a different set of constraints, in general. Iterating the registration process with new constraints is not guaranteed to lead to a global minimum; in practice, with a good initial estimate, convergence is often rapid and robust.

22.2.6 Relative Pose Estimation

Central to many tasks is the estimation of the coordinate system relative position or pose transformation between

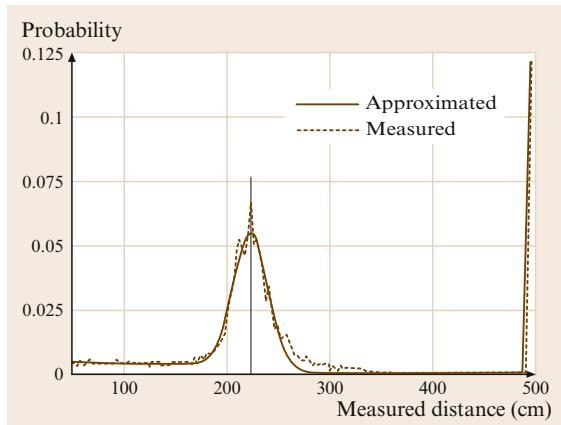

Fig. 22.14 Probability profile $p(r|\bar{r})$ for a laser sensor reading. The Gaussian peak occurs at the distance \bar{r} of the obstacle [22.43]

two coordinate systems, for example, this might be the pose of a scanner mounted on a mobile vehicle relative to scene landmarks, or it might be the relative pose of some scene features as observed in two views taken from different positions.

We present here three algorithms that cover most instances of the pose estimation process, which differ slightly based on the type of feature being matched.

Point Set Relative Pose Estimation

The first algorithm matches point sets. Assume that N 3-D points $\{\mathbf{m}_i\}$ in one structure or coordinate system are matched to points $\{\mathbf{d}_i\}$ in a different coordinate system. The matching might be found as part of the alignment process in the ICP algorithm just described or they might be observed triangle vertices matched to a previously constructed triangulated scene model, for example. The desired pose is the rotation matrix \mathbf{R} and translation vector \mathbf{t} that minimizes $\sum_i \|\mathbf{R}\mathbf{m}_i + \mathbf{t} - \mathbf{d}_i\|^2$. Compute the mean vectors $\boldsymbol{\mu}_m$ and $\boldsymbol{\mu}_d$ of the two sets. Compute the centralized point sets by $\mathbf{a}_i = \mathbf{m}_i - \boldsymbol{\mu}_m$ and $\mathbf{b}_i = \mathbf{d}_i - \boldsymbol{\mu}_d$. Construct the $3 \times N$ matrix \mathbf{A} that consists of the vectors $\{\mathbf{a}_i\}$ stacked up. Construct the $3 \times N$ matrices \mathbf{B} in a similar way from the vectors $\{\mathbf{b}_i\}$. Compute the singular value decomposition $\text{svd}(\mathbf{BA}') = \mathbf{U}'\mathbf{D}\mathbf{V}'$ [22.50]. Compute the rotation matrix $\mathbf{R} = \mathbf{V}\mathbf{U}'$. If the data points are nearly planar then this calculation can introduce a mirror-image transformation. This can be checked with the vector triple product and, if mirrored, the diagonal correction matrix $\mathbf{C}(1,1,-1)$ can be used in $\mathbf{R} = \mathbf{VCU}'$. Finally, compute the translation vector $\mathbf{t} = \boldsymbol{\mu}_d - \mathbf{R}\boldsymbol{\mu}_m$. With these least-squares estimates of the transformation, a point \mathbf{m}_i transforms to point $\mathbf{R}\mathbf{m}_i + \mathbf{t}$, which should be near to point \mathbf{d}_i .

Straight Line Relative Pose Estimation

If 3-D lines are the features that are extracted, then the relative pose transformation can be estimated as follows. Assume N paired lines. The first set of lines is described by direction vectors $\{\mathbf{e}_i\}$ and a point on each line $\{\mathbf{a}_i\}$. The second set of lines is described by direction vectors $\{\mathbf{f}_i\}$ and a point on each line $\{\mathbf{b}_i\}$. In this algorithm, we assume that the direction vectors on the matched segments always point the same direction (i.e., they are not inverted). This can be achieved by exploiting some scene constraints, or trying all combinations and eliminating inconsistent solutions. The points \mathbf{a}_i and \mathbf{b}_i need not correspond to the same point after alignment. The desired rotation matrix \mathbf{R} minimizes $\sum_i \|\mathbf{Re}_i - \mathbf{f}_i\|^2$. Construct the $3 \times N$ matrices \mathbf{E} that consist of the vectors $\{\mathbf{e}_i\}$ stacked up. Construct the $3 \times N$ matrices \mathbf{F} in a sim-

ilar way from the vectors $\{\mathbf{f}_i\}$. Compute the singular value decomposition $\text{svd}(\mathbf{FE}') = \mathbf{U}'\mathbf{D}\mathbf{V}'$. Compute the rotation matrix $\mathbf{R} = \mathbf{V}\mathbf{U}'$. The translation estimate \mathbf{t} minimizes the sum of the square of the distances λ_i between the rotated points \mathbf{a}_i and corresponding line $(\mathbf{f}_i, \mathbf{b}_i)$. Define the matrix $\mathbf{L} = \sum_i (I - \mathbf{f}_i \mathbf{f}'_i)'(I - \mathbf{f}_i \mathbf{f}'_i)(\mathbf{Ra}_i - \mathbf{b}_i)$. Define the vector $\mathbf{n} = \sum_i (I - \mathbf{f}_i \mathbf{f}'_i)'(I - \mathbf{f}_i \mathbf{f}'_i)(\mathbf{Ra}_i - \mathbf{b}_i)$. Then the translation is $\mathbf{t} = -\mathbf{L}^{-1}\mathbf{n}$.

Plane Relative Pose Estimation

Finally, if planes are the 3-D features extracted for matching, then the relative pose transformation can be estimated as follows. Assume N paired planes. The first set of planes is described by surface normals $\{\mathbf{e}_i\}$ and a point on each plane $\{\mathbf{a}_i\}$. The second set of planes is described by surface normals $\{\mathbf{f}_i\}$ and a point on each plane $\{\mathbf{b}_i\}$. Here we assume that the surface normals always point outward from the surface. The points \mathbf{a}_i and \mathbf{b}_i need not correspond to the same point after alignment. The desired rotation matrix \mathbf{R} minimizes $\sum_i \|\mathbf{Re}_i - \mathbf{f}_i\|^2$. Construct the $3 \times N$ matrices \mathbf{E} that consist of the vectors $\{\mathbf{e}_i\}$ stacked up. Construct the $3 \times N$ matrices \mathbf{F} in a similar way from the vectors $\{\mathbf{f}_i\}$. Compute the singular value decomposition $\text{svd}(\mathbf{FE}') = \mathbf{U}'\mathbf{D}\mathbf{V}'$ [22.50]. Compute the rotation matrix $\mathbf{R} = \mathbf{V}\mathbf{U}'$. The translation estimate \mathbf{t} minimizes the sum of the square of the distances λ_i between the rotated point \mathbf{a}_i and the corresponding plane $(\mathbf{f}_i, \mathbf{b}_i)$. Define the matrix $\mathbf{L} = \sum_i \mathbf{f}_i \mathbf{f}'_i$. Define the vector $\mathbf{n} = \sum_i \mathbf{f}_i \mathbf{f}'_i (\mathbf{Ra}_i - \mathbf{b}_i)$. Then the translation is $\mathbf{t} = -\mathbf{L}^{-1}\mathbf{n}$.

In all of the calculations described above, we assumed normally distributed errors. For techniques to make these sorts of calculations more robust, see Zhang [22.51].

22.2.7 3-D Applications

This section links the techniques presented above to the robotics applications of 3-D localization of parts for robot manipulation, self-localization of robot vehicles, and scene understanding for robot navigation. The robotics tasks mentioned here are discussed in more detail in other chapters in the series. While this chapter focuses on robotics applications, there are many other 3-D sensing applications. An area of much current research is that of acquiring 3-D models, particularly for reverse engineering of mechanical parts [22.52], historical artifacts [22.53], buildings [22.54], and people for computer games and movies (see, e.g., Cyberware's Whole-Body X 3-D scanner).

The key tasks in robot manipulation are: (1) identification of grasping points (Chaps. 27 and 28),

(2) identification of a collision-free grasp (Chaps. 27 and 28), (3) recognition of parts to be manipulated (Chap. 23) and (4) position estimation of parts for manipulation (Chaps. 23 and 42).

The key tasks in robot navigation and self-localization are: (5) identification of a navigable ground plane (Sect. 22.3), (6) identification of a collision-free path (Chap. 35), (7) identification of landmarks (Chap. 36), and (8) estimation of vehicle location (Chaps. 37 and 40).

The mobile and assembly robotics tasks link together rather naturally. Tasks 1 and 5 have a connection, when we consider these tasks in the context of unknown parts or paths. Part grasping requires finding regions on a part that are graspable, which usually means locally planar patches that are large enough that a gripper can make good contact with them. Similarly, navigation usually requires smooth ground regions that are large enough for the vehicle – again locally planar patches. Both tasks are commonly based on triangulated scene methods to rep-

resent the data, from which connected regions of nearly coplanar patches can be extracted. The main difference between these two tasks is the ground-plane detection task is looking for a larger patch, that must be on the *ground* and upward facing.

Tasks 2 and 6 require a method of representing empty space along the proposed trajectory of the gripper contacts or the vehicle. The voxel representation is good for this task.

Tasks 3 and 7 are model matching tasks and can use the methods of Sect. 22.2.3 to match observed scene features to prestored models of known parts or scene locations. Commonly used features are large planar surfaces, 3-D edges, and 3-D feature points.

Tasks 4 and 8 are pose estimation tasks and can use the methods of Sect. 22.2.6 to estimate the pose of the object relative to the sensor or vehicle (i.e., sensor) relative to the scene. Again, commonly used features are large planar surfaces, 3-D edges, and 3-D feature points.

22.3 Navigation and Terrain Classification

One of the more compelling uses for range data is for navigation of mobile robot vehicles. Range data provides information about obstacles and free space for the vehicle, in a direct geometric form. Because of the real-time constraints of navigation, it is often impractical to reconstruct a full 3-D model of the terrain using the techniques presented in this Chapter. Instead, most systems use an *elevation model*. An elevation model is a tessellated 2-D representation of space, where at each cell there is information about the distribution of 3-D points in the cell. In its simplest incarnation, the elevation map just contains the mean height of range points above the nominal ground plane (Fig. 22.16). This representation is sufficient for some indoor and urban environments; more sophisticated versions that determine a local plane, scatter of points in the cell, etc., are useful for more complicated off-road driving. Elevation maps marked with obstacles have obvious utility for planning a collision-free path for the vehicle.

22.3.1 Indoor Reconstruction

SLAM algorithms (Chap. 37) using 2-D laser range finders can reconstruct floor plans with centimeter precision. Some research has extended this work to 3-D reconstruc-

tion, using 2-D lasers that are swept along as the robot moves [22.56]. The resultant point cloud is typically registered using the pose of the robot as corrected by the 2-D SLAM algorithm, rather than any of the 3-D registration techniques covered in this chapter, because the laser is swept using robot motion.

The raw points can be presented as a 3-D image, or triangulated to give a planar or mesh reconstruction of indoor surfaces. The latter is especially compelling when camera images are texture-mapped onto the surfaces, creating a realistic 3-D model. Figure 22.17 shows some results from indoor mapping using this technique.

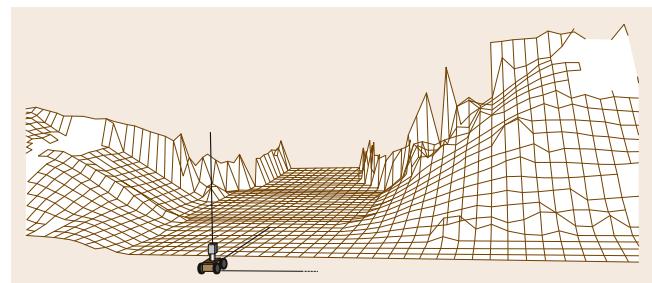

Fig. 22.16 Elevation map in urban terrain. Each cell holds the height of the terrain at that point. More extensive features can also be incorporated: slope, point variance, etc. [22.55]

Fig. 22.17 3-D indoor map from a swept vertical plane LADAR. Registration is from a horizontal LADAR using SLAM algorithms [22.56]

Smoothing of surface facets can be used to recover planar surfaces [22.57].

22.3.2 Urban Navigation

In urban navigation, the environment is structured, with roads, buildings, sidewalks, and also moving objects – people and other vehicles. There are two main challenges: how to register laser scans from a fast-moving vehicle for consistent mapping, and how to detect moving objects using range scans (of course, other methods are also used for detecting moving objects, e.g., appearance-based vision).

Outdoor vehicles can use precision global positioning system (GPS), inertial measurement units, and wheel odometry to keep track of their position and orientation, typically with an extended Kalman filter. This method is good enough to obviate the need for precise registration matching among scans, as long as the motion model of

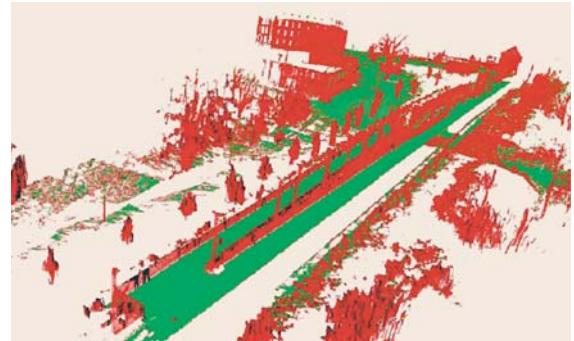

Fig. 22.18 Elevation map of an urban scene, using $10\text{ cm} \times 10\text{ cm}$ cells. Obstacles in red, ground plane in green [22.55]

the vehicle, and timing from the range scanner, is used to place each scan reading in its proper position in the world model. This method also works in relatively easy off-road terrain such as in the Defense Advanced Research Projects Agency (DARPA) Grand Challenge [22.59]. In all cases, the reduction of pose estimation error is critical for good performance [22.60].

Once scan readings are registered using the vehicle pose estimation, they can be put into an elevation map, and obstacles detected using the slope and vertical extent of the range readings in the cells of the map. A complication is that there may be multiple levels of elevation in an urban setting, for example, an overpass would not be an obstacle if it were high enough. One proposal is to use multiple elevation clusters within each cell; this technique is called a *multilevel surface map* (MLS, [22.55]). Each cell in the map stores a set of surfaces represented by a mean height and variance. Figure 22.18 shows an MLS with a cell size of 10 cm^2 , with ground plane and obstacles marked.

For dynamic objects, real-time stereo at 15–30 Hz can capture the motion of the objects. When the stereo rig is fixed, range background subtraction isolates just

Fig. 22.19a–c Independent motion detection from a moving platform. The reference image (a) is forward-projected using the motion homography to (b); (c) is the difference with the actual image [22.58]

the moving objects [22.61]. When the rig is on a moving vehicle, the problem is more difficult, since the whole scene is moving with respect to the rig. It can be solved by estimating the motion of the rig with respect to the dominant rigid background of the scene. Let R, t be the motion of the rig between two frames, estimated by extracting features and matching them across the two temporal frames, using the techniques of Chap. 37. The homography $H(R, t)$ of (22.6) provides a direct projection of the disparity vectors $p_0 = (x_0, y_0, d_0, 1)$ of the first frame to their correspondences $H(R, t)p_0$ under R, t in the second frame. Using the homography allows the points in the reference frame to be directly projected onto the next frame, without translating to 3-D points. Figure 22.19 shows the projected pixels under rigid motion from a reference scene. The difference between the projected and actual pixels gives the independently moving objects [22.58].

22.3.3 Rough Terrain

Rough outdoor terrain presents two challenges:

- There may be no extensive ground plane to characterize driveability and obstacles.
- Vegetation that is pliable and driveable may appear as an obstacle in range images.

Figure 22.20 shows a typical outdoor scene, with a small (1 m) robot driving through vegetation and rough ground [22.62]. Range data from stereo vision on the robot will see the top of the vegetation and some ground points below. The elevation model can be extended to look at *point statistics* within each cell, to capture the notion of a local ground plane and penetrability related to vegetation. In [22.65], for example, the set of proposed features includes:

- major plane slope using a robust fit (Sect. 22.2.2)
- height difference of maximum and minimum heights
- points above the major plane
- density: the ratio of points in the cell to rays that pass through the cell

The density feature is interesting (and expensive to compute), and attempts to characterize vegetation such as grass or bushes, by looking at whether range readings penetrate an elevation cell. The idea of using range readings to estimate vegetation has been discussed in several other projects on off-road driving [22.64, 66, 67].

Elevation map cells can be characterized as obstacles or driveable through learning or hand-built classifiers. Among the learning techniques are neu-

Fig. 22.20 Rough terrain, no ground plane, driveable vegetation [22.62]

ral nets [22.65] and Gaussian mixture models with expectation-maximization learning [22.63]. The latter work also includes a lower level of interpretation, classifying surfaces into planar patches (ground plane, solid obstacles), linear features (telephone wires), and scattered features (vegetation). Figure 22.21 shows some results from a laser-scanned outdoor scene. Linear features such as telephone wires and the telephone pole are accurately determined, as well as vegetation with high penetrability.

Some additional problems occur in rough-terrain navigation. For planar laser range finders that are swept over the terrain by vehicle motion, the precision of vehicle pose estimation is important for accurate reconstruction. Attitude errors of less than 0.5° can cause false positives in obstacle detection, especially for sweeps far

Fig. 22.21 Classification using point statistics, from [22.63]. Red is planar surface, blue is thin linear surface, green is scattered penetrable surface [22.64]

ahead of the vehicle. In [22.60], this problem is solved by looking at the time of each laser reading, and noting a correlation between height errors and time difference in the readings.

Negative obstacles (ditches and cliffs) are difficult to detect with range information, because the sensor may not see the bottom of the obstacle. This is espe-

cially true for vehicle-mounted sensors that are not very high off the ground, and that are looking far ahead. Negative obstacles can be inferred when there is a gap in the ground plane, and a plane slanted upwards at the back edge of the gap. Such artifacts can be efficiently found using column search on the disparity image [22.68].

22.4 Conclusions and Further Reading

Range sensing is an active and expanding field of research in robotics. The presence of new types of devices – flash LADARs, multi-beam LADARs, on-camera stereo processing – and the continuing development of robust algorithms for object reconstruction, localization, and mapping has helped to bring applications out of the laboratory and into the real world. Indoor navigation with LADARs is already being exploited in commercial products (see, for example, [22.69]). As the basic capabilities become more robust, researchers are looking to perform useful tasks, such as fetching items or doing dishes [22.70].

Another set of challenges are found in less benign environments, such as urban and off-road driving (DARPA Grand Challenge and Urban Challenge [22.59]). Stereo vision and laser range finding also will play a role in helping to provide autonomy for a new generation of more capable robotic platforms that rely on walking for locomotion [22.71]. The challenges are dealing with motion that is less smooth than wheeled platforms, environments that contain dynamic obstacles, and task-oriented recognition of objects.

3-D Vision and Recognition

Kostas Daniilidis, Jan-Olof Eklundh

In this chapter, we describe methods to be applied on a robot equipped with one or more camera sensors. Our goal is to present representations and models for both three-dimensional (3-D) motion and structure estimation as well as recognition. We do not delve into estimation and inference issues since these are extensively treated in other chapters. The same applies to the fusion with other sensors, which we heavily encourage but do not describe here.

In the first part we describe the main methods in 3-D inference from two-dimensional (2-D) images. We are at the point where we could propose a recipe, at least for a small spatial extent. If we are able to track a few visual features in our images, we are able to estimate the self-motion of the robot as well as its pose with respect to any known landmark. Having solutions for minimal case problems, the obvious way here is to apply random sample consensus. If no known 3-D landmark is given then the trajectory of the camera exhibits drift. From the trajectory of the camera, time windows over several frames are selected and a 3-D dense depth map is obtained through solving the stereo problem. Large-scale reconstructions based on camera only do raise challenges with respect to drift and loop closing.

In the second part we deal with recognition as appealed to robotics. The main challenge here is to detect an instance of an object and recognize or categorize it. Since in robotics applications an

object of interest always resides in a cluttered environment any algorithm has to be insensitive to missing parts of the object of interest and outliers. The dominant paradigm is based on matching the appearance of pictures. Features are detected and quantized into visual words. Similarity is based on the difference between histograms of such visual words. Recognition has a long way to go but robotics provides the opportunity to explore an object and be active in the recognition process.

With the rapid progress and cost reduction in digital imaging, cameras became the standard and probably the cheapest sensor on a robot. Unlike positioning (global position system, **GPS**), inertial measurement unit (**IMU**), and distance sensors (sonar, laser, infrared) cameras produce the highest bandwidth of data. One video camera of very modest resolution yields a bandwidth of

140 Mbit/s (= 30 frames/s × (640 × 480) pixels/frame × 16 bits/pixel). Exploiting information useful for a robot from such a bit stream is less explicit than in the case of **GPS** or a laser scanner but semantically richer.

Assume for example the scenario that a robot vehicle is given the task of going from place A to place B given as instruction only intermediate visual landmarks and/or

GPS waypoints. The robot starts at A and has to decide where is a drivable path. Such a decision can be accomplished through the detection of obstacles from at least two images by estimating a depth or occupancy map with a *stereo* algorithm. While driving, the robot wants to estimate its trajectory which can be accomplished with a *structure-from-motion* algorithm. The result of the trajectory can be used to build a layout of the environment through *matching* and *triangulation*, which in turn can be used as a reference for a subsequent *pose estimation*. At each time instance the robot has to parse the surrounding environment for risks like pedestrians,

or for objects it is searching for like a trash can. It has to become aware of *loop closing* or a reentry if the robot has been kidnaped or blinded for a while. This can be accomplished through *object and scene recognition* yielding the *what* and *where* of objects around the robot. In an extreme scenario, a vehicle can be left to explore a city and build a semantic 3-D map as well as a trajectory of all places it visited, the ultimate *visual simultaneous localization and semantic mapping* problem. In the next section we will deal with 3-D motion and estimation and mapping and in the last section with object recognition.

23.1 3-D Vision and Visual SLAM

In this section, we are going to treat all the above problems assuming that we have only one or two cameras capturing visible light. Though many of those problems can be considerably simplified if we assume the existence of active sensors (for example, based on structured light projection) or if we restrict the configuration space of a robot, we are not going to make use of any such assumptions. Instead we want to increase the understanding of a reasonably general setting and leave to the user the fusion with estimates from other sensors or the reduction of the space of unknowns. The reader is referred to Chaps. 21, 22, and 36 regarding range sensors and to Chap. 20 regarding **GPS** and inertial sensors. In this chapter we mainly present models, leaving the probabilistic estimation to the chapters about sensor fusion (Chap. 25) and **SLAM** (Chap. 37). Throughout this section we assume that the correspondence between point features has been solved. The matching problem and the detection of features and their descriptors is treated in the recognition session.

Let us start by introducing the projection of the world to an image plane. Assume that a point in the world (X, Y, Z) has coordinates (X_{ci}, Y_{ci}, Z_{ci}) with respect to the coordinate system of a camera c_i related to each other by the following transformation

$$\begin{pmatrix} X_{ci} \\ Y_{ci} \\ Z_{ci} \end{pmatrix} = \mathbf{R}_i \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} + \mathbf{t}_i, \quad (23.1)$$

where \mathbf{R}_i is a rotation matrix whose columns are the world axes with respect to the camera. The translation vector \mathbf{t}_i is starting from the origin of the camera and

ending at the origin of the world coordinate system. The rotation matrix is orthogonal $\mathbf{R}^\top \mathbf{R} = \mathbf{1}$, with determinant 1. We assume that the center of projection is the origin of the coordinate system and that the optical axis is the Z_{ci} -axis of the camera. If we assume that the image plane is the plane $Z_{ci} = 1$ then the image coordinates (x_i, y_i) read

$$x_i = \frac{X_{ci}}{Z_{ci}} \quad y_i = \frac{Y_{ci}}{Z_{ci}}. \quad (23.2)$$

In practice, what we measure are the pixel coordinates (u_i, v_i) in the image, which are related to the image coordinates (x_i, y_i) by the affine transformation

$$u_i = f\alpha x_i + \beta y_i + c_u \quad v_i = fy_i + c_v, \quad (23.3)$$

where f is the distance of the image plane to the projection center measured in pixels. It is also called the focal length, because they are considered approximately equal. The aspect ratio α is a scaling induced by non-square sensor cells or different sampling rates horizontally and vertically. The skew factor β accounts for a shearing induced by a non-perfectly frontal image plane. The image center c_u, c_v is the point of intersection of the image plane with the optical axis. These five parameters are called intrinsic parameters and the process of recovering them is called intrinsic calibration. Upon recovering them we can talk about a calibrated system and we can work with the image coordinates (x_i, y_i) instead of the pixel coordinates (u_i, v_i) . In many vision systems, in particular on mobile robots, wide-angle lenses introduce a radial distortion around the image

center which can be modeled polynomially:

$$\begin{aligned}x_i^{\text{dist}} &= x_i(1 + k_1r + k_2r^2 + k_3r^3 + \dots), \\y_i^{\text{dist}} &= y_i(1 + k_1r + k_2r^2 + k_3r^3 + \dots),\end{aligned}$$

where $r^2 = x_i^2 + y_i^2$,

where we temporarily assumed that the image center is at $(0,0)$. The image coordinates (x_i, y_i) in (23.3) have to be replaced with the distorted coordinates $(x_{\text{dist}}, y_{\text{dist}})$.

Recovering the intrinsic parameters when we can make multiple views of a reference pattern like a checkerboard without variation of the intrinsic parameters has become a standard procedure using tools like the MATLAB calibration toolbox or Zhang's OpenCV calibration function [23.1]. When intrinsics like the focal length vary during operation and viewing reference patterns is not practically feasible, we rely on the state-of-the-art method by Pollefeys et al. [23.2, 3]. When all intrinsics are unknown we can use the Kruppa equations and several stratified self-calibration approaches [23.4, 5] that require at least three views. Apart from radial distortion, the projection relations shown above can be summarized in matrix form. By denoting $\mathbf{u}_i = (u_i, v_i, 1)$ and $\mathbf{X} = (X, Y, Z, 1)$ we obtain

$$\lambda_i \mathbf{u}_i = \mathbf{K}_i (\mathbf{R}_i \ t_i) \mathbf{X} = \mathbf{P} \mathbf{X}, \quad (23.4)$$

where $\lambda_i = Z_{ci}$ is the depth of point \mathbf{X} in camera coordinates and \mathbf{P} is the 3×4 projection matrix. The depth λ_i can be eliminated to obtain two equations relating the world to the pixel coordinates.

23.1.1 Pose Estimation Solution

When we have landmarks in the world with known positions \mathbf{X} , and we can measure their projections, the problem of recovering the unknown rotation and translation in the calibrated case is called pose estimation. Of course, this presumes the identification of the world landmarks in the image. In robotics, pose estimation is rather known as a variant of localization in a known environment. We assume that a camera is calibrated and that measurements of N points are given in world coordinates $\mathbf{X}_{j=1,\dots,N}$ and calibrated image coordinates $\mathbf{x}_{j=1,\dots,N}$. Let us assume two scene points and denote the known angle between their projections \mathbf{x}_1 and \mathbf{x}_2 as δ_{12} (Fig. 23.1). Let us denote the squared distance $\|\mathbf{X}_i - \mathbf{X}_j\|^2$ by d_{ij}^2 and the lengths of \mathbf{X}_j by d_j^2 . Then the cosine law reads

$$d_1^2 + d_2^2 - 2d_1d_2 \cos \delta_{12} = d_{12}^2. \quad (23.5)$$

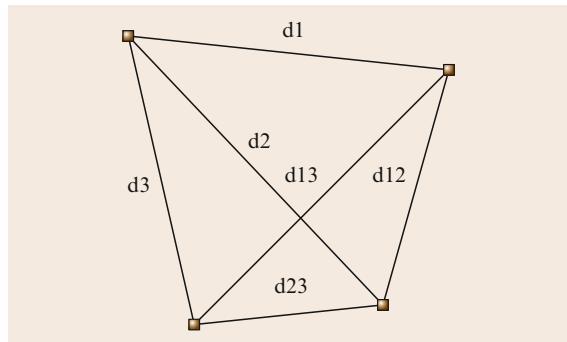

Fig. 23.1 Pose estimation problem: a camera seeing three points at unknown distances d_1 , d_2 , and d_3 with known angles between the rays and known point distances d_{12} , d_{13} , and d_{23}

If we can recover d_1 and d_2 the rest will be an absolute orientation problem

$$d_j \mathbf{x}_j = \mathbf{R} \mathbf{X}_j + \mathbf{t} \quad (23.6)$$

to recover the translation and rotation between the camera and the world coordinate system.

The cosine law has two unknowns d_1 and d_2 so with three points we should be able to solve for the pose estimation problem. Indeed, three points yield a system of three quadratic equations in three unknowns, with a maximum of eight solutions.

We follow here the analysis of the classic solution in [23.6] and set $d_2 = ud_1$ and $d_3 = vd_1$ and solve all three equations for d_1 :

$$\begin{aligned}d_1 &= \frac{d_{23}^2}{u^2 + v^2 - 2uv \cos \delta_{23}}, \\d_1 &= \frac{d_{13}^2}{1 + v^2 - 2v \cos \delta_{13}}, \\d_1 &= \frac{d_{12}^2}{u^2 + 1 - 2u \cos \delta_{12}},\end{aligned}$$

which is equivalent to two quadratic equations in u and v , one we call E3 involving d_{23} and d_{13} and one we call E1, involving d_{13} and d_{12} . Solving E3 for u^2 and substituting in E1 allows E1 to be solved for u without involving radicals. Substituting u back in E3 yields a quartic in v , which can have as many as four real roots. For each v we obtain two roots for u through any of the quadratic equations, yielding a maximum of eight solutions [23.6, 7]. Popular pose estimation algorithms are based either on an iterative method [23.8, 9] or linear versions using auxiliary unknowns of higher dimension [23.10, 11].

23.1.2 Triangulation

When we know both the intrinsics and extrinsics or their summarization in the matrix \mathbf{P} and we measure a point we cannot recover its depth from just one camera position. Assuming that we have the projection of the same point X in two cameras

$$\begin{aligned}\lambda_1 \mathbf{u}_1 &= \mathbf{P}_1 \begin{pmatrix} X \\ 1 \end{pmatrix}, \\ \lambda_2 \mathbf{u}_2 &= \mathbf{P}_2 \begin{pmatrix} X \\ 1 \end{pmatrix},\end{aligned}\quad (23.7)$$

with known projection matrices \mathbf{P}_1 and \mathbf{P}_2 we can recover the position X in space, a process well known as triangulation. Observe that we can achieve triangulation without decomposing the projection matrices into intrinsic and extrinsic parameters, although we need to remove the distortion in order to write them as above.

Having correspondences of the same point in two cameras with known projection matrices \mathbf{P}_1 and \mathbf{P}_r we can solve the two projection equations for the world point X . It is worth noting that each point provides two independent equations so that triangulation becomes an overconstrained problem for two views. This is not a contradiction since two rays do not intersect in general in space unless they satisfy the epipolar constraint as presented in the next paragraph. The following matrix in the left-hand side has in general rank 4 unless the epipolar constraint is satisfied, in which case it has rank 3.

$$\begin{pmatrix} x\mathbf{P}_1(3,:) & -\mathbf{P}_1(1,:) \\ y\mathbf{P}_1(3,:) & -\mathbf{P}_1(2,:) \\ x\mathbf{P}_r(3,:) & -\mathbf{P}_r(1,:) \\ y\mathbf{P}_r(3,:) & -\mathbf{P}_r(2,:) \end{pmatrix} \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix} = \mathbf{0}, \quad (23.8)$$

where $\mathbf{P}(i,:)$ means the i -th row of matrix \mathbf{P} .

Obviously, the homogeneous system above can be transformed into an inhomogeneous linear system with unknowns (X, Y, Z) . Otherwise it can be solved by finding the vector closest to the null-space of the 4×4 matrix above using singular value decomposition (SVD). A thorough treatment of triangulation is the classic [23.12].

23.1.3 Moving Stereo

Imagine now that a rigid stereo system consisting of cameras c_l (left) and c_r (right)

$$\mathbf{u}_{li} \sim \mathbf{P}_l X_i, \quad (23.9)$$

$$\mathbf{u}_{ri} \sim \mathbf{P}_r X_i, \quad (23.10)$$

is attached to a moving robot and observe this system at two time instances

$$\mathbf{X}_0 = \mathbf{R}_1 \mathbf{X}_1 + \mathbf{t}_1, \quad (23.11)$$

where \mathbf{X}_0 are point coordinates with respect to the world coordinate system, usually assumed to be with one of the camera instances, and \mathbf{X}_1 are the coordinates of the same point with respect to the camera rig, after a motion $(\mathbf{R}_1, \mathbf{t}_1)$. To estimate the motion of the rig, we have to solve two correspondence problems, first between the left and right image, and second between left (or right) at the first time instance and left (or right, respectively) at the second time instance. The left-to-right correspondence enables the solution of the triangulation problem at each time instance. Motion can then be obtained by solving (23.11) for $(\mathbf{R}_1, \mathbf{t}_1)$, a problem called absolute orientation. Alternatively one can avoid the second triangulation and solve the pose estimation problem between triangulated points in 3D and points in the left image only. In the robotics context, this is the setup most similar to the simultaneous localization and mapping (SLAM) (Chap. 37) problem when range sensors are used, and here we call it binocular SLAM.

Absolute Orientation

The treatment for moving stereo will be short and the reader is referred to a similar treatment in the chapter about range sensing. We assume that correspondences between two time instances have been established based on tracking in the images so that we can formulate equations of the form

$$\mathbf{X}_2 = \mathbf{R} \mathbf{X}_1 + \mathbf{t}.$$

The standard way [23.13, 14] to solve this problem is to eliminate the translation by subtracting the centroids, yielding

$$\mathbf{X}_2 - \bar{\mathbf{X}}_2 = \mathbf{R}(\mathbf{X}_1 - \bar{\mathbf{X}}_1).$$

We need at least three points in total to obtain at least two non-collinear mean-free $\mathbf{X} - \bar{\mathbf{X}}$ vectors. If we concatenate the mean free vectors for n points into an $3 \times n$ matrix $\mathbf{A}_{1,2}$ we can formulate the following minimization of the Frobenius norm

$$\min_{\mathbf{R} \in SO(3)} \|\mathbf{A}_2 - \mathbf{R} \mathbf{A}_1\|_F,$$

which is known as the Procrustes problem. It can be shown [23.14] that the solution is obtained through SVD

as

$$\mathbf{R} = \text{sign}(\det(\mathbf{U}\mathbf{V}^\top))\mathbf{U}\mathbf{V}^\top, \quad (23.12)$$

where \mathbf{U} , \mathbf{V} are obtained from the singular value decomposition

$$\mathbf{A}_2\mathbf{A}_1^\top = \mathbf{U}\mathbf{S}\mathbf{V}^\top.$$

Solutions are usually obtained with RANSAC by sampling triples of points and verification with the Procrustes method.

23.1.4 Structure from Motion (SfM)

Relax now the assumption that the projection matrices are known and focus on measuring and matching the corresponding points \mathbf{u}_1 and \mathbf{u}_2 . This is the well-known structure-from-motion problem or, more precisely, structure and 3-D motion from 2-D motion. In photogrammetry, this is well known as the relative orientation problem. Even after eliminating the λ 's from (23.9) or by writing them in projective equivalence form

$$\begin{aligned} \mathbf{u}_1 &\sim \mathbf{P}_1 \begin{pmatrix} X \\ 1 \end{pmatrix}, \\ \mathbf{u}_2 &\sim \mathbf{P}_2 \begin{pmatrix} X \\ 1 \end{pmatrix}, \end{aligned} \quad (23.13)$$

we realize that, if $(X, \mathbf{P}_1, \mathbf{P}_2)$ is a solution, than $(\mathbf{H}X, \mathbf{P}_1\mathbf{H}^{-1}, \mathbf{P}_2\mathbf{H}^{-1})$ is also a solution, where \mathbf{H} is an invertible 4×4 real matrix or in other words a collineation in \mathbb{P}^3 . Even if we align the world coordinate system with the coordinate system of the first camera, which is common in practice,

$$\begin{aligned} \mathbf{u}_1 &\sim (\mathbf{1} \ 0) X, \\ \mathbf{u}_2 &\sim \mathbf{P}_2 X, \end{aligned} \quad (23.14)$$

we retain the same ambiguity, where \mathbf{H} is of the form

$$\mathbf{H} \sim \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ h_{41} & h_{42} & h_{43} & h_{44} \end{pmatrix}, \quad (23.15)$$

with $h_{44} \neq 0$. This ambiguity is possible when the projection matrices are arbitrary rank-3 real matrices without any constraint on their elements. If we assume that we have calibrated our cameras then the projection matrices depend only on displacements

$$\begin{aligned} \mathbf{u}_1 &\sim (\mathbf{1} \ 0) X, \\ \mathbf{u}_2 &\sim (\mathbf{R} \ t) X, \end{aligned} \quad (23.16)$$

and the only remaining ambiguity is the scale ambiguity, where \mathbf{H} looks like an identity matrix except with $h_{44} = s \neq 1$ being the scale factor. In other words, if $(\mathbf{R}, \mathbf{t}, X)$ is a solution, then $(\mathbf{R}, st, 1/sX)$ is a solution, too. These remarks generalize to multiple views. Because in robotics the (\mathbf{R}, \mathbf{t}) matrices correspond to location and X to mapping of the environment, the problem is more properly described as simultaneous localization and mapping (SLAM). However, because the term SLAM has been used with a variety of sensors, such as sonar and laser range scanners, the term monocular SLAM is better suited to describe structure from motion based on multiple views [23.15].

Epipolar Geometry

This is probably one of the most studied problems in computer vision. We constrain ourselves to the calibrated case, which is most relevant to robotics applications. The necessary and sufficient condition for the two rays \mathbf{Rx}_1 and \mathbf{x}_2 to intersect is that the two rays are coplanar with the baseline \mathbf{t} :

$$\mathbf{x}_2^\top (\mathbf{t} \times \mathbf{Rx}_1) = 0, \quad (23.17)$$

which is the epipolar constraint (Fig. 23.2). To avoid the scale ambiguity we assume that \mathbf{t} is a unit vector. We proceed by summarizing the unknowns into one matrix

$$\mathbf{E} = \hat{\mathbf{t}}\mathbf{R}, \quad (23.18)$$

where $\hat{\mathbf{t}}$ is the 3×3 skew-symmetric matrix to the vector \mathbf{t} . The \mathbf{E} matrix is called the essential matrix. The epipolar constraint then reads

$$\mathbf{x}_2^\top \mathbf{E} \mathbf{x}_1 = 0, \quad (23.19)$$

which is the equation of a line in the \mathbf{x}_2 plane with coefficients \mathbf{Ex}_1 or a coefficient of a line in the \mathbf{x}_1 plane with

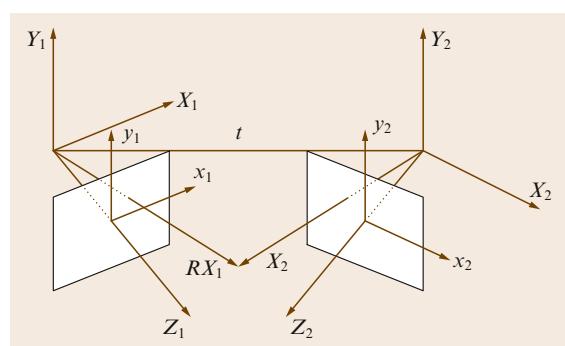

Fig. 23.2 Two views illustrating the coordinate transformations and the perspective projection of the world to a camera

coefficients $\mathbf{E}^\top \mathbf{x}_2$. These lines are called epipolar and form pencils whose centers are the epipoles \mathbf{e}_1 and \mathbf{e}_2 in the first and second image plane, respectively. Looking at Fig. 23.2, we can see that the epipoles are the intersections of the baseline with the two image planes, hence $\mathbf{e}_2 \sim \mathbf{t}$ and $\mathbf{e}_1 \sim -\mathbf{R}^\top \mathbf{t}$. Looking at the equations of the epipolar lines we can immediately infer that $\mathbf{E}^\top \mathbf{e}_1 = 0$ and $\mathbf{E} \mathbf{e}_2 = 0$.

The set of all essential matrices

$$\mathcal{E}_2 = \left\{ \mathbf{E} \in \mathbb{R}^{3 \times 3} \mid \mathbf{E} = [\mathbf{t}]_\times \mathbf{R}, \text{ where } \mathbf{t} \in \mathbb{S}^2 \text{ and } \mathbf{R} \in \text{O}(3) \right\} \quad (23.20)$$

has been characterized as a manifold of degree five. The following result has been proven [23.16].

Proposition 23.1

A matrix $\mathbf{E} \in \mathbb{R}^{3 \times 3}$ is essential if and only if it has two singular values equal to each other and the third singular value equal zero.

We present here a very recent method introduced by Nister [23.17] for recovering an essential matrix from five point correspondences, which has gained in popularity because of its suitability for RANSAC methods.

Minimal Case

We expand the epipolar constraint in terms of the homogeneous coordinates $\mathbf{x}_1 = (x_1, y_1, z_1)$ and $\mathbf{x}_2 = (x_2, y_2, z_2)$ (when the points are not at infinity $z_i = 1$):

$$\begin{pmatrix} x_1 \mathbf{x}_2^\top & y_1 \mathbf{x}_2^\top & z_1 \mathbf{x}_2^\top \end{pmatrix} \mathbf{E}_s = 0, \quad (23.21)$$

where \mathbf{E}_s is the raw-by-raw stacked version of matrix \mathbf{E} .

When we use only five point correspondences the resulting linear homogeneous system will have as a solution any vector in the four-dimensional kernel of the data matrix:

$$\mathbf{E}_s = \lambda_1 \mathbf{u}_1 + \lambda_2 \mathbf{u}_2 + \lambda_3 \mathbf{u}_3 + \lambda_4 \mathbf{u}_4. \quad (23.22)$$

At this point we want the matrix \mathbf{E} resulting from \mathbf{E}_s to be an essential matrix satisfying Proposition 23.1. It has been proven [23.16] that

Proposition 23.2

A matrix $\mathbf{E} \in \mathbb{R}^{3 \times 3}$ is essential if and only if

$$\mathbf{E} \mathbf{E}^\top \mathbf{E} = \frac{1}{2} \text{trace}(\mathbf{E} \mathbf{E}^\top) \mathbf{E}. \quad (23.23)$$

Though the $\det(\mathbf{E}) = 0$ constraint can be inferred from (23.23) we are still going to use it together with (23.23) to use ten cubic equations in \mathbf{E} . As described in [23.17], one can obtain a tenth-degree polynomial in λ_4 . The number of real roots of this polynomial are computed with a Sturm sequence. There is no proof that a real root will exist at all, beyond the physical plausibility of the existence of at least one solution.

Assuming that we have recovered an essential matrix from point correspondences, the next task is to recover an orthogonal matrix \mathbf{R} and a unit vector translation \mathbf{t} from the essential matrix. It can be shown that, if $\mathbf{E} = \mathbf{U} \mathbf{S} \mathbf{V}^\top$ is the singular value decomposition (SVD) of \mathbf{E} with $\det(\mathbf{U}) > 0$ and $\det(\mathbf{V}) > 0$, then \mathbf{t} is parallel to the last column of \mathbf{U} and \mathbf{R} is $\mathbf{U} \mathbf{R}_{z\pi} \mathbf{V}^\top$ or $\mathbf{U} \mathbf{R}_{z\pi}^\top \mathbf{V}^\top$, where $\mathbf{R}_{z\pi}$ is a rotation of $\pi/2$ about the z -axis. Each of the rotations is equal to the other followed by a π -rotation around the baseline. The correct pairing of rotation and translation is chosen so that the reconstructed points are in front of the cameras.

Ambiguities

The approach with five point correspondences has a finite number of feasible (feasible means that they may produce multiple interpretations of structures in front of the camera) solutions when the points in the scene lie on a plane (a twofold ambiguity) [23.18] or when the points on the scene and the camera centers lie on a double sheet hyperboloid with the additional constraint that the camera centers lie symmetrically to the main generator of the hyperboloid [23.19]. These are inherent ambiguities which hold for any number of point correspondences when one seeks a solution for an exact essential matrix.

When solving the linear least-squares system for the essential matrix, a planar scene as well as the case of all points and the camera centers lying on a quadric causes a rank deficiency of the system and thus infinite solutions for \mathbf{E} .

Beyond the ambiguous situations, there is a considerable amount of literature regarding instabilities in the two-view problem. In particular, it has been shown [23.18, 20, 21] that a small field of view and insufficient depth variation can cause an indeterminacy in the estimation of the angle between translation and optical axis. An additional small rotation can cause a confounding effect between translation and rotation [23.22]. Moreover, it has been shown that there exist local minima close to the global minimum that can fool any iterative scheme [23.23, 24].

23.1.5 Monocular SLAM or Multiple-View SfM

When we talk about simultaneous localization and mapping we obviously mean over a longer period of time. The question is how to integrate additional frames into our 3-D motion estimation (localization) process.

To exploit multiple frames we introduce rank constraints [23.25]. We assume that the world coordinate system coincides with the coordinate system of the first frame and that a scene point is projected onto \mathbf{x}_i in the i -th frame and that its depth with respect to the first frame is λ_1 :

$$\mathbf{x}_i = \mathbf{R}_i(\lambda_1 \mathbf{x}_1) + \mathbf{t}_i. \quad (23.24)$$

Taking the cross product with \mathbf{x}_i and writing it for n frames yields a homogeneous system

$$\begin{pmatrix} \hat{\mathbf{x}}_2 \times \mathbf{R}_2 \mathbf{x}_1 & \hat{\mathbf{x}}_2 \mathbf{t}_2 \\ \vdots & \vdots \\ \hat{\mathbf{x}}_n \times \mathbf{R}_n \mathbf{x}_1 & \hat{\mathbf{x}}_2 \mathbf{t}_n \end{pmatrix} \begin{pmatrix} \lambda_1 \\ 1 \end{pmatrix} = 0 \quad (23.25)$$

that has the depth of a point in the first frame as an unknown. The $3n \times 2$ multiple view matrix has to have rank one [23.26], a constraint that infers both the epipolar and the trifocal equations. The least-squares solution for the depth can easily be derived as

$$\lambda_1 = -\frac{\sum_{i=1}^n (\mathbf{x}_i \times \mathbf{t}_i)^\top (\mathbf{x}_i \times \mathbf{R}_i \mathbf{x}_1)}{\|\mathbf{x}_i \times \mathbf{R}_i \mathbf{x}_1\|^2}. \quad (23.26)$$

Given a depth for each point we can solve for motion by rearranging the multiple-views constraint (23.25) as

$$\begin{pmatrix} \lambda_1^1 \mathbf{x}_1^{1\top} \otimes \hat{\mathbf{x}}_i^1 & \hat{\mathbf{x}}_i^1 \\ \vdots & \vdots \\ \lambda_1^n \mathbf{x}_1^{n\top} \otimes \hat{\mathbf{x}}_i^n & \hat{\mathbf{x}}_i^n \end{pmatrix} \begin{pmatrix} \mathbf{R}_i^{\text{stacked}} \\ \mathbf{t}_i \end{pmatrix} = 0 \quad (23.27)$$

where \mathbf{x}_i^n is the n -th image point in the i -th frame and $\mathbf{R}_i, \mathbf{t}_i$ is the motion from the first to the i -th frame and $\mathbf{R}_i^{\text{stacked}}$ is the 12×1 vector of stacked elements of the rotation matrix \mathbf{R}_i . Suppose that \mathbf{k} is the 12×1 kernel (or closest kernel in a least-squares sense) of the $3n \times 12$ matrix in the left hand side obtained through singular value decomposition and let us call \mathbf{A} the 3×3 matrix obtained from the first nine elements of \mathbf{k} and \mathbf{a} the vector of elements 10–12. To obtain a rotation matrix we follow the SVD steps in the solution of absolute orientation (23.12) to find the closest orthogonal matrix to an arbitrary invertible matrix.

On top of such an approach, a bundle adjustment [23.27] minimizes the sum of all deviations between image coordinates and the backprojections of the points to be reconstructed. For N points and M motions, the sum of squares of $2N(M+1)$ residuals has to be minimized with respect to all 3-D coordinates and all motions modulo a universal scale, yielding $3N+6M-1$ unknowns. Lourakis [23.28] exploits the sparse structure of the Jacobian involved in any nonlinear minimization. It is worth mentioning that bundle adjustment, though extremely slow, captures the correlation between motion estimates and structure (3-D points) estimates which is artificially hidden in the iterative scheme in (23.25).

The largest-scale motion estimation and registration of views have been performed by Teller [23.29] with a decoupled computation first of relative rotations and finally of relative translations. The above multiple-view SfM techniques can only be applied in a sliding-window mode in time due to their batch nature. Davison [23.15] showed the first real-time recursive approach by decoupling the direction of the viewing rays from the depth unknowns.

23.1.6 Dense Depth Maps from Stereo

In this section we treat a particular aspect of the ‘M’ in the visual SLAM, namely how we can obtain a *dense* map of the environment from two simultaneous (stereo) or consecutive images (structure from motion). We emphasized the density of the map to differentiate this task from visual SLAM approaches establishing only layout maps of landmark points.

We start with a simple explanation, namely, how to extract dense depth maps from a pair of cameras with parallel coordinate axes. Given the projection matrices or the essential matrix of two views we can always rotate the two cameras so that corresponding points lie on the same image row, a process called *rectification* [23.30]. Knowledge of the epipolar geometry is sufficient for rectification. We already described how to triangulate given a correspondence so the focus of this section is really solving the matching problem: for each pixel in the image what is the most similar point in the right image, and vice versa. Assume that we have a *similarity function* between two neighborhoods in the left I_l and right I_r images, respectively, whose central pixels differ by a disparity d . Each similarity measure defines a function of (x_l, d) called the *disparity space image* [23.31, 32]. Recent approaches based on the plane-sweeping method [23.33–35] use

a different domain for computing the correlation, which can be the backprojection of the image on frontoparallel planes and using the interdistance of these layers instead of the disparity. Such a backprojection requires the epipolar geometry and contains a different rectification. The choice of the *similarity* or *matching cost* function and the local *aggregation* directly affects the disparity space image and, depending on the time resources, can become quite nonlinear and elaborate. Of particular concern is the aggregation, which implicitly assumes that disparity is constant over a neighborhood. Such an assumption produces several artifacts at discontinuities unless offseted bilateral aggregation is applied [23.36].

Given a disparity space image, algorithms differ from each other in the way they assign a disparity d to each point x_l based on a local or global *optimization*. In local algorithms, the decision for x_l is independent of that for other points in the image and the classical procedure is the greedy one, yielding the most similar pixel in the same scanline. Global algorithms solve either an entire image row (scanline) at once (dynamic programming) [23.31, 36, 39] or formulate a cost functional over the entire image that consists of the data term, a regularizing smoothness term, and a discontinuity-preserving step. Labeling all pixels with a disparity label is an NP -hard problem and the two dominant approximation paradigms are graph cuts [23.40, 41] or belief propagation [23.42–44].

The challenges in disparity computation arise from three circumstances: pixels might be occluded in one of the images (occlusions), image variation might be minimal (texturelessness), and the appearance of the same point/area might change due to perspective foreshortening or even due to violation of the Lambertian assumption. The latter effect is rather prominent in specularities and is accentuated when the baseline increases.

Occlusions are handled by local algorithms through bilateral windows and left-right consistency checks for the same correspondences independent of which of the two frames is used as reference. Occlusions are best processed by the dynamic programming approach (illustrated in Fig. 23.3), which we illustrate because of its real-time appeal. Applying dynamic programming in stereo presumes that disparity is a monotone function of the image positions, which means that, if we have x_{l1}, d_1 and x_{l2}, d_2 (two point-disparity pairs) and $x_{l1} < x_{l2}$ then $d_1 < d_2$. A further constraint subsumed by all algorithms is the uniqueness constraint, which dictates that a point in the left can have only one corresponding point in

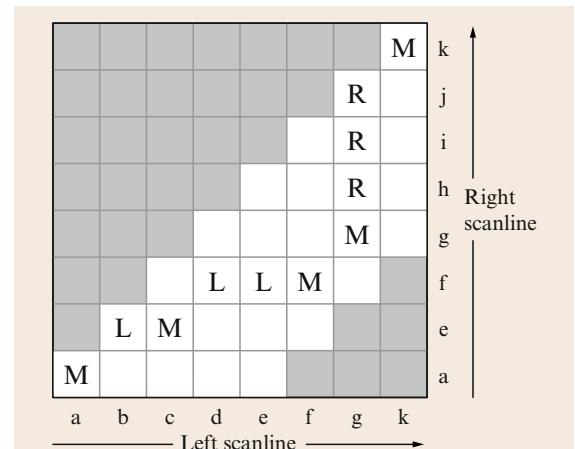

Fig. 23.3 The dynamic programming approach in stereo is based on finding the optimal path in the cost matrix of the picture. Matches are denoted by ‘M’, while ‘L’ and ‘R’ indicate visibility in the left or right image only, respectively [23.37]

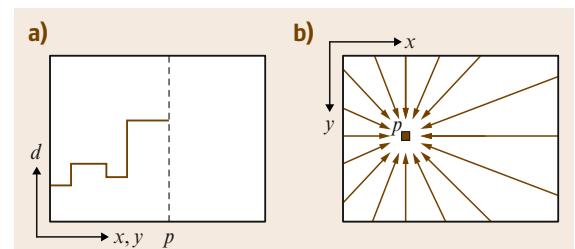

Fig. 23.4 (a) Minimum-cost path in disparity space. (b) Aggregation of costs in 16 directions [23.38]

the right, and vice versa. Several attempts have been made to overcome its single-scanline optimization character. One of the most successful and ranking highly in the stereo vision benchmark is the semiglobal approach in [23.38, 45] which aggregates the costs of scanlines in many directions (Fig. 23.4).

When multiple concatenated stereo pairs are used, for example, for a given a camera trajectory. We have to combine all depth maps into one 3-D model that is as consistent as possible with all the views. Multiple-view stereo [23.46] takes advantage of the existence of multiple cameras around an object by computing the visual hull of objects and refining depth by applying photoconsistency [23.47]. In the context of robotics, we rarely have such a surround capture but we definitely have multiple views captured by a moving system with estimated motion.

23.2 Recognition

Whatever task a robot performs it must be able to determine where things are in the environment and also identify relevant objects, structures, and events. Vision provides rich information about both *where* and *what*, and visual recognition is therefore an essential capability for robots. However, generic visual object recognition is far from easy. It is not even easy to define, since what constitutes an object in the world is not trivial to define without additional constraints (see, e.g., [23.48]). The problem becomes even more difficult if one talks about classes or categories of objects or, say, places. Visual recognition lies at the heart of computer vision research and a vast number of methods have been proposed to deal with it. Still, much remains unknown about how to realize it.

Fortunately, in many cases in robotics we are not faced with the most general aspects of object recognition or classification. More precisely, the problem is often to find an object that either is known or was recently seen. This is typically the case in tracking, navigation, and manipulation. Other situations concern recognizing landmarks or structures such as roads, or more generally places. These tasks all involve recognition, but mainly in the sense of establishing correspondence between phenomena in different images or between an image and a model. Other cases concern the determination of whether something belongs to a class of objects or establishing whether what is seen is a particular type of object, e.g., a road. This is usually called object classification or categorization and constitutes an even more difficult problem. The most general form of the categorization problem, of course, also includes forming the categories, but that is beyond this treatment.

The literature on computer-based visual object recognition, classification, and categorization is very rich and a multitude of methods have been proposed since the very early days of computer vision. Characteristically certain approaches have waxed and waned in popularity. For instance, the purely statistical pattern recognition methods advocated during the early days, but discounted around 1970–80 when 3-D reconstruction and physical and geometrical modeling were the focus, are again being strongly emphasized, not least due to advances in machine learning and increasingly powerful computers. Surveying all existing techniques would require volumes rather than chapters. In the next few sections we will therefore describe some of the methods that seem particularly useful in the type of

robot applications that we have mentioned. The focus on these applications has resulted in many interesting approaches being left out. A comprehensive set of references has been given as entry points to several of these techniques and to the extensive literature on the subject. Moreover, good surveys can be found in the slides from the short course by *Fei Fei* et al. [23.49] or in *Pinz* [23.50], even though they treat categorization rather than recognition.

23.2.1 Approaches to Recognition

Early approaches to object recognition considered objects as represented by 3-D models or by a decomposition into surfaces or volumetric primitives. The first attempts by *Roberts* and *Guzman* [23.51] considered simple geometric parts. *Binford* [23.52] introduced generalized cylinders, which were used by *Brooks* [23.53] in the ACRONYM system and later in the model of *Marr* and *Nishihara* [23.54]. These approaches were based on object-centered representations to enable view invariance. *Marr* [23.55] and others assumed that these could be obtained by 3-D reconstruction from 2-D images using stereo or monocular cues, or by direct acquisition of range images. Several such systems were presented, e.g., *Faugeras* et al. [23.56] and *Bolles* et al. [23.57]. *Biederman* [23.58] introduced his recognition-by-components (RBC) theory as a model for human object recognition from 2-D images. This work inspired numerous attempts to implement RBC-based systems on computers. However, extracting the needed geometric primitives from images turned out to be difficult. The first step of edge detection seldom led to robust indications of where to find the parts. In the ACRONYM system this was addressed by advanced reasoning, in other systems, such as those of *Mohan* and *Nevatia* [23.59] and *Zisserman* et al. [23.60], edges were grouped to generate part hypotheses. Another system using the same principle, but going for the object without any intermediate part representation was, proposed by *Nelson* and *Selinger* [23.61]. Increasingly advanced methods for representing and analyzing shapes based on skeletons have also been proposed. These usually require a silhouette curve and therefore also assume prior segmentation. The influence of these techniques on object recognition has consequently been limited at least insofar that they assume object-centered representations.

The general development has instead been towards viewer-centered representations. In fact, there is an on-

going debate on the role of such representations in human recognition (see, e.g., *Tarr* and *Bülthoff* [23.62]). In computer vision, methods of this sort go back to very early pattern-recognition-based approaches. A revived interest in these first arose in work on face recognition, e.g., *Turk* and *Pentland* [23.63]. This was paralleled by advances on neural network models, e.g., *Poggio* and *Edelman* [23.64]. By showing that training a system on different views of a set of objects resulted in excellent recognition rates *Murase* and *Nayar* [23.65] initiated an interest in learning and statistical approaches that has continued and developed substantially ever since. Notably the focus has changed from global to local methods, which was already suggested by *Rao* and *Ballard* [23.66]. Discriminative as well as generative models have been proposed, which in turn has implied that the methods apply to object categorization as well as recognition. Moreover, more explicit representation of structure and parts have also been incorporated. This introduction of what is now often called constellation-based approaches has in fact decreased the difference between part- and appearance-based methods and again implied a return to very early methods such as the spring-loaded template matching proposed by *Fischler* and *Elschläger* [23.67]. Nevertheless, we will in the sequel describe methods as being appearance-based or constellation- or part-based as a way of stressing different aspects of them.

23.2.2 Appearance-Based Methods

Appearance-based approaches to object recognition rely on the extraction of distinctive features in the images. In pattern recognition and image processing features are defined as N -tuples or vectors whose components are functions of the initial pattern variables or a subset of them (from *Haralick* and *Shapiro* [23.68]). Features can be computed both locally and globally in the images, but in robotics applications local features tend to be most appropriate. In matching one needs to find distinguishing features that characterize the patterns one is looking for. Hence, one separates the steps of detecting features and computing feature descriptors.

As described in the section on *Ambiguities* features computed at discrete locations of the images should preferably be invariant to observer and scene motion. Therefore, geometric features, such as points, lines, and curves have been extensively used, both in computer vision and robotics. These types of features can be computed using derivatives of the image function. Also more general derivative-based features can be derived (see

Lindeberg [23.69]), and in fact sets of differential invariants that completely represent the image function can be defined. However, simple point features and even extended features such as lines only partly represent the visual information at their locations. Therefore, richer descriptors of these locations are often needed to address, e.g., the correspondence problem. Furthermore, invariance, or at least covariance, is desirable not only for motion or small viewpoint changes, but also for illumination variations and large-scale motions and distance changes. These issues have been considered in recent approaches to extraction of features and feature descriptors (*Lowe* [23.70], *Schmid* and *Mohr* [23.71], *Mikolajczyk* and *Schmid* [23.72], *Matas* et al. [23.73], and *Mikolajczyk* et al. [23.74]). Building on decades of development of feature extractors this work today provides a set techniques with rather well-studied performance. The features as well as the feature descriptors are generally computed over small regions around some geometric feature, say a point. In that sense region properties are accounted for, for instance, the scale-invariant feature transformation (**SIFT**) descriptor by *Lowe* captures local luminance variations. However, to achieve invariance to illumination the actual luminance values are eliminated in these approaches, and color is not used at all. By including color features additional properties are captured, even though computational models for color constancy, i.e., deriving surface color independently of illumination, have turned out to be very difficult. Color features are still valuable for discrimination. In general, the different features used in the literature are complementary in applicability both with regard to imaging conditions and scene content.

Distinctive Features

The idea of finding interest points for matching was pioneered by *Moravec* [23.75]. His method was furthered in the frequently used detector proposed by *Harris* and *Stephens* [23.76], usually called the Harris detector. It is based on the windowed second moment matrix,

$$\mathbf{M} = \mathbf{E} \begin{pmatrix} I_x^2 & I_x I_y \\ I_x I_y & I_y^2 \end{pmatrix} = \mathbf{E}((\nabla I)(\nabla I)^\top). \quad (23.28)$$

The eigenvalues of the matrix in (23.28) are proportional to the principal curvatures of the autocorrelation function of I . When both these curvatures are high one has a corner in the image, that is moreover stable with respect to lighting variations. Generally, this detector represents the local distribution of orientations. It was independently introduced as such by *Förstner* [23.77]

and *Bigün* and *Granlund* [23.78]. Typically a Gaussian function is used both for windowing and differentiation, and then the operator takes the form

$$\begin{aligned} \mathbf{M} &= \mathbf{E}(\cdot, \sigma_I \sigma_D) \\ &= \sigma_D^2 G(\sigma_I) \begin{pmatrix} I_x^2(\cdot, \sigma_D) & I_x I_y(\cdot, \sigma_D) \\ I_x I_y(\cdot, \sigma_D) & I_y^2(\cdot, \sigma_D) \end{pmatrix} \quad (23.29) \end{aligned}$$

where σ_I and σ_D are the scales of the Gaussian kernels for windowing and differentiation. This matrix is positive semidefinite with eigenvalues $\lambda_1, \lambda_2 \geq 0$. Its trace

$$\mathbf{M} = \lambda_1 + \lambda_2 \quad (23.30)$$

represents the strength of the operator response. The direction of the eigenvector corresponding to the largest eigenvalue gives the average gradient direction in the neighborhood. Moreover

$$\det(\mathbf{M}) = \lambda_1 \lambda_2 \quad (23.31)$$

provides a measure of the spread of directions around the point. An alternative to the Harris detector is given by the Hessian matrix

$$\mathbf{H} = \mathbf{H}(\cdot, \sigma_I \sigma_D) = \begin{pmatrix} I_{xx}(\cdot, \sigma_D) & I_{xy}(\cdot, \sigma_D) \\ I_{xy}(\cdot, \sigma_D) & I_{yy}(\cdot, \sigma_D) \end{pmatrix}. \quad (23.32)$$

This operator gives somewhat stronger responses at blobs and ridges (see, e.g., *Lindeberg* [23.69] or *Lowe* [23.79] for details), but of course requires second-order derivatives. The eigenvalues are in this case proportional to the principal curvatures of the greylevel function and can again be computed from the trace and the determinant. *Lowe* [23.70] uses this for a test on the ratio of the eigenvalues to reject keypoints that are on edges. We refer to his paper for details.

Robust Methods for Finding Distinctive Points

The response of these operators depend on and are sensitive to scale changes. To find distinctive points suitable for matching one therefore needs to find the points of maximum response in both space and scale, i.e., search for maxima in a 3-D space. *Lindeberg* [23.80] presents a method for this based on the notion of characteristic scale. *Mikolajczyk* and *Schmid* [23.72] and *Lowe* [23.70, 79] later described efficient ways of implementing this. *Mikolajczyk* and *Schmid* first use the Harris detector to localize points in 2D and then select the points at which the Laplacian attains a maximum over scales as the final set. This detector, the Harris-Laplacian, is shown to give the best repeatability over

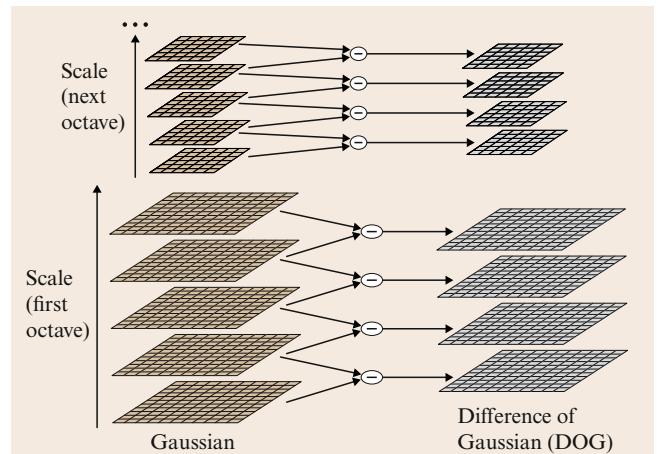

Fig. 23.5 For each octave of scale space, the initial image is repeatedly convolved with Gaussians to produce the set of scale space images shown on the left. Adjacent Gaussian images are subtracted to produce the difference-of-Gaussian (DOG) images on the right. After each octave, the Gaussian image is downsampled by a factor of 2, and the process is repeated

scale changes among several other common interest point detectors.

Lindeberg showed that one needs to normalize the Laplacian with the factor σ to obtain scale invariance, and indeed *Mikolajczyk* [23.72] demonstrated experimentally that the extrema of $\sigma^2 \nabla^2 G$ produce the over scale most stable image features of several operators. *Lowe* [23.70] presents an efficient approximate method for computing these extrema using D , the difference of Gaussians (DOG) instead. This scale space computation is shown in Fig. 23.5. Introducing the factor k he writes

$$D(\cdot, \delta) = G(\cdot, kt) - G(\cdot, t). \quad (23.33)$$

From the heat diffusion equation it follows that

$$\frac{\partial G}{\partial t} = t \nabla^2 G. \quad (23.34)$$

Hence

$$\partial \nabla^2 G = \frac{\partial G}{\partial t} \approx \frac{D}{kt - t} \quad (23.35)$$

that is

$$D \approx (k-1) \delta^2 \nabla^2 G. \quad (23.36)$$

Lowe's efficient method is based on using the approximation to find the points using a set of DOG images. The result of these operations is a set of keypoints with associated location (x - and y -coordinates),

scale, and orientation. The described operators are not affinely invariant, but can be made so, see e.g. Mikolajczyk et al. [23.74]. However, as pointed out by Lowe one can adapt the descriptor so that this becomes unnecessary in many cases, at least if the scene contains enough distinctive features.

Distinctive Regions

Matas et al. [23.73] proposed a method for finding distinguished regions that has turned out to give good results on wide-baseline matching and also in applications to object recognition. It is based on maximally stable extremal regions (**MSER**), that is connected components of thresholded images. The appropriate way to threshold will become clear below. The regions are extremal in the sense that all pixels inside the **MSER** have either higher (bright extremal regions) or lower intensity (dark extremal regions) than all the pixels on its boundary. They are stable in the sense that this property is optimized at threshold selection.

The set of extremal regions have a number of desirable properties, see Matas et al. [23.73]. For instance, they are unaffected by monotonic or affine intensity changes and to continuous geometric image transformations that preserve topology. Hence, they are stable with respect to many geometric and photometric changes that are common and not always known well enough to be corrected.

To describe the algorithm we follow Matas et al. [23.73]. On a digital image I defined on \mathbb{D} with values in \mathbb{S} , typically 0–255 regions are defined as connected components under the topology given by 4-neighborhoods. An extremal region \mathbb{D} is a region such that $p \in \mathbb{D}, q \in \partial\mathbb{D} : I(p) > I(q)$ (maximum intensity region) or $I(p) < I(q)$ (minimum intensity region).

To define a maximally stable extremal region we consider a nested set of regions $D_1 \subset \dots \subset D_i \subset D_{i+1} \subset \dots$. Region D_i^* is maximally stable if q has a maximum at i , where

$$q(i) = |D_{i+h}| \setminus |D_{i-h}| / |D_i| \quad (23.37)$$

and $|.|$ denotes cardinality; h is a parameter of the method.

The nested set of regions is obtained by successively thresholding I with a threshold that transcends \mathbb{S} , e.g., steps from 0 to 255. The regions obtained from such an operation can be enumerated in a straightforward manner. First the pixels are sorted by intensity. Then the pixels are placed in the image, either in decreasing or increasing order, and the list of connected components

and their areas are maintained using, e.g., an efficient union-find algorithm [23.81]. If \mathbb{S} is a small discrete set, such as $0, \dots, 255$ this algorithm is almost linear in the number of pixels and allows an efficient implementation. Notably, the extremal regions can be messy, but the **MSER** operation only retains rather simple regions, which is important for subsequent computation of feature descriptors.

The described method finds salient structure without using derivatives. Other techniques of this nature also exist, e.g., the detector by Kadir and Brady [23.82], the SUSAN corner detection by Smith and Brady [23.83] and morphological methods.

Descriptors for Distinctive Points and Regions

As mentioned above interest point as well as region detectors provide information about local regions over which suitable descriptors can be computed. Hence, Lowe uses scale information to determine an elliptical region, Matas et al. the convex hull of the **MSER**, and Mikolajczyk et al. perform an affine normalization to obtain comparable regions in different images.

Numerous region-based descriptors have been proposed for appearance-based object recognition. These have included methods using the local image patch itself [23.84], its statistics (Schiele and Crowley [23.85]), and more generally filtered versions of it (Rao and Ballard [23.66]). The success of the second-order moment matrix in motion and shape computation indicates the importance of utilizing the directional statistics. Lowe [23.70] suggested a particularly useful descriptor in his scale-invariant feature transformation (**SIFT**) features.

These descriptors are computed at the distinctive points found, e.g., by the methods described earlier in this section, which determine keypoints with an associated scale. To compute them an orientation is first assigned to the keypoint so as to achieve invariance to image rotation. Notably, this is different from using rotationally invariant measures, as in Schmid and Mohr [23.71]. Lowe [23.70] computes the orientation by finding peaks in the histograms of gradient orientations, with the entries weighted by gradient magnitude. The peaks correspond to dominant directions of local gradients. More than one peak can be accepted if several exist that almost reach the highest value. As a consequence several feature descriptors can be assigned to a single image point. Lowe sets the threshold to 80% of the maximum and keeps up to two peaks. Experiments show that as many as four peaks can be useful.

We refer readers to [23.70] for more details on the computations.

Given these steps we have a set of keypoints with associated locations, scales, and orientations. At each point in a window around such a keypoint we again compute the gradient magnitude and orientation. Weighting the values with a Gaussian we histogram them in $n \times n$ subregions in a $k \times k$ pattern around the keypoint; see Fig. 23.6. Lowe [23.70] in his experiments uses $n = k = 4$. In the figure $n = 4$ and $k = 2$. The number of bins for orientation is eight. More details on the computations and the choice of parameters are given in the paper. An important aspect is the choice of measurement region and how it is related to the scale at which the keypoint is detected. This is discussed in the paper, but also in Matas et al. [23.73] and in Mikolajczyk et al. [23.74]. In the latter paper affine normalization is introduced in the comparison to affine invariant detectors. Lowe discusses the usefulness of that in his article as well.

The notion of considering directional statistics around keypoints has also been used in character recognition, where of course the idea of representing the objects (the characters) as patterns arranged around a central point is natural.

Patches and Local Histograms as Features

An alternative and a complement to using features of the kind described above is to use the image patches directly as local descriptors. Such methods can of course be preceded by a step for determining interest points to limit the amount of computation. Agarwal and Roth [23.86] proposed a method based on a codebook of patches that later was furthered by Leibe et al. [23.84] and several other authors.

The patch preserves local image structure, but it has been shown that also histograms of the information in the patch might be sufficient for object recognition and localization. Swain and Ballard [23.87] showed examples of recognition based on comparisons of color information. However, they used red-green-blue (RGB) data directly, which turns out to be sensitive to illumination variations. Schiele and Crowley [23.85] instead used histograms of the output of receptive field computations, either first-order Gaussian derivative operators or differential invariants at three scales. Schneiderman and Kanade [23.88] showed that efficient recognition of faces and cars could be obtained from histograms of wavelet coefficients. More recently Linde and Lindeberg [23.89] introduced higher-order histograms and showed that they can be efficiently computed. Gener-

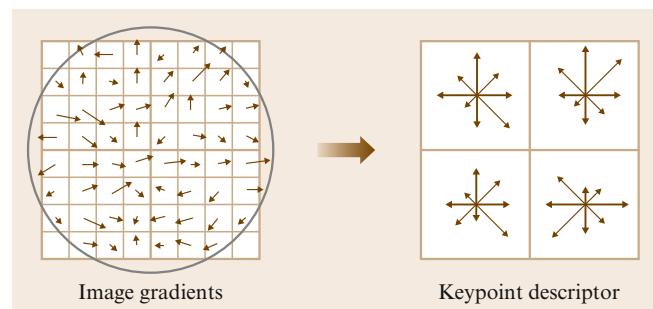

Fig. 23.6 A keypoint descriptor is created by first computing the gradient magnitude and orientation at each image sample point in a region around the keypoint location, as shown on the left. These are weighted by a Gaussian window, indicated by the *overlaid circle*. The samples are then accumulated into orientation histograms summarizing the contents over 4×4 subregions, as shown on the right, with the length of each arrow corresponding to the sum of the gradient magnitudes near that direction within the region. This figure shows a 2×2 descriptor array computed from an 8×8 set of samples, whereas the experiments in this chapter use 4×4 descriptors computed from a 16×16 sample array

ally, these types of methods are simple to use and give good performance provided that sufficient local variations are at hand. A more general framework for such methods has been proposed by Koenderink and van Doorn [23.90], introducing the notion of locally orderless images. Methods for comparing histograms are well known in statistics. An excellent and concise overview of such techniques is given in Rubner and Tomasi [23.91].

23.2.3 Matching

Visual recognition implies matching features or quantities derived from an image to stored representations of objects or images. This is a classical and extensively studied problem that is treated in most standard textbooks on image and signal processing as well as pattern recognition. With new feature-based techniques and with the applications to increasingly large data sets it has attracted considerable interest in recent years and novel contributions have appeared. Some of these will be discussed in the section on constellation based methods. Here we consider some approaches to matching in feature- and appearance-based recognition.

Vocabulary-Based Methods

Straightforward matching using descriptors such as SIFT implies finding nearest neighbors in high-dimensional spaces, which is computationally difficult.

Therefore, Lowe and others use clustering methods to create what can be regarded as an alphabet. Information represented in this way is amenable to general information retrieval methods.

To index an image database *Sivic* and *Zisserman* [23.92] introduced the idea to vector-quantize region descriptors into clusters using k -means and letting these clusters serve as visual *words* in a text retrieval approach. Given a vocabulary generated from a set of training images descriptors are extracted from each new image and assigned to the nearest cluster. In this way matches are immediately obtained for each new image. Sivic and Zisserman applied this to video retrieval, but the method is useful also for other sets of images. Text retrieval is performed using term-frequency inverse document frequency (TF-IDF) relevance scoring (*Baeza-Yates* and *Ribiero-Neto* [23.93]). This technique has been generalized by *Nister* and *Stewenius* [23.94] in the method described next.

Recognition Using Vocabulary Trees

Nister and *Stewenius* [23.94] introduced a hierarchical TF-IDF. In this approach a vocabulary tree is defined by hierarchically defined words. They obtain a very efficient lookup of visual words and can therefore use a larger vocabulary that in turn is shown to give improved retrieval quality (Fig. 23.7).

The vocabulary tree is built up by hierarchical k -means clustering, where k defines a branch factor for the tree. A vector forming a branch of the tree represents a visual word. To compute the score of a new image one needs to determine how similar its descriptors are to the paths down the vocabulary tree. *Nister* and *Stewenius*

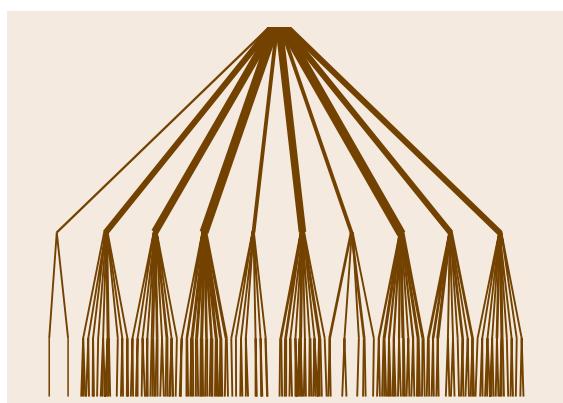

Fig. 23.7 Three levels of a vocabulary tree with branch factor 10 populated to represent an image with 400 features

propose assigning a weight w_i to each node i in the tree, for example, based on entropy, and then define the query q and the database vector according to the assigned weights

$$q_i = n_i w_i ,$$

$$d_i = m_i w_i ,$$

where n_i and w_i are the number of descriptors in the two images. The relevance score is then set to

$$S(q, d) = \left\| \frac{q}{\|q\|} - \frac{d}{\|d\|} \right\|. \quad (23.38)$$

Nister and *Stewenius* recommend the L_1 -norm, but any norm can be used. Furthermore, they suggest computing the weights as

$$w_i = \ln \frac{N}{N_i} ,$$

where N is the number of images in the database, and N_i is the number of images in the database with at least one descriptor vector path through node. The proposed method has been shown to give real-time high-quality performance for retrieval from databases of thousands of images.

A related method using vocabulary-based pyramid matching is presented in *Grauman* and *Darrell* [23.95]. They compute an approximate partial matching between two sets of feature vectors. It should be added that these methods mainly address the indexing problem and give the set of most similar images. For localization an additional step for more precise matching and alignment may be required.

High-Dimensional Feature Matching

As mentioned above feature matching in high dimensions is computationally difficult. However, useful progress on this problem has also been made. Theoretically it is known that exact identification of the nearest neighbor in high-dimensional spaces in general leads to exhaustive search. Approximative methods have been proposed, e.g., by *Beis* and *Lowe* [23.96] and *Indyk* and *Motwani* [23.97], but they need to trade off speed of computation for quality of approximation. A promising approach to deal with this problem has recently been proposed by *Omercevic* et al. [23.98]. Their method is based on the notion of meaningful nearest neighbors. Such neighbors should be sufficiently close to a query feature that it is an outlier to the background feature distribution. This idea is based on the finding that the tail of the distribution of random outliers can be modeled by

an exponential and that nearest neighbors can therefore be weighted by how much they are similar to the query and dissimilar to the background. Dot products are used to measure the similarity between feature vectors. The authors also introduce a search method based on sparse coding and obtain an approximate method that outperforms other techniques either with respect to speed or accuracy. For instance, while slower than the vocabulary tree method it gave better recognition performance on the same data sets.

23.2.4 Constellation-Based Methods – Recognition by Parts

As mentioned above the success of feature and appearance-based methods together with the difficulty in defining and localizing parts have decreased interest in part-based techniques. However, the obvious advantage of using structural information has led to a renewed focus on the problem and in this subsection we will discuss some recent advances in this area. We will consider methods that use structural relations between the parts, but do not assume that the parts necessarily correspond to geometric primitives of some sort or even geometric parts at all. In fact, it turns out that in this way the distinction between part- and appearance-based becomes rather fuzzy, at least in cases when appearance refers to local parts of the object and not the entire object. Forsyth and Ponce in their book unify such methods by talking about them as being based on structural relations between templates, where the templates can be geometric and defined by 3-D or 2-D shape, or by visual appearance, e.g., given by intensity, color, or texture.

A structural model of an object can be given by a collection of parts together with a representation of how these are connected. Connections between pairs of parts are expressed by an undirected graph $G(V, E)$, where the vertices $v = \{v_1, \dots, v_n\}$ correspond to the n parts and the edge $(v_i, v_j) \in E$ implies that parts v_i and v_j are connected. An instance of an object is given by a configuration $L = (l_1, \dots, l_n)$, l_i , being the location of part v_i . There are many ways of parameterizing the locations, including simple image positions or, e.g., positions and joining angles in 2D or 3D for the parts. The idea of using parts in this way is appealing in many ways. Parts provide a modular representation and they may be shared by many objects. Since parts can be simple they are less variable than the entire objects and also often less sensitive to pose variations. Furthermore, occlusion, clutter, and lighting variations

are unlikely to influence the recognition of all the parts.

However, it is important to cope with two problems. One has been discussed already, namely that of detecting and localizing the parts. The second one concerns matching, which is generally computationally difficult. *Fischler and Elschlager* [23.67] proposed to address it as an energy-minimization problem in the image domain. Such an approach is described by *Felzenschwalb* and *Huttenlocher* [23.99] as follows.

The cost or energy of a given configuration depends on how well a part matches the image data and on how well the parts agree with the model. Given an image, let $m_i(l_i)$ be a measure of the degree of mismatch when part v_i is placed at location l_i in the image. For a pair of connected parts let $d_{ij}(l_i, l_j)$ measure the degree of deformation of the model when part v_i has location l_i and part v_j location l_j . An optimal match of the model to the image can then be defined as

$$L^* = \arg \min_L \left(\sum_{i=1}^n m_i(l_i) + \sum_{(v_i, v_j) \in E} d_{ij}(l_i, l_j) \right). \quad (23.39)$$

This expression gives a configuration that minimizes the sum of match costs for each part and the deformation costs d_{ij} for connected pairs of parts. If the deformation costs only depend on the relative positions of the parts in the pairs the model is invariant to common global transformations.

A problem with this type of formulation is that it generally lacks efficient solutions. If the objects are complicated and especially if the amount of non-rigidity is high the number of parameters required is often also high. Modern approaches to these issues use probabilistic models. Hence, they rely on probabilistic estimates of where parts are rather than on deterministic segmentation steps. The estimates are obtained using learned representations of the appearance of the parts and priors on the configurations. This allows statistical formulations that include both the part finding and configuration problem. However, to initiate such algorithms one still has to find good candidate hypotheses with methods of the type described in the next section.

Let Θ be a set of parameters defining the object and L be the configuration, i.e., the location of each part. Then $P(I | L, \Theta)$ is the distribution that measures the likelihood of image I given a viewed object. From Bayes' rule follows that the posterior distribution of the

object configuration L given the model Θ and the image I is

$$P(L | I, \Theta) \propto P(I | L, \Theta)P(L | \Theta), \quad (23.40)$$

where $P(L | \Theta)$ is the prior probability that an object is at a particular location.

Following *Felzenschwalb* and *Huttenlocher* [23.99], the matching problem formulated as an energy-minimization problem can in this framework be regarded as an **MAP** estimation problem. They propose an efficient algorithm for this. In their framework the model parameters are $\Theta = (u, E, c)$, where $u = \{u_1, \dots, u_r\}$ are appearance parameters, E is the set of edges telling what parts are connected (in a graph representation), and $c = \{c_{ij} | (v_i, v_j) \in E\}$ are connection parameters. The model parameters are learned from a set of training images using maximum-likelihood estimation. Energy minimization in this formulation is generally *NP*-hard, but Felzenschwalb and Huttenlocher use the fact that the graph describing the structure has a restricted form to present an efficient algorithm. In other work *Fergus* et al. [23.100] parameterize with respect to appearance, location, and scale, not including any explicit graph representation of the configuration. Their method is aimed at recognizing classes of objects rather than single exemplars.

23.2.5 Place Recognition and Terrain Classification

Localization is a fundamental problem in mobile robotics. Two central aspects of this problem concern continuous pose maintenance and global localization, sometimes called the *robot kidnapping* problem. These problems are generally treated in the context of **SLAM**. Vision-based techniques form but one class of approaches and the way they are applied largely depends on the type of additional information that is available. In

any case, landmark detection and recognition as well as global localization can be addressed using vision and in both cases the problems then share many aspects with object recognition and image retrieval. Hence, several of the techniques presented in the previous sections also apply in these cases.

Scale-invariant key points and **SIFT** features have been used by *Kosecka* et al. [23.101]. They perform global localization indoors by recognizing locations and exploit information from neighborhood relations from a map using **HMMs**. *Wolf* et al. [23.102] propose a similar approach. Others have used histogram descriptors to represent the scenes. *Ulrich* and *Nourbakhsh* [23.103] compute color histograms from omnidirectional camera images and match them to stored images in combination with predictions from a topological map. In that way near-real-time performance is obtained through a simple voting process over the color bands. The method is successfully applied to indoor as well as outdoor environments. *Davidson* and *Murray* [23.104] used actively controlled cameras to find landmarks indoors following *Bajcsy*'s active perception paradigm [23.105].

Learning is a central problem in place recognition. In most cases many training images are needed to obtain robust recognition. Moreover, additional information in terms of maps or approximate position is used to facilitate the recognition stage. *Ramos* et al. [23.106] propose a Bayesian approach to deal with these problems. Hence, their method can learn from few (3–10) training images and requires no map. Images are divided into patches and the world is interpreted as a set of places, each having a probabilistic representation. Matching is performed in near real time. They first perform dimensionality reduction on a patch representation of the scenes and then derive a generative probabilistic model of the output in terms of a set of linear mixture models through expectation maximization. The result of this inference process is a mixture of Gaussians that is used in a multiclass classification scheme in which the log likelihood for the model that best explains the given set of patches is selected.

23.3 Conclusion and Further Reading

As main additional sources of reading, we recommend the books by *Hartley* and *Zisserman* [23.5], *Ma* et al. [23.26], *Faugeras* [23.107], and *Faugeras* and *Lelong* [23.4]. There is no textbook updated with the most recent results in recognition but the reader is encouraged

to browse through the ICCV'05 and CVPR'07 tutorials by Fei-Fei Li, Antonio Torralba, and Rob Fergus. The most representative and real-time implemented system to recognize instances of objects is *Nister*'s [23.94] vocabulary tree approach.

Fig. 23.8 Reconstruction from a camera mounted on a vehicle (after 23.108) obtained from the fusion of 13 depth maps. Each depth map was obtained from 11-view stereo ►

We will close with a system of motion and dense mapping representing the state of the art: the work in [23.108] represents the state of the art in large-scale dense reconstruction from monocular image sequences without the use of an additional sensor. The camera poses are obtained by applying the algorithm described above [23.17]. A temporary model is obtained and subsequent poses are estimated by applying pose estimation with preemptive RANSAC [23.109] for a time window after which a reinitialization with a novel triple of views is obtained. A depth map is obtained by back-projecting multiple views on planes that sweep space in prominent directions and maximizing a correlation in the sweeping direction. Multiple depth maps are combined (Fig. 23.8) through median fusion and taking visibility into consideration [23.110].

Visual Servoing and Visual Tracking

François Chaumette, Seth Hutchinson

This chapter introduces visual servo control, using computer vision data in the servo loop to control the motion of a robot. We first describe the basic techniques that are by now well established in the field. We give a general overview of the formulation of the visual servo control problem, and describe the two archetypal visual servo control schemes: image-based and position-based visual servo control. We then discuss performance and stability issues that pertain to these two schemes, motivating advanced techniques. Of the many advanced techniques that have been developed, we discuss 2.5-D, hybrid, partitioned, and switched approaches. Having covered a variety of control schemes, we conclude by turning briefly to the problems of target tracking and controlling motion directly in the joint space.

Visual servo (VS) control refers to the use of computer vision data to control the motion of a robot. The vision data may be acquired from a camera that is mounted directly on a robot manipulator or on a mobile robot, in which case motion of the robot induces camera motion, or the camera can be fixed in the workspace so that it can observe the robot motion from a stationary configuration. Other configurations can be considered, such as for instance several cameras mounted on pan-

tilt heads observing the robot motion. The mathematical development of all these cases is similar, and in this chapter we will focus primarily on the former, so-called *eye-in-hand*, case.

Visual servo control relies on techniques from image processing, computer vision, and control theory. In the present chapter, we will deal primarily with the issues from control theory, making connections to previous chapters when appropriate.

24.1 The Basic Components of Visual Servoing

The aim of all vision-based control schemes is to minimize an error $\mathbf{e}(t)$, which is typically defined by

$$\mathbf{e}(t) = \mathbf{s}[\mathbf{m}(t), \mathbf{a}] - \mathbf{s}^*. \quad (24.1)$$

This formulation is quite general, and it encompasses a wide variety approaches, as we will see below. The parameters in (24.1) are defined as follows. The vector $\mathbf{m}(t)$ is a set of image measurements (e.g., the image coordinates of interest points, or the parameters of a set of image segments). These image measurements are used to compute a vector of k visual features, $\mathbf{s}(\mathbf{m}(t), \mathbf{a})$, in which \mathbf{a} is a set of parameters that represent potential additional knowledge about the system (e.g., coarse camera intrinsic parameters or three-dimensional model of objects). The vector \mathbf{s}^* contains the desired values of the features.

For now, we consider the case of a fixed goal pose and a motionless target, i.e., \mathbf{s}^* is constant, and changes in \mathbf{s} depend only on camera motion. Further, we consider here the case of controlling the motion of a camera with six degrees of freedom (e.g., a camera attached to the end effector of a six-degree-of-freedom arm). We will treat more general cases in later sections.

Visual servoing schemes mainly differ in the way that \mathbf{s} is designed. In Sects. 24.2 and 24.3, we describe classical approaches, including image-based visual servo control (IBVS), in which \mathbf{s} consists of a set of features that are immediately available in the image data, and position-based visual servo control (PBVS), in which \mathbf{s} consists of a set of three-dimensional (3-D) parameters, which must be estimated from image measurements. We also present in Sect. 24.4 several more-advanced methods.

Once \mathbf{s} is selected, the design of the control scheme can be quite simple. Perhaps the most straightforward approach is to design a velocity controller. To do this, we require the relationship between the time variation of \mathbf{s} and the camera velocity. Let the spatial velocity of the camera be denoted by $\mathbf{v}_c = (\mathbf{v}_c, \boldsymbol{\omega}_c)$ where \mathbf{v}_c is the instantaneous linear velocity of the origin of the camera frame and $\boldsymbol{\omega}_c$ is the instantaneous angular velocity of the camera frame. The relationship between $\dot{\mathbf{s}}$ and \mathbf{v}_c is given by

$$\dot{\mathbf{s}} = \mathbf{L}_s \mathbf{v}_c, \quad (24.2)$$

in which $\mathbf{L}_s \in \mathbb{R}^{k \times 6}$ is called the *interaction matrix* related to \mathbf{s} [24.1]. The term *feature Jacobian* is also used somewhat interchangeably in the visual servo literature [24.2], but in the present chapter we will use this

last term to relate the time variation of the features to the joints velocity (Sect. 24.8).

Using (24.1) and (24.2) we immediately obtain the relationship between camera velocity and the time variation of the error:

$$\dot{\mathbf{e}} = \mathbf{L}_e \mathbf{v}_c, \quad (24.3)$$

where $\mathbf{L}_e = \mathbf{L}_s$. Considering \mathbf{v}_c as the input to the robot controller, and if we would like, for instance, to try to ensure an exponential decoupled decrease of the error (i.e., $\dot{\mathbf{e}} = -\lambda \mathbf{e}$), we obtain using (24.3)

$$\mathbf{v}_c = -\lambda \mathbf{L}_e^+ \mathbf{e}, \quad (24.4)$$

where $\mathbf{L}_e^+ \in \mathbb{R}^{6 \times k}$ is chosen as the Moore–Penrose pseudo-inverse of \mathbf{L}_e , that is, $\mathbf{L}_e^+ = (\mathbf{L}_e^\top \mathbf{L}_e)^{-1} \mathbf{L}_e^\top$ when \mathbf{L}_e is of full rank 6. This choice allows $\|\dot{\mathbf{e}} - \lambda \mathbf{L}_e \mathbf{L}_e^+ \mathbf{e}\|$ and $\|\mathbf{v}_c\|$ to be minimal. When $k = 6$, if $\det \mathbf{L}_e \neq 0$ it is possible to invert \mathbf{L}_e , giving the control $\mathbf{v}_c = -\lambda \mathbf{L}_e^{-1} \mathbf{e}$.

In real visual servo systems, it is impossible to know perfectly in practice either \mathbf{L}_e or \mathbf{L}_e^+ . So an approximation or an estimation of one of these two matrices must be realized. In the sequel, we denote both the pseudo-inverse of the approximation of the interaction matrix and the approximation of the pseudo-inverse of the interaction matrix by the symbol $\widehat{\mathbf{L}}_e^+$. Using this notation, the control law is in fact

$$\mathbf{v}_c = -\lambda \widehat{\mathbf{L}}_e^+ \mathbf{e} = -\lambda \widehat{\mathbf{L}}_s^+ (\mathbf{s} - \mathbf{s}^*). \quad (24.5)$$

Closing the loop and assuming that the robot controller is able to realize perfectly \mathbf{v}_c , that is inserting (24.5) into (24.3), we obtain

$$\dot{\mathbf{e}} = -\lambda \mathbf{L}_e \widehat{\mathbf{L}}_e^+ \mathbf{e}. \quad (24.6)$$

This equation characterizes the real behavior of the closed-loop system, which is different from the specified one ($\dot{\mathbf{e}} = -\lambda \mathbf{e}$) as soon as $\widehat{\mathbf{L}}_e \widehat{\mathbf{L}}_e^+ \neq \mathbf{I}_6$, where \mathbf{I}_6 is the 6×6 identity matrix. It is also at the basis of the stability analysis of the system using Lyapunov theory.

What we have presented above is the basic design implemented by most visual servo controllers. All that remains is to fill in the details. How should \mathbf{s} be chosen? What then is the form of \mathbf{L}_s ? How should we estimate \mathbf{L}_e^+ ? What are the performance characteristics of the resulting closed-loop system? These questions are addressed in the remainder of the chapter. We first describe the two basic approaches, IBVS and PBVS, whose principles were proposed more than 20 years ago [24.3]. We then present more-recent approaches that have improved their performance.

24.2 Image-Based Visual Servo

Traditional image-based control schemes [24.3, 4] use the image-plane coordinates of a set of points to define the set s . The image measurements \mathbf{m} are usually the pixel coordinates of the set of image points (although this is not the only possible choice), and the parameters \mathbf{a} in the definition of $s = s(\mathbf{m}, \mathbf{a})$ in (24.1) are nothing but the camera intrinsic parameters to go from image measurements expressed in pixels to the features.

24.2.1 The Interaction Matrix

For a 3-D point with coordinates $\mathbf{X} = (X, Y, Z)$ in the camera frame, which projects in the image as a two-dimensional (2-D) point with coordinates $\mathbf{x} = (x, y)$, we have

$$\begin{cases} x = X/Z = (u - c_u)/f\alpha \\ y = Y/Z = (v - c_v)/f \end{cases}, \quad (24.7)$$

where $\mathbf{m} = (u, v)$ gives the coordinates of the image point expressed in pixel units, and $\mathbf{a} = (c_u, c_v, f, \alpha)$ is the set of camera intrinsic parameters as defined in Chap. 23: c_u and c_v are the coordinates of the principal point, f is the focal length, and α is the ratio of the pixel dimensions. The intrinsic parameter β defined in Chap. 23 has been assumed to be 0 here. In this case, we take $s = \mathbf{x} = (x, y)$, the image plane coordinates of the point. The details of the imaging geometry and perspective projection can be found in many computer vision texts, including [24.5, 6].

Taking the time derivative of the projection equations (24.7), we obtain

$$\begin{cases} \dot{x} = \dot{X}/Z - X\dot{Z}/Z^2 = (\dot{X} - x\dot{Z})/Z \\ \dot{y} = \dot{Y}/Z - Y\dot{Z}/Z^2 = (\dot{Y} - y\dot{Z})/Z \end{cases}. \quad (24.8)$$

We can relate the velocity of the 3-D point to the camera spatial velocity using the well-known equation

$$\dot{\mathbf{X}} = -\mathbf{v}_c - \boldsymbol{\omega}_c \times \mathbf{X} \Leftrightarrow \begin{cases} \dot{X} = -v_x - \omega_y Z + \omega_z Y \\ \dot{Y} = -v_y - \omega_z X + \omega_x Z \\ \dot{Z} = -v_z - \omega_x Y + \omega_y X \end{cases}. \quad (24.9)$$

Inserting (24.9) into (24.8), grouping terms, and using (24.7) we obtain

$$\begin{cases} \dot{x} = -v_x/Z + xv_z/Z + xy\omega_x - (1+x^2)\omega_y + y\omega_z \\ \dot{y} = -v_y/Z + yv_z/Z + (1+y^2)\omega_x - xy\omega_y - x\omega_z \end{cases}, \quad (24.10)$$

which can be written

$$\dot{\mathbf{x}} = \mathbf{L}_x \mathbf{v}_c, \quad (24.11)$$

where the interaction matrix \mathbf{L}_x is given by

$$\mathbf{L}_x = \begin{pmatrix} -1/Z & 0 & x/Z & xy & -(1+x^2) & y \\ 0 & -1/Z & y/Z & 1+y^2 & -xy & -x \end{pmatrix}. \quad (24.12)$$

In the matrix \mathbf{L}_x , the value Z is the depth of the point relative to the camera frame. Therefore, any control scheme that uses this form of the interaction matrix must estimate or approximate the value of Z . Similarly, the camera intrinsic parameters are involved in the computation of x and y . Thus \mathbf{L}_x^+ cannot be directly used in (24.4), and an estimation or an approximation $\widehat{\mathbf{L}}_x^+$ must be used, as in (24.5). We discuss this in more detail below.

To control the six degrees of freedom, at least three points are necessary (i.e., we require $k \geq 6$). If we use the feature vector $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$, by merely stacking interaction matrices for three points we obtain

$$\mathbf{L}_x = \begin{pmatrix} \mathbf{L}_{x_1} \\ \mathbf{L}_{x_2} \\ \mathbf{L}_{x_3} \end{pmatrix}.$$

In this case, there will exist some configurations for which \mathbf{L}_x is singular [24.7]. Furthermore, there exist four distinct camera poses for which $\mathbf{e} = \mathbf{0}$, i.e., four global minima exist, and it is impossible to differentiate them [24.8]. For these reasons, more than three points are usually considered.

24.2.2 Approximating the Interaction Matrix

There are several choices available for constructing the estimate $\widehat{\mathbf{L}}_e^+$ to be used in the control law. One popular scheme is of course to choose $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$ if $\mathbf{L}_e = \mathbf{L}_x$ is known, that is if the current depth Z of each point is available [24.2]. In practice, these parameters must be estimated at each iteration of the control scheme. The basic IBVS methods use classical pose-estimation methods (see Chap. 23 and the beginning of Sect. 24.3). Another popular approach is to choose $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$ where \mathbf{L}_{e^*} is the value of \mathbf{L}_e for the desired position $\mathbf{e} = \mathbf{e}^* = \mathbf{0}$ [24.1]. In this case, $\widehat{\mathbf{L}}_e^+$ is constant, and only the desired depth of each point has to be set, which means no varying

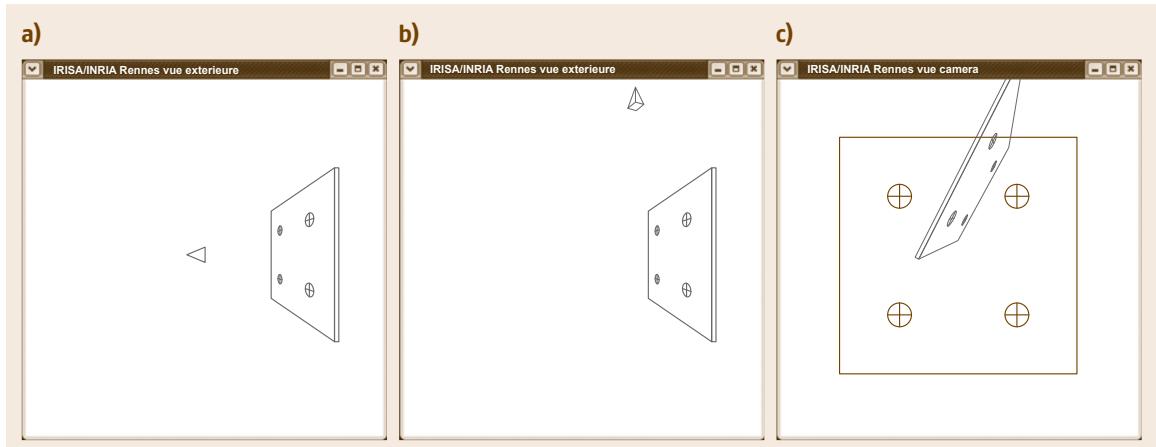

Fig. 24.1a–c Example of positioning task: (a) the desired camera pose with respect to a simple target, (b) the initial camera pose, and (c) the corresponding initial and desired image of the target

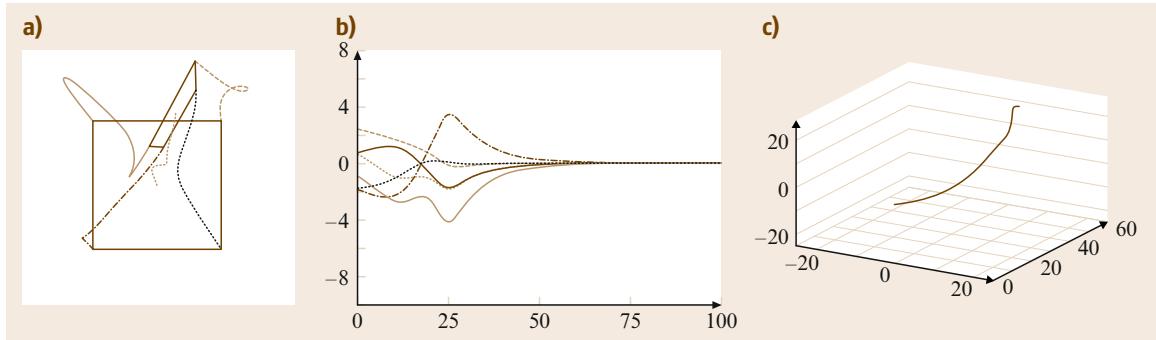

Fig. 24.2a–c System behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$: (a) image point trajectories including the trajectory of the center of the square, which is not used in the control scheme, (b) v_c components (cm/s and deg/s) computed at each iteration of the control scheme, and (c) the 3-D trajectory of the camera optical center expressed in \mathcal{R}_{e^*} (cm)

3-D parameters have to be estimated during the visual servo. Finally, the choice $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_{e^*}/2)^+$ has recently been proposed [24.9]. Since \mathbf{L}_e is involved in this method, the current depth of each point also has to be available.

We illustrate the behavior of these control schemes with an example. The goal is to position the camera so that it observes a square as a centered square in the image (see Fig. 24.1). We define s to include the x and y coordinates of the four points forming the square. Note that the initial camera pose has been selected far away from the desired pose, particularly with regard to the rotational motions, which are known to be the most problematic for IBVS. In the simulations presented in

the following, no noise or modeling errors have been introduced in order to allow comparison of different behaviors in perfect conditions.

The results obtained by using $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$ are given in Fig. 24.2. Note that despite the large displacement that is required the system converges. However, neither the behavior in the image, nor the computed camera velocity components, nor the 3-D trajectory of the camera present desirable properties far from the convergence (i. e., for the first 30 or so iterations).

The results obtained using $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$ are given in Fig. 24.3. In this case, the trajectories of the points in the image are almost straight lines, but the behavior induced in the camera frame is even less satisfactory than

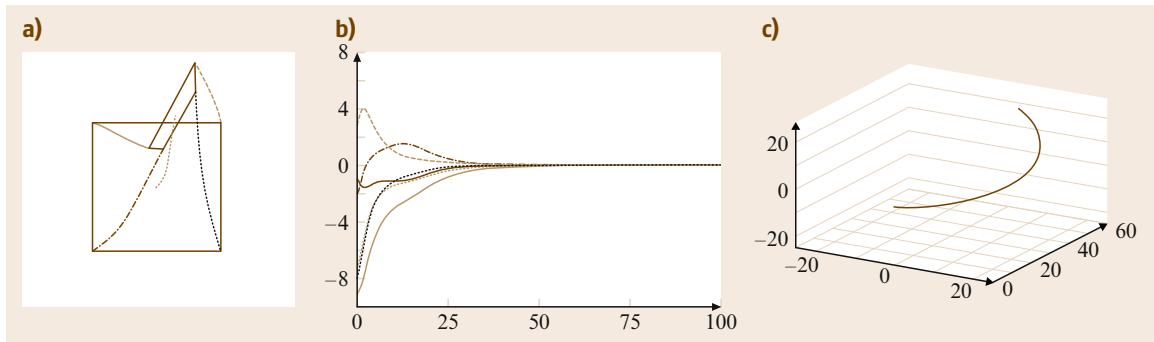

Fig. 24.3a–c System behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$

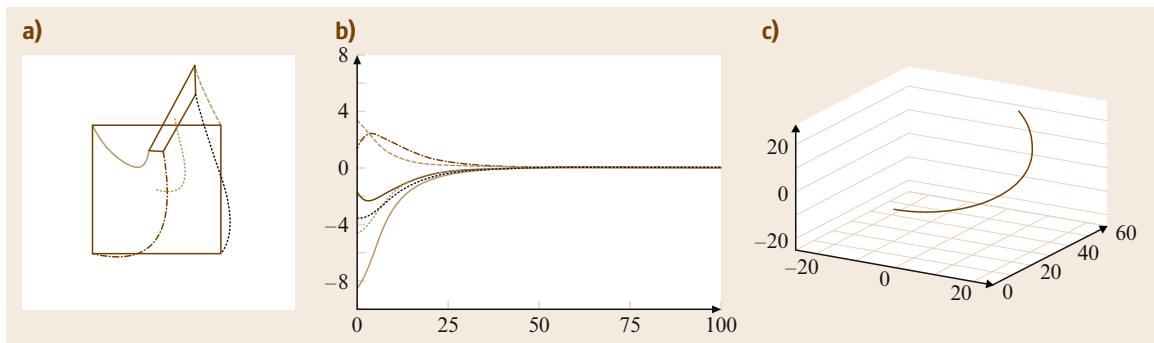

Fig. 24.4a–c System behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_e^*/2)^+$

for the case of $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$. The large camera velocities at the beginning of the servo indicate that the condition number of $\widehat{\mathbf{L}}_e^+$ is high at the start of the trajectory, and the camera trajectory is far from a straight line.

The choice $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_e^*/2)^+$ provides good performance in practice. Indeed, as can be seen in Fig. 24.4, the camera velocity components do not include large oscillations, and provide a smooth trajectory in both the image and in 3-D space.

24.2.3 A Geometrical Interpretation of IBVS

It is quite easy to provide a geometric interpretation of the behavior of the control schemes defined above. The example illustrated in Fig. 24.5 corresponds to a pure rotation around the optical axis from the initial configuration (shown in blue) to the desired configuration of four coplanar points parallel to the image plane (shown in red).

As explained above, using \mathbf{L}_e^+ in the control scheme attempts to ensure an exponential decrease of the error \mathbf{e} . This means that, when x and y image point coordi-

nates compose this error, the points' trajectories in the image follow straight lines from their initial to their desired positions, when this is possible. This leads to the image motion plotted in green in the figure. The camera motion to realize this image motion can be easily deduced and is indeed composed of a rotational motion around the optical axis, but combined with a retreating translational motion along the optical axis [24.10]. This unexpected motion is due to the choice of the features, and to the coupling between the third and sixth columns in the interaction matrix. If the rotation between the initial and desired configurations is very large, this phenomenon is amplified, and leads to a particular case for a rotation of π radians where no rotational motion at all will be induced by the control scheme [24.11]. On the other hand, when the rotation is small, this phenomenon almost disappears. To conclude, the behavior is locally satisfactory (i.e., when the error is small), but it can be unsatisfactory when the error is large. As we will see below, these results are consistent with the local asymptotic stability results that can be obtained for IBVS.

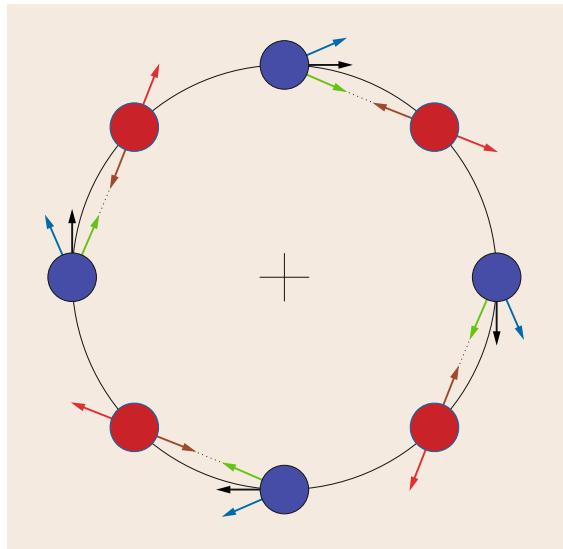

Fig. 24.5 Geometrical interpretation of IBVS: going from the blue position to the red one. In red, image motion when \mathbf{L}_e^+ is used in the control scheme; in blue, when $\mathbf{L}_{e^*}^+$ is used; and in black when $(\mathbf{L}_e/2 + \mathbf{L}_{e^*}/2)^+$ is used (see the text for more details)

If instead we use $\mathbf{L}_{e^*}^+$ in the control scheme, the image motion generated can easily be shown to be the blue one plotted in Fig. 24.5. Indeed, if we consider the same control scheme as before but starting from s^* to reach s , we obtain

$$\mathbf{v}_c = -\lambda \mathbf{L}_{e^*}^+ (s^* - s),$$

which again induces straight-line trajectories from the red points to the blue ones, causing the image motion plotted in brown. Going back to our problem, the control scheme computes a camera velocity that is exactly the opposite one

$$\mathbf{v}_c = -\lambda \mathbf{L}_{e^*}^+ (s - s^*),$$

and thus generates the image motion plotted in red at the red points. Transformed at the blue points, the camera velocity generates the blue image motion and corresponds once again to a rotational motion around the optical axis, combined now with an unexpected forward motion along the optical axis. The same analysis as before can be done, as for large or small errors. We can add that, as soon as the error decreases significantly, both control schemes get closer, and tend to the same one (since $\mathbf{L}_e = \mathbf{L}_{e^*}$ when $\mathbf{e} = \mathbf{e}^*$) with a nice behavior characterized with the image motion plotted in black and

a camera motion composed of only a rotation around the optical axis when the error tends towards zero.

If we instead use $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_{e^*}/2)^+$, it is intuitively clear that considering the mean of \mathbf{L}_e and \mathbf{L}_{e^*} generates the image motion plotted in black, even when the error is large. In all cases but the rotation around π radians, the camera motion is now a pure rotation around the optical axis, without any unexpected translational motion.

24.2.4 Stability Analysis

We now consider the fundamental issues related to the stability of IBVS. To assess the stability of the closed-loop visual servo systems, we will use Lyapunov analysis. In particular, consider the candidate Lyapunov function defined by the squared error norm $\mathcal{L} = \frac{1}{2} \|\mathbf{e}(t)\|^2$, whose derivative is given by

$$\begin{aligned}\dot{\mathcal{L}} &= \mathbf{e}^\top \dot{\mathbf{e}} \\ &= -\lambda \mathbf{e}^\top \mathbf{L}_e \widehat{\mathbf{L}}_e^+ \mathbf{e}\end{aligned}$$

since $\dot{\mathbf{e}}$ is given by (24.6). The global asymptotic stability of the system is thus obtained when the following sufficient condition is satisfied:

$$\mathbf{L}_e \widehat{\mathbf{L}}_e^+ > 0. \quad (24.13)$$

If the number of features is equal to the number of camera degrees of freedom (i.e., $k = 6$), and if the features are chosen and the control scheme designed so that \mathbf{L}_e and $\widehat{\mathbf{L}}_e^+$ are of full rank 6, then the condition (24.13) is satisfied if the approximations involved in $\widehat{\mathbf{L}}_e^+$ are not too coarse.

As discussed above, for most IBVS approaches we have $k > 6$. Therefore the condition (24.13) can never be ensured since $\mathbf{L}_e \widehat{\mathbf{L}}_e^+ \in \mathbb{R}^{k \times k}$ is at most of rank 6, and thus $\mathbf{L}_e \widehat{\mathbf{L}}_e^+$ has a nontrivial null space. In this case, configurations such that $\mathbf{e} \in \ker \widehat{\mathbf{L}}_e^+$ correspond to local minima. Reaching such a local minimum is illustrated in Fig. 24.6. As can be seen in Fig. 24.6d, each component of \mathbf{e} has a nice exponential decrease with the same convergence speed, causing straight-line trajectories to be realized in the image, but the error reached is not exactly zero, and it is clear from Fig. 24.6c that the system has been attracted to a local minimum far away from the desired configuration. Thus, only local asymptotic stability can be obtained for IBVS.

To study local asymptotic stability when $k > 6$, let us first define a new error \mathbf{e}' with $\mathbf{e}' = \widehat{\mathbf{L}}_e^+ \mathbf{e}$. The time

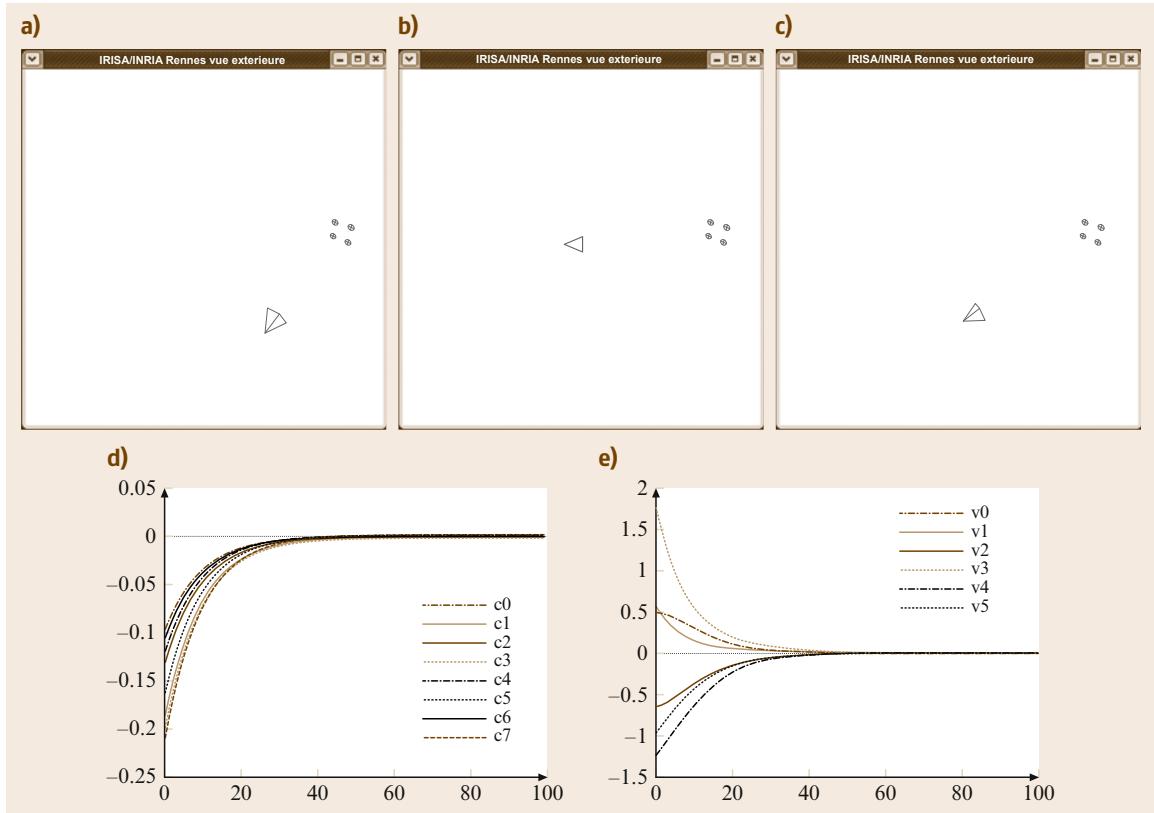

Fig. 24.6a–e Reaching a local minimum using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$: (a) the initial configuration, (b) the desired one, (c) the configuration reached after the convergence of the control scheme, (d) the evolution of the error e at each iteration of the control scheme, and (e) the evolution of the six components of the camera velocity v_c

derivative of this error is given by

$$\begin{aligned}\dot{e}' &= \widehat{\mathbf{L}}_e^+ \dot{e} + \dot{\widehat{\mathbf{L}}}_e^+ e \\ &= (\widehat{\mathbf{L}}_e^+ \mathbf{L}_e + \mathbf{O}) v_c,\end{aligned}$$

where $\mathbf{O} \in \mathbb{R}^{6 \times 6}$ is equal to $\mathbf{0}$ when $e = 0$, whatever the choice of $\widehat{\mathbf{L}}_e^+$ [24.12]. Using the control scheme (24.5), we obtain

$$\dot{e}' = -\lambda(\widehat{\mathbf{L}}_e^+ \mathbf{L}_e + \mathbf{O}) e',$$

which is known to be locally asymptotically stable in a neighborhood of $e = e^* = \mathbf{0}$ if

$$\widehat{\mathbf{L}}_e^+ \mathbf{L}_e > 0, \quad (24.14)$$

where $\widehat{\mathbf{L}}_e^+ \mathbf{L}_e \in \mathbb{R}^{6 \times 6}$. Indeed, only the linearized system $\dot{e}' = -\lambda \widehat{\mathbf{L}}_e^+ \mathbf{L}_e e'$ has to be considered if we are interested in the local asymptotic stability [24.13].

Once again, if the features are chosen and the control scheme designed so that \mathbf{L}_e and $\widehat{\mathbf{L}}_e^+$ are of full rank 6, then condition (24.14) is ensured if the approximations involved in $\widehat{\mathbf{L}}_e^+$ are not too coarse.

To end the demonstration of local asymptotic stability, we must show that there does not exist any configuration $e \neq e^*$ such that $e \in \ker \widehat{\mathbf{L}}_e^+$ in a small neighborhood of e^* and in a small neighborhood of the corresponding pose p^* . Such configurations correspond to local minima where $v_c = 0$ and $e \neq e^*$. If such a pose p would exist, it is possible to restrict the neighborhood around p^* so that there exists a camera velocity v to reach p^* from p . This camera velocity would imply a variation of the error $\dot{e} = \mathbf{L}_e v$. However, such a variation cannot belong to $\ker \widehat{\mathbf{L}}_e^+$ since $\widehat{\mathbf{L}}_e^+ \mathbf{L}_e > 0$. Therefore, we have $v_c = 0$ if and only if $\dot{e} = \mathbf{0}$, i.e., $e = e^*$, in a neighborhood of p^* .

Even though local asymptotic stability can be ensured when $k > 6$, we recall that global asymptotic stability cannot be ensured. For instance, as illustrated in Fig. 24.6, there may exist local minima corresponding to configurations where $e \in \ker \widehat{\mathbf{L}}_e^+$, which are outside of the neighborhood considered above. Determining the size of the neighborhood in which stability and the convergence are ensured is still an open issue, even if this neighborhood is surprisingly quite large in practice.

24.2.5 IBVS with a Stereo Vision System

It is straightforward to extend the IBVS approach to a multicamera system. If a stereo vision system is used, and a 3-D point is visible in both left and right images (see Fig. 24.7), it is possible to use as visual features

$$\mathbf{s} = \mathbf{x}_s = (\mathbf{x}_l, \mathbf{x}_r) = (x_l, y_l, x_r, y_r)$$

i.e., to represent the point by just stacking in \mathbf{s} the x and y coordinates of the observed point in the left and right images [24.14]. However, care must be taken when constructing the corresponding interaction matrix since the form given in (24.11) is expressed in either the left or right camera frame. More precisely, we have

$$\begin{cases} \dot{\mathbf{x}}_l = \mathbf{L}_{\mathbf{x}_l} \mathbf{v}_l, \\ \dot{\mathbf{x}}_r = \mathbf{L}_{\mathbf{x}_r} \mathbf{v}_r, \end{cases}$$

where \mathbf{v}_l and \mathbf{v}_r are the spatial velocity of the left and right camera, respectively, and where the analytical form of $\mathbf{L}_{\mathbf{x}_l}$ and $\mathbf{L}_{\mathbf{x}_r}$ are given by (24.12).

By choosing a sensor frame rigidly linked to the stereo vision system, we obtain

$$\dot{\mathbf{x}}_s = \begin{pmatrix} \dot{\mathbf{x}}_l \\ \dot{\mathbf{x}}_r \end{pmatrix} = \mathbf{L}_{\mathbf{x}_s} \mathbf{v}_s,$$

where the interaction matrix related to \mathbf{x}_s can be determined using the spatial motion transform matrix \mathbf{V}

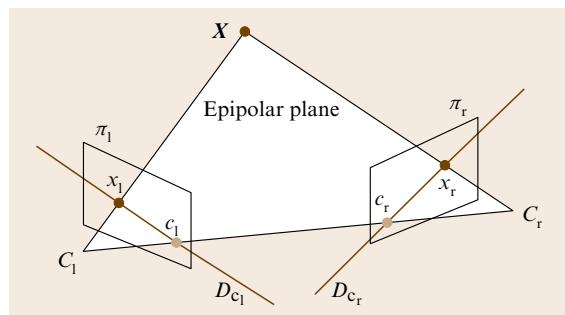

Fig. 24.7 A stereo vision system

defined in Chap. 1 to transform velocities expressed in the left or right cameras frames to the sensor frame. We recall that \mathbf{V} is given by

$$\mathbf{V} = \begin{pmatrix} \mathbf{R} & [\mathbf{t}]_{\times} \mathbf{R} \\ \mathbf{0} & \mathbf{R} \end{pmatrix}, \quad (24.15)$$

where $[\mathbf{t}]_{\times}$ is the skew-symmetric matrix associated to the vector \mathbf{t} and where $(\mathbf{R}, \mathbf{t}) \in SE(3)$ is the rigid-body transformation from the camera to the sensor frame. The numerical values for these matrices are directly obtained from the calibration step of the stereo vision system. Using this equation, we obtain

$$\mathbf{L}_{\mathbf{x}_s} = \begin{pmatrix} \mathbf{L}_{\mathbf{x}_l}^{-1} \mathbf{V}_s \\ \mathbf{L}_{\mathbf{x}_r}^{-1} \mathbf{V}_s \end{pmatrix}.$$

Note that $\mathbf{L}_{\mathbf{x}_s} \in \mathbb{R}^{4 \times 6}$ is always of rank 3 because of the epipolar constraint that links the perspective projection of a 3-D point in a stereo vision system (see Fig. 24.7). Another simple interpretation is that a 3-D point is represented by three independent parameters, which makes it impossible to find more than three independent parameters using any sensor observing that point.

To control the six degrees of freedom of the system, it is necessary to consider at least three points, as the rank of the interaction matrix considering only two points is 5.

Using a stereo vision system, since the 3-D coordinates of any point observed in both images can be easily estimated by a simple triangulation process it is possible and quite natural to use these 3-D coordinates in the features set \mathbf{s} . Such an approach would be, strictly speaking, a position-based approach, since it would require 3-D parameters in \mathbf{s} .

24.2.6 IBVS with Cylindrical Coordinates of Image Points

In the previous sections, we have considered the Cartesian coordinates of images points. As proposed in [24.15], it may be interesting to use the cylindrical coordinates (ρ, θ) of the image points instead of their Cartesian coordinates (x, y) . They are given by:

$$\rho = \sqrt{x^2 + y^2}, \quad \theta = \arctan \frac{y}{x}$$

from which we deduce

$$\dot{\rho} = (x\dot{x} + y\dot{y})/\rho, \quad \dot{\theta} = (y\dot{x} - x\dot{y})/\rho^2.$$

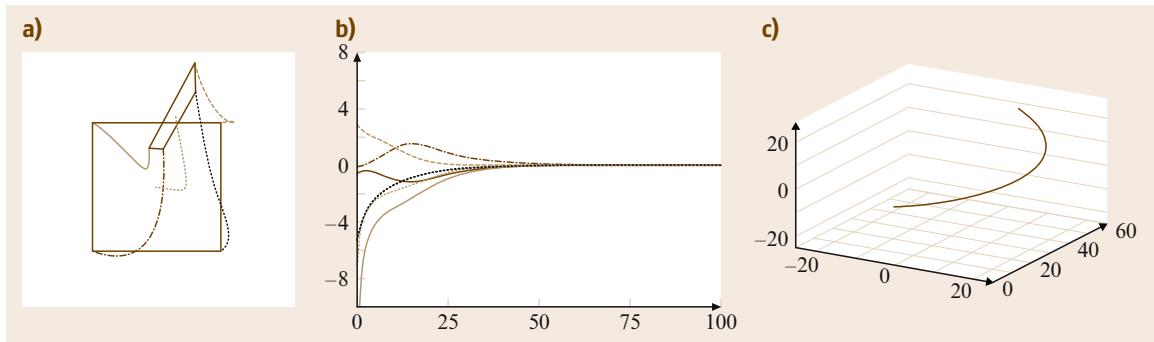

Fig. 24.8a–c System behavior using $s = (\rho_1, \theta_1, \dots, \rho_4, \theta_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^{*+}$

Using (24.11) and then substituting x by $\rho \cos \theta$ and y by $\rho \sin \theta$, we obtain immediately

$$\begin{aligned}\mathbf{L}_\rho &= \begin{pmatrix} -\frac{c}{Z} & -\frac{s}{Z} & \frac{\rho}{Z} & (1+\rho^2)s & -(1+\rho^2)c & 0 \end{pmatrix}, \\ \mathbf{L}_\theta &= \begin{pmatrix} \frac{s}{\rho Z} & -\frac{c}{\rho Z} & 0 & \frac{c}{\rho} & \frac{s}{\rho} & -1 \end{pmatrix},\end{aligned}$$

where $c = \cos \theta$ and $s = \sin \theta$.

The behavior obtained in that case is quite satisfactory. Indeed, by considering the same example as before, and using now $s = (\rho_1, \theta_1, \dots, \rho_4, \theta_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^{*+}$ (that is, a constant matrix), the system behavior shown on Fig. 24.8 has the same nice properties as when using $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_e^*/2)^+$ with $s = (x_1, y_1, \dots, x_4, y_4)$. If we go back to the example depicted in Fig. 24.5, the behavior obtained will be also the expected one thanks to the decoupling between the third and sixth columns of the interaction matrix.

24.2.7 IBVS with Other Geometrical Features

In the previous sections, we have only considered image point coordinates in s . Other geometrical primitives can of course be used. There are several reasons to do so. First, the scene observed by the camera cannot always be described merely by a collection of points, in which case the image processing provides other types of measurements, such as a set of straight lines or the contours of an object. Second, richer geometric primitives may ameliorate the decoupling and linearizing issues that motivate the design of partitioned systems. Finally, the robotic task to be achieved may be expressed in terms of virtual linkages (or fixtures) between the camera and the observed objects [24.16, 17], sometimes expressed directly by constraints between primitives, such as point-

to-line [24.18] (which means that an observed point must lie on a specified line).

For the first point, it is possible to determine the interaction matrix related to the perspective projection of a large class of geometrical primitives, such as segments, straight lines, spheres, circles, and cylinders. The results are given in [24.1] and [24.16]. Recently, the analytical form of the interaction matrix related to any image moments corresponding to planar objects has been computed. This makes it possible to consider planar objects of any shape [24.19]. If a collection of points is measured in the image, moments can also be used [24.20]. In both cases, moments allow the use of intuitive geometrical features, such as the center of gravity or the orientation of an object. By selecting an adequate combination of moments, it is then possible to determine partitioned systems with good decoupling and linearizing properties [24.19, 20].

Note that, for all these features (geometrical primitives, moments), the depth of the primitive or of the object considered appears in the coefficients of the interaction matrix related to the translational degrees of freedom, as was the case for the image points. An estimation of this depth is thus generally still necessary. A few exceptions occur, using for instance an adequate normalization of moments, which allow in some particular cases to make only the constant desired depth appear in the interaction matrix [24.20].

24.2.8 Direct Estimation

In the previous sections, we have focused on the analytical form of the interaction matrix. It is also possible to estimate its numerical value directly using either an offline learning step, or an online estimation scheme.

All the methods proposed to estimate the interaction matrix numerically rely on the observation of a variation of the features due to a known or measured camera motion. More precisely, if we measure a feature's variation Δs due to a camera motion $\Delta \mathbf{v}_c$, we have from (24.2):

$$\mathbf{L}_s \Delta \mathbf{v}_c = \Delta s,$$

which provides k equations while we have $k \times 6$ unknown values in \mathbf{L}_s . Using a set of N independent camera motions with $N > 6$, it is thus possible to estimate \mathbf{L}_s by solving

$$\mathbf{L}_s \mathbf{A} = \mathbf{B},$$

where the columns of $\mathbf{A} \in \mathbb{R}^{6 \times N}$ and $\mathbf{B} \in \mathbb{R}^{k \times N}$ are, respectively, formed from the set of camera motions and the set of corresponding features variations. The least-square solution is of course given by

$$\widehat{\mathbf{L}}_s = \mathbf{B}\mathbf{A}^+. \quad (24.16)$$

Methods based on neural networks have also been developed to estimate \mathbf{L}_s [24.21, 22]. It is also possible to estimate the numerical value of \mathbf{L}_s^+ directly, which in practice provides a better behavior [24.23]. In this case, the basic relation is

$$\mathbf{L}_s^+ \Delta s = \Delta \mathbf{v}_c,$$

which provides six equations. Using a set of N measurements, with $N > k$, we now obtain

$$\widehat{\mathbf{L}}_s^+ = \mathbf{A}\mathbf{B}^+. \quad (24.17)$$

In the first case (24.16), the six columns of \mathbf{L}_s are estimated by solving six linear systems, while in the second case (24.17), the k columns of \mathbf{L}_s^+ are estimated by solving k linear systems, which explains the difference in the results.

Estimating the interaction matrix online can be viewed as an optimization problem, and consequently a number of researchers have investigated approaches that derive from optimization methods. These methods typically discretize the system equation (24.2), and use an iterative updating scheme to refine the estimate of $\widehat{\mathbf{L}}_s$ at each stage. One such online and iterative formulation uses the Broyden update rule given by [24.24, 25]:

$$\widehat{\mathbf{L}}_s(t+1) = \widehat{\mathbf{L}}_s(t) + \frac{\alpha}{\Delta \mathbf{v}_c^\top \Delta \mathbf{v}_c} [\Delta \mathbf{x} - \widehat{\mathbf{L}}_s(t) \Delta \mathbf{v}_c] \Delta \mathbf{v}_c^\top,$$

where α defines the update speed. This method has been generalized to the case of moving objects in [24.26].

The main interest of using such numerical estimations in the control scheme is that it avoids all the modeling and calibration steps. It is particularly useful when using features whose interaction matrix is not available in analytical form. For instance, in [24.27], the main eigenvalues of the principal component analysis of an image have been considered in a visual servoing scheme. The drawback of these methods is that no theoretical stability and robustness analysis can be made.

24.3 Position-Based Visual Servo

Position-based control schemes (PBVS) [24.3, 28, 29] use the pose of the camera with respect to some reference coordinate frame to define s . Computing this pose from a set of measurements in one image necessitates the camera intrinsic parameters and the 3-D model of the object observed to be known. This classic computer vision problem is called the 3-D localization problem. While this problem is beyond the scope of the present chapter, many solutions have been presented in the literature [24.30, 31] and its basic principles are recalled in Chap. 23.

It is then typical to define s in terms of the parameterization used to represent the camera pose. Note that the parameters \mathbf{a} involved in the definition (24.1) of s are now the camera intrinsic parameters and the 3-D model of the object.

It is convenient to consider three coordinate frames: the current camera frame \mathcal{F}_c , the desired camera frame

\mathcal{F}_c^* , and a reference frame \mathcal{F}_0 attached to the object. We adopt here the standard notation of using a leading superscript to denote the frame with respect to which a set of coordinates is defined. Thus, the coordinate vectors ${}^c t_0$ and ${}^{c^*} t_0$ give the coordinates of the origin of the object frame expressed relative to the current camera frame, and relative to the desired camera frame, respectively. Furthermore, let $\mathbf{R} = {}^{c^*} \mathbf{R}_c$ be the rotation matrix that gives the orientation of the current camera frame relative to the desired frame.

We can define s to be $(t, \theta \mathbf{u})$, in which t is a translation vector, and $\theta \mathbf{u}$ gives the angle/axis parameterization for the rotation. We now discuss two choices for t , and give the corresponding control laws.

If t is defined relative to the object frame \mathcal{F}_0 , we obtain $s = ({}^c t_0, \theta \mathbf{u})$, $s^* = ({}^{c^*} t_0, 0)$, and $e = ({}^c t_0 - {}^{c^*} t_0, \theta \mathbf{u})$. In this case, the interaction matrix related to e is given

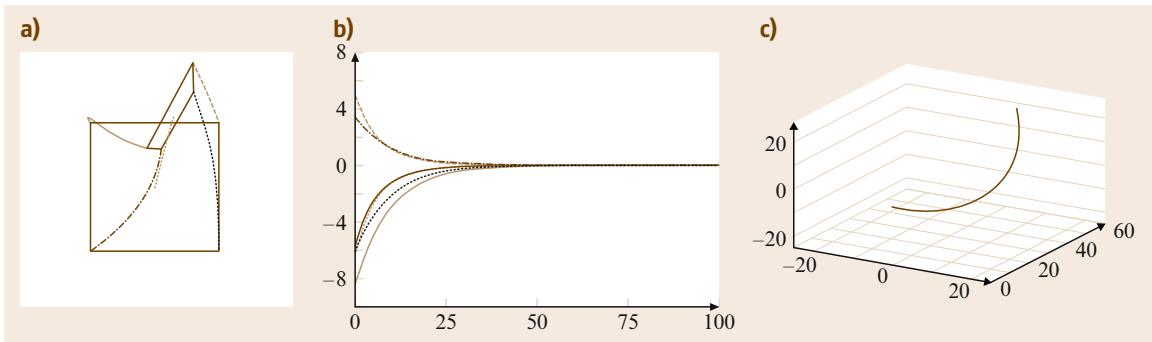

Fig. 24.9a–c System behavior using $s = ({}^c t_0, \theta u)$

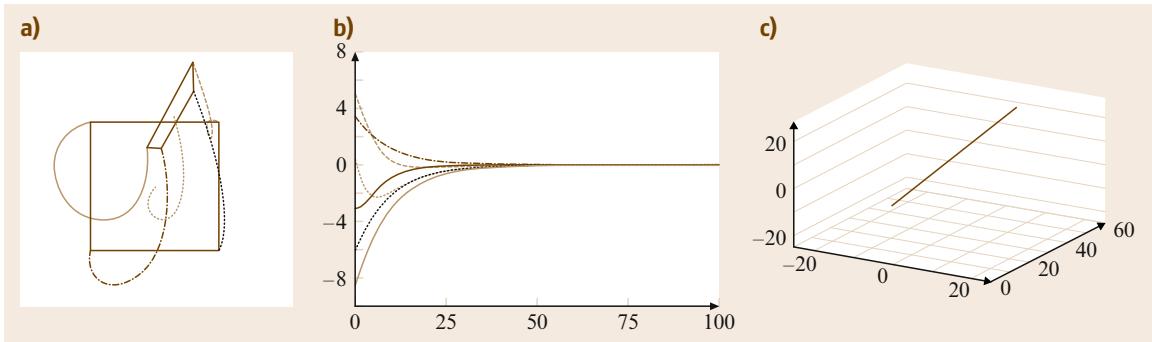

Fig. 24.10a–c System behavior using $s = ({}^* t_c, \theta u)$

by

$$\mathbf{L}_e = \begin{pmatrix} -\mathbf{I}_3 & [{}^c t_0]_x \\ \mathbf{0} & L_{\theta u} \end{pmatrix}, \quad (24.18)$$

in which \mathbf{I}_3 is the 3×3 identity matrix and $L_{\theta u}$ is given by [24.32]

$$\mathbf{L}_{\theta u} = \mathbf{I}_3 - \frac{\theta}{2} [\mathbf{u}]_x + \left(1 - \frac{\text{sinc } \theta}{\text{sinc}^2 \frac{\theta}{2}} \right) [\mathbf{u}]_x^2, \quad (24.19)$$

where $\text{sinc } x$ is the sinus cardinal defined such that $x \text{sinc } x = \sin x$ and $\text{sinc } 0 = 1$.

Following the development in Sect. 24.1, we obtain the control scheme

$$v_c = -\lambda \widehat{\mathbf{L}_e^{-1}} \mathbf{e}$$

since the dimension k of s is six, that is, the number of camera degrees of freedom. By setting

$$\widehat{\mathbf{L}_e^{-1}} = \begin{pmatrix} -\mathbf{I}_3 & [{}^c t_0]_x L_{\theta u}^{-1} \\ \mathbf{0} & L_{\theta u}^{-1} \end{pmatrix}, \quad (24.20)$$

we obtain after simple developments:

$$\begin{aligned} v_c &= -\lambda [{}^* t_c - {}^c t_0] + [{}^c t_0]_x \theta u \\ R_c &= -\lambda \theta u \end{aligned}. \quad (24.21)$$

since $\mathbf{L}_{\theta u}$ is such that $\mathbf{L}_{\theta u}^{-1} \theta u = \theta u$.

Ideally, that is, if the pose parameters are perfectly estimated, the behavior of \mathbf{e} will be the expected one ($\dot{\mathbf{e}} = -\lambda \mathbf{e}$). The choice of \mathbf{e} causes the rotational motion to follow a geodesic with an exponential decreasing speed and causes the translational parameters involved in s to decrease with the same speed. This explains the nice exponential decrease of the camera velocity components in Fig. 24.9. Furthermore, the trajectory in the image of the origin of the object frame follows a pure straight line (here the center of the four points has been selected as this origin). On the other hand, the camera trajectory does not follow a straight line.

Another PBVS scheme can be designed by using $s = ({}^* t_c, \theta u)$. In this case, we have $s^* = \mathbf{0}$, $\mathbf{e} = s$, and

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{R} & \mathbf{0} \\ \mathbf{0} & L_{\theta u} \end{pmatrix}. \quad (24.22)$$

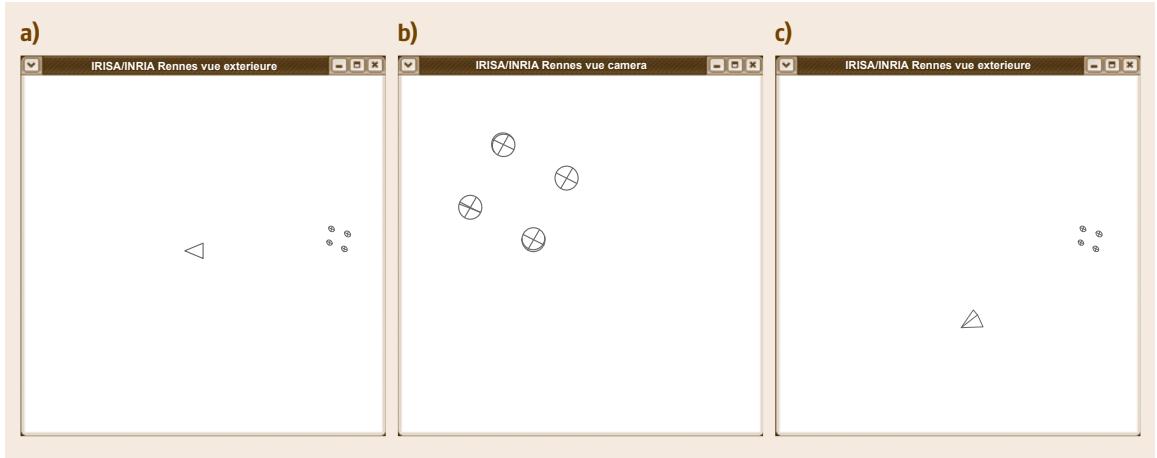

Fig. 24.11a–c Two different camera poses (a, c) that provide almost the same image of four coplanar points (b)

Note the decoupling between translational and rotational motions, which allows us to obtain a simple control scheme

$$\begin{cases} v_c &= -\lambda \mathbf{R}^\top c^* \mathbf{t}_c \\ \omega_c &= -\lambda \theta \mathbf{u} \end{cases}. \quad (24.23)$$

In this case, as can be seen in Fig. 24.10, if the pose parameters involved in (24.23) are estimated perfectly, the camera trajectory is a pure straight line, while the image trajectories are less satisfactory than before. Some particular configurations can even be found so that some points leave the camera field of view.

The stability properties of PBVS seem quite attractive. Since $\mathbf{L}_{\theta u}$ given in (24.19) is nonsingular when $\theta \neq 2k\pi$, we obtain from (24.13) the global asymptotic stability of the system since $\mathbf{L}_e \widehat{\mathbf{L}}_e^{-1} = \mathbf{I}_6$, under the strong hypothesis that all the pose parameters are perfect. This is true for both methods presented above, since the interaction matrices given in (24.18)

and (24.22) are full rank when $\mathbf{L}_{\theta u}$ is nonsingular.

With regard to robustness, feedback is computed using *estimated* quantities that are a function of the image measurements and the system calibration parameters. For the first method presented in Sect. 24.3 (the analysis for the second method is analogous), the interaction matrix given in (24.18) corresponds to perfectly estimated pose parameters, while the real one is unknown since the estimated pose parameters may be biased due to calibration errors, or inaccurate and unstable due to noise [24.11]. The true positivity condition (24.13) should in fact be written:

$$\widehat{\mathbf{L}}_e \widehat{\mathbf{L}}_e^{-1} > 0, \quad (24.24)$$

where $\widehat{\mathbf{L}}_e^{-1}$ is given by (24.20) but where $\widehat{\mathbf{L}}_e$ is unknown, and not given by (24.18). Indeed, even small errors in computing the points position in the image can lead to pose errors that can impact significantly the accuracy and the stability of the system (see Fig. 24.11).

24.4 Advanced Approaches

24.4.1 Hybrid VS

Suppose we have access to a clever control law for ω_c , such as the one used in PBVS [see (24.21) or (24.23)]:

$$\omega_c = -\lambda \theta \mathbf{u}. \quad (24.25)$$

How could we use this in conjunction with traditional IBVS?

Considering a feature vector s_t and an error e_t devoted to control the translational degrees of freedom, we can partition the interaction matrix as follows

$$\begin{aligned} \dot{s}_t &= \mathbf{L}_{s_t} v_c \\ &= (\mathbf{L}_v \mathbf{L}_\omega) \begin{pmatrix} v_c \\ \omega_c \end{pmatrix} \\ &= \mathbf{L}_v v_c + \mathbf{L}_\omega \omega_c. \end{aligned}$$

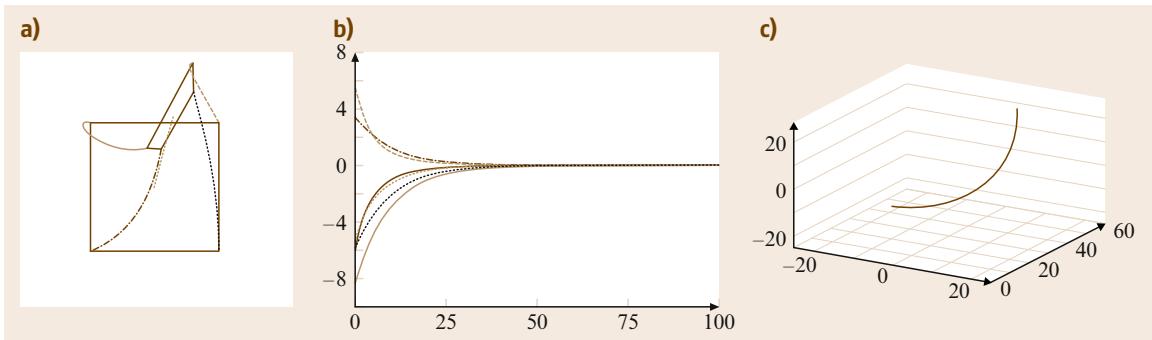

Fig. 24.12a–c System behavior using $s = (x_g, \log(Z_g), \theta u)$

Now, setting $\dot{e}_t = -\lambda e_t$, we can solve for the desired translational control input as

$$\begin{aligned} -\lambda e_t &= \dot{e}_t = \dot{s}_t = \mathbf{L}_v v_c + \mathbf{L}_\omega \omega_c, \\ \Rightarrow v_c &= -\mathbf{L}_v^+ (\lambda e_t + \mathbf{L}_\omega \omega_c). \end{aligned} \quad (24.26)$$

We can think of the quantity $(\lambda e_t + \mathbf{L}_\omega \omega_c)$ as a modified error term, one that combines the original error with the error that would be induced by the rotational motion due to ω_c . The translational control input $v_c = -\mathbf{L}_v^+ (\lambda e_t + \mathbf{L}_\omega \omega_c)$ will drive this error to zero. The method known as 2.5-D visual servo [24.32] was the first to exploit such a partitioning in combining IBVS and PBVS. More precisely, in [24.32], s_t has been selected as the coordinates of an image point, and the logarithm of its depth, so that \mathbf{L}_v is a triangular always invertible matrix. More precisely, we have $s_t = (x, \log Z)$, $s_t^* = (x^*, \log Z^*)$, $e_t = (x - x^*, \log \rho_Z)$ where $\rho_Z = Z/Z^*$, and

$$\begin{aligned} \mathbf{L}_v &= \frac{1}{Z^* \rho_Z} \begin{pmatrix} -1 & 0 & x \\ 0 & -1 & y \\ 0 & 0 & -1 \end{pmatrix} \\ \mathbf{L}_\omega &= \begin{pmatrix} xy & -(1+x^2) & y \\ 1+y^2 & -xy & -x \\ -y & x & 0 \end{pmatrix}. \end{aligned}$$

Note that the ratio ρ_Z can be obtained directly from the partial pose estimation algorithm that will be described in Sect. 24.6.

If we come back to the usual global representation of visual servo control schemes, we have $e = (e_t, \theta u)$ and \mathbf{L}_e given by

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{L}_v & \mathbf{L}_\omega \\ \mathbf{0} & \mathbf{L}_{\theta u} \end{pmatrix},$$

from which we immediately obtain the control law (24.25) and (24.26) by applying (24.5).

The behavior obtained using this choice for s_t is shown in Fig. 24.12. Here, the point that has been considered in s_t is the center of gravity x_g of the target. We note the image trajectory of that point, which is a straight line as expected, and the nice decreasing of the camera velocity components, which makes this scheme very near from the first PBVS one.

As for stability, it is clear that this scheme is globally asymptotically stable in perfect conditions. Furthermore, thanks to the triangular form of the interaction matrix \mathbf{L}_e , it is possible to analyze the stability of this scheme in the presence of calibration errors using the partial pose-estimation algorithm that will be described in Sect. 24.6 [24.33]. Finally, the only unknown constant parameter involved in this scheme, that is Z^* , can be estimated online using adaptive techniques [24.34].

Other hybrid schemes can be designed, for instance, in [24.35], the third component of s_t is different and has been selected so that all the target points remain in the camera field of view as far as possible. Another example has been proposed in [24.36]. In that case, s is selected as $s = ({}^*t_c, x_g, \theta u_z)$ which provides with a block-triangular interaction matrix of the form:

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{R} & \mathbf{0} \\ \mathbf{L}'_v & \mathbf{L}'_\omega \end{pmatrix}$$

where \mathbf{L}'_v and \mathbf{L}'_ω can easily be computed. This scheme is such that, under perfect conditions, the camera trajectory is a straight line (since *t_c is a part of s), and the image trajectory of the center of gravity of the object is also a straight line (since x_g is also a part of s). The translational camera degrees of freedom are de-

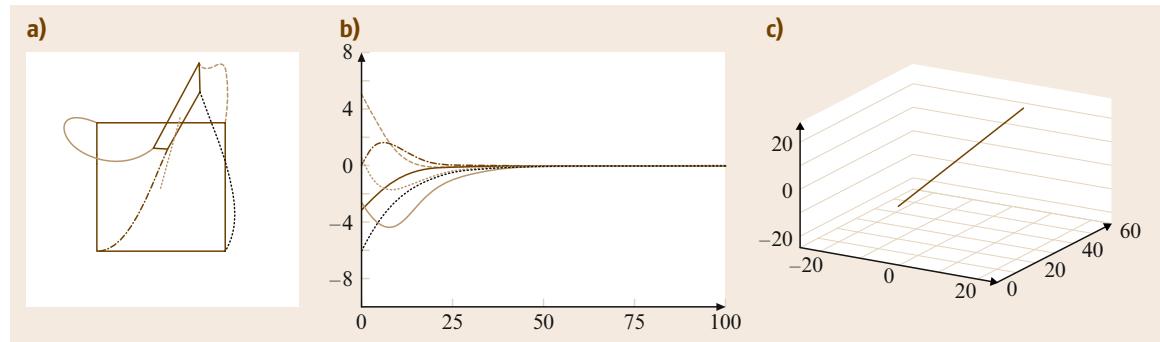

Fig. 24.13a–c System behavior using $s = ({}^*t_c, x_g, \theta u_z)$

voted to realize the 3-D straight line, while the rotational camera degrees of freedom are devoted to realize the 2-D straight line and compensate also the 2-D motion of x_g due to the translational motion. As can be seen in Fig. 24.13, this scheme is particularly satisfactory in practice.

Finally, it is possible to combine 2-D and 3-D features in different ways. For instance, in [24.37], it has been proposed to use in s the 2-D homogeneous coordinates of a set of image points expressed in pixels multiplied by their corresponding depth: $s = (u_1 Z_1, v_1 Z_1, Z_1, \dots, u_n Z_n, v_n Z_n, Z_n)$. As for classical IBVS, we obtain in this case a set of redundant features, since at least three points have to be used to control the six camera degrees of freedom (here $k \geq 9$). However, it has been demonstrated in [24.38] that this selection of redundant features is free of attractive local minima.

24.4.2 Partitioned VS

The hybrid visual servo schemes described above have been designed to decouple the rotational motions from the translational ones by selecting adequate visual features defined in part in 2-D, and in part in 3-D (which is why they have been called 2.5-D visual servoing). This work has inspired some researchers to find features that exhibit similar decoupling properties but using only features expressed directly in the image. More precisely, the goal is to find six features such that each is related to only one degree of freedom (in which case the interaction matrix is a diagonal matrix), the Grail is to find a diagonal interaction matrix whose elements are constant, as near as possible to the identity matrix, leading to a pure, direct, and simple linear control problem.

The first work in this area partitioned the interaction matrix to isolate motion related to the optic axis [24.10]. Indeed, whatever the choice of s , we have

$$\begin{aligned}\dot{s} &= \mathbf{L}_s \mathbf{v}_c \\ &= \mathbf{L}_{xy} \mathbf{v}_{xy} + \mathbf{L}_z \mathbf{v}_z \\ &= \dot{s}_{xy} + \dot{s}_z\end{aligned}$$

in which \mathbf{L}_{xy} includes the first, second, fourth, and fifth columns of \mathbf{L}_s , and \mathbf{L}_z includes the third and sixth columns of \mathbf{L}_s . Similarly, $\mathbf{v}_{xy} = (v_x, v_y, \omega_x, \omega_y)$ and $\mathbf{v}_z = (v_z, \omega_z)$. Here, $\dot{s}_z = \mathbf{L}_z \mathbf{v}_z$ gives the component of \dot{s} due to the camera motion along and rotation about the optic axis, while $\dot{s}_{xy} = \mathbf{L}_{xy} \mathbf{v}_{xy}$ gives the component of \dot{s} due to velocity along and rotation about the camera x and y axes.

Proceeding as above, by setting $\dot{\mathbf{e}} = -\lambda \mathbf{e}$ we obtain

$$-\lambda \mathbf{e} = \dot{\mathbf{e}} = \dot{s} = \mathbf{L}_{xy} \mathbf{v}_{xy} + \mathbf{L}_z \mathbf{v}_z,$$

which leads to

$$\mathbf{v}_{xy} = -\mathbf{L}_{xy}^+ [\lambda \mathbf{e}(t) + \mathbf{L}_z \mathbf{v}_z].$$

As before, we can consider $[\lambda \mathbf{e}(t) + \mathbf{L}_z \mathbf{v}_z]$ as a modified error that incorporates the original error while taking into account the error that will be induced by \mathbf{v}_z .

Given this result, all that remains is to choose s and \mathbf{v}_z . As for basic IBVS, the coordinates of a collection of image points can be used in s , while two new image features can be defined to determine \mathbf{v}_z .

- Define α , with $0 \leq \alpha < 2\pi$, as the angle between the horizontal axis of the image plane and the directed line segment joining two feature points.

It is clear that α is closely related to the rotation around the optic axis.

- Define σ^2 to be the area of the polygon defined by these points. Similarly, σ^2 is closely related to the translation along the optic axis.

Using these features, v_z has been defined in [24.10] as

$$\begin{cases} v_z &= \lambda_{v_z} \ln \frac{\sigma^*}{\sigma}, \\ \omega_z &= \lambda_{\omega_z} (\alpha^* - \alpha). \end{cases}$$

24.5 Performance Optimization and Planning

In some sense, partitioned methods represent an effort to optimize system performance by assigning distinct features and controllers to individual degrees of freedom. In this way, the designer performs a sort of offline optimization when allocating controllers to degrees of freedom. It is also possible to explicitly design controllers that optimize various system performance measures. We describe a few of these in this section.

24.5.1 Optimal Control and Redundancy Framework

An example of such an approach is given in [24.39] and [24.40], in which linear quadratic Gaussian (LQG) control design is used to choose gains that minimize a linear combination of state and control input. This approach explicitly balances the trade-off between tracking errors (since the controller attempts to drive $s - s^*$ to zero) and robot motion. A similar control approach is proposed in [24.41] where joint limit avoidance is considered simultaneously with the positioning task.

It is also possible to formulate optimality criteria that explicitly express the observability of robot motion in the image. For example, the singular value decomposition of the interaction matrix reveals which degrees of freedom are most apparent and can thus be easily controlled, while the condition number of the interaction matrix gives a kind of global measure of the visibility of motion. This concept has been called resolvability in [24.42] and motion perceptibility in [24.43]. By selecting features and designing controllers that maximize these measures, either along specific degrees of freedom or globally, the performance of the visual servo system can be improved.

The constraints considered to design the control scheme using the optimal control approach may be contradictory in some cases, leading the system to fail due to local minima in the objective function to be minimized. For example, it may happen that the motion produced to move away from a robot joint limit is exactly the opposite of the motion produced to near the desired pose, which results in a zero global motion. To avoid

this potential problem, it is possible to use the gradient projection method, which is classical in robotics. Applying this method to visual servoing has been proposed in [24.1] and [24.17]. The approach consists of projecting the secondary constraints e_s onto the null space of the vision-based task e so that they have no effect on the regulation of e to 0:

$$e_g = \widehat{L}_e^\dagger e + P_e e_s,$$

where e_g is the new global task considered and $P_e = (I_6 - \widehat{L}_e^\dagger \widehat{L}_e)$ is such that $\widehat{L}_e P_e e_s = 0, \forall e_s$. Avoiding the robot joint limits using this approach has been presented in [24.44]. However, when the vision-based task constrains all the camera degrees of freedom, the secondary constraints cannot be considered since, when \widehat{L}_e is of full rank 6, we have $P_e e_s = 0, \forall e_s$. In this case, it is necessary to insert the constraints into a global objective function, such as navigation functions that are free of local minima [24.45, 46].

24.5.2 Switching Schemes

The partitioned methods described previously attempt to optimize performance by assigning individual controllers to specific degrees of freedom. Another way to use multiple controllers to optimize performance is to design switching schemes that select at each moment in time which controller to use based on criteria to be optimized.

A simple switching controller can be designed using an IBVS and a PBVS controller as follows [24.47]. Let the system begin by using the IBVS controller. Consider the Lyapunov function for the PBVS controller given by $\mathcal{L} = \frac{1}{2} \|e(t)\|^2$, with $e(t) = ({}^c t_o - {}^c t_o^*, \theta u)$. If at any time the value of this Lyapunov function exceeds a threshold γ_P , the system switches to the PBVS controller. While using the PBVS controller, if at any time the value of the Lyapunov function for the IBVS controller exceeds a threshold, $\mathcal{L} = \frac{1}{2} \|e(t)\|^2 > \gamma_I$, the system switches to the IBVS controller. With this scheme, when the Lyapunov function for a particular controller exceeds

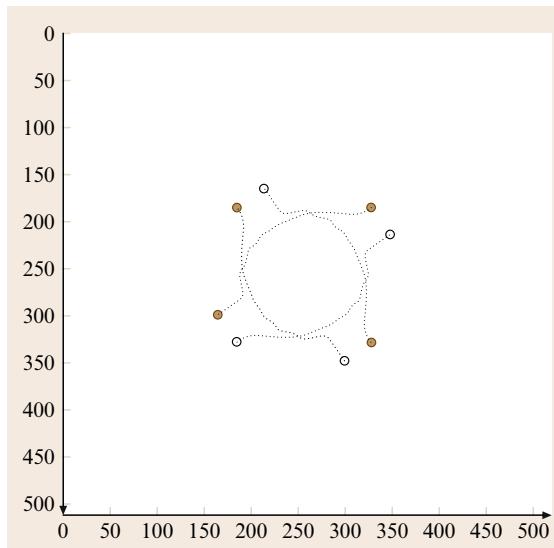

Fig. 24.14 Image feature trajectories for a rotation of 160° about the optical axis using a switched control scheme (initial point positions in *blue*, and desired points position in *red*)

a threshold, that controller is invoked, which in turn reduces the value of the corresponding Lyapunov function. If the switching thresholds are selected appropriately, the system is able to exploit the relative advantages of IBVS and PBVS, while avoiding their shortcomings.

An example of such a system is shown in Fig. 24.14 for the case of a rotation by 160° about the optical axis. Note that the system begins in IBVS mode and the features initially move on straight lines toward their goal positions in the image. However, as the camera retreats, the system switches to PBVS, which allows the camera to reach its desired position by combining a rotational motion around its optic axis and a forward translational motion, producing the circular trajectories observed in the image.

Other examples of temporal switching schemes can be found, such as the one developed in [24.48], to ensure the visibility of the target observed.

24.5.3 Feature Trajectory Planning

It is also possible to treat the optimization problem offline, during a planning stage. In this case, several constraints can be taken into account simultaneously, such as obstacle avoidance [24.49], joint limit and occlusions avoidance, and ensuring the visibility of the target [24.50]. The feature trajectories $s^*(t)$ that allow the camera to reach its desired pose while ensuring that the constraints are satisfied are determined using path planning techniques, such as the well-known potential field approach.

Coupling path planning with trajectory following also allows the robustness of the visual servo with respect to modeling errors to be significantly improved. Indeed, modeling errors may have large effects when the error $s - s^*$ is large, but have little effect when $s - s^*$ is small. Once the desired features trajectories $s^*(t)$ such that $s^*(0) = s(0)$ have been designed during the planning stage, it is easy to adapt the control scheme to take into account the fact that s^* is varying, and to make the error $s - s^*$ remain small. More precisely, we now have

$$\dot{e} = \dot{s} - \dot{s}^* = \mathbf{L}_e \mathbf{v}_c - \dot{s}^*,$$

from which we deduce, by selecting as usual $\dot{e} = -\lambda e$ as the desired behavior,

$$\mathbf{v}_c = -\lambda \widehat{\mathbf{L}}_e^+ e + \widehat{\mathbf{L}}_e^+ \dot{s}^*.$$

The new second term of this control law anticipates the variation of s^* , removing the tracking error it would produce. We will see in the Sect. 24.7 that the form of the control law is similar when tracking of a moving target is considered.

24.6 Estimation of 3-D Parameters

All the control schemes described in the previous sections use 3-D parameters that are not directly available from the image measurements. As for IBVS, we recall that the range of the object with respect to the camera appears in the coefficients of the interaction matrix related to the translational degrees of freedom. Noticeable exceptions are the schemes based on a numerical estima-

tion of \mathbf{L}_e or of \mathbf{L}_e^+ (see Sect. 24.2.8). Another exception is the IBVS scheme that uses the constant matrix $\mathbf{L}_{e^*}^+$ in the control scheme, in which only the depth for the desired pose is required, which is not so difficult to obtain in practice. As for PBVS and hybrid schemes that combine 2-D and 3-D data in e , 3-D parameters appear both in the error e to be regulated to $\mathbf{0}$ and in the interaction matrix.

A correct estimation of the 3-D parameters involved is thus important for IBVS since they will have an effect on the camera motion during the task execution (they appear in the stability conditions (24.13) and (24.14)), while a correct estimation is crucial in PBVS and hybrid schemes since they will have also an effect on the accuracy of the pose reached after convergence.

If a calibrated stereo vision system is used, all 3-D parameters can be easily determined by triangulation, as evoked in Sect. 24.2.5 and described in Chap. 23. Similarly, if a 3-D model of the object is known, all 3-D parameters can be computed from a pose-estimation algorithm. However, we recall that such an estimation can be quite unstable due to image noise. It is also possible to estimate 3-D parameters by using the epipolar geometry that relates the images of the same scene observed from different viewpoints. Indeed, in visual servoing, two images are generally available: the current one and the desired one.

Given a set of matches between the image measurements in the current image and in the desired one, the fundamental matrix, or the essential matrix if the camera is calibrated, can be recovered [24.6], and then used in visual servoing [24.51]. Indeed, from the essential matrix, the rotation and the translation up to a scalar factor between the two views can be estimated. However, near the convergence of the visual servo, that is, when the current and desired images are similar, the epipolar geometry becomes degenerate and it is not possible to estimate accurately the partial pose between the two views. For this reason, using homography is generally preferred.

Let \mathbf{x}_i and \mathbf{x}_i^* denote the homogeneous image coordinates for a point in the current and desired images. Then \mathbf{x}_i is related to \mathbf{x}_i^* by

$$\mathbf{x}_i = \mathbf{H}_i \mathbf{x}_i^*$$

in which \mathbf{H}_i is a homography matrix.

If all feature points lie on a 3-D plane, then there is a single homography matrix \mathbf{H} such that $\mathbf{x}_i = \mathbf{H} \mathbf{x}_i^*$ for all i . This homography can be estimated using the position of four matched points in the desired and the current images. If all the features points do not belong to the same 3-D plane, then three points can be used to define such a plane and five supplementary points are needed to estimate \mathbf{H} [24.52].

Once \mathbf{H} is available, it can be decomposed as

$$\mathbf{H} = \mathbf{R} + \frac{\mathbf{t}}{d^*} \mathbf{n}^{*\top}, \quad (24.27)$$

in which \mathbf{R} is the rotation matrix relating the orientation of the current and desired camera frames, \mathbf{n}^* is the normal to the chosen 3-D plane expressed in the desired frame, d^* is the distance to the 3-D plane from the desired frame, and \mathbf{t} is the translation between current and desired frames. From \mathbf{H} , it is thus possible to recover \mathbf{R} , \mathbf{t}/d^* , and \mathbf{n} . In fact, two solutions for these quantities exist [24.53], but it is quite easy to select the correct one using some knowledge about the desired pose. It is also possible to estimate the depth of any target point up to a common scale factor [24.50]. The unknown depth of each point that appears in classical IBVS can thus be expressed as a function of a single, constant parameter. Similarly, the pose parameters required by PBVS can be recovered up to a scalar factor as for the translation term. The PBVS schemes described previously can thus be revisited using this approach, with the new error defined as the translation up to a scalar factor and the angle/axis parameterization of the rotation. Finally, this approach has also been used for the hybrid visual servoing schemes described in Sect. 24.4.1. In that case, using such homography estimation, it has been possible to analyze the stability of hybrid visual servoing schemes in the presence of calibration errors [24.32].

24.7 Target Tracking

We now consider the case of a moving target and a constant desired value \mathbf{s}^* for the features, the generalization to varying desired features $\mathbf{s}^*(t)$ being immediate. The time variation of the error is now given by

$$\dot{\mathbf{e}} = \mathbf{L}_e \mathbf{v}_c + \frac{\partial \mathbf{e}}{\partial t}, \quad (24.28)$$

where the term $\partial \mathbf{e} / \partial t$ expresses the time variation of \mathbf{e} due to the generally unknown target motion. If the con-

trol law is still designed to try to ensure an exponential decoupled decrease of \mathbf{e} (that is, once again $\dot{\mathbf{e}} = -\lambda \mathbf{e}$), we now obtain using (24.28):

$$\mathbf{v}_c = -\lambda \widehat{\mathbf{L}_e^+} \mathbf{e} - \widehat{\mathbf{L}_e^+} \frac{\widehat{\partial \mathbf{e}}}{\partial t}, \quad (24.29)$$

where $\widehat{\partial \mathbf{e}} / \partial t$ is an estimation or an approximation of $\partial \mathbf{e} / \partial t$. This term must be introduced into the control law to compensate for the target motion.

Closing the loop, that is, inserting (24.29) into (24.28), we obtain

$$\dot{\mathbf{e}} = -\lambda \mathbf{L}_e \widehat{\mathbf{L}_e^+} \mathbf{e} - \mathbf{L}_e \widehat{\mathbf{L}_e^+} \frac{\widehat{\partial \mathbf{e}}}{\partial t} + \frac{\partial \mathbf{e}}{\partial t}. \quad (24.30)$$

Even if $\mathbf{L}_e \widehat{\mathbf{L}_e^+} > 0$, the error will converge to zero only if the estimation of $\widehat{\partial \mathbf{e}}/\partial t$ is sufficiently accurate so that

$$\mathbf{L}_e \widehat{\mathbf{L}_e^+} \frac{\widehat{\partial \mathbf{e}}}{\partial t} = \frac{\partial \mathbf{e}}{\partial t}, \quad (24.31)$$

otherwise tracking errors will be observed. Indeed, by just solving the scalar differential equation $\dot{\mathbf{e}} = -\lambda \mathbf{e} + b$, which is a simplification of (24.30), we obtain $\mathbf{e}(t) = \mathbf{e}(0) \exp(-\lambda t) + b/\lambda$, which converges towards b/λ . On one hand, setting a high gain λ will reduce the tracking error, but on the other hand, setting the gain too high can make the system unstable. It is thus necessary to make b as small as possible.

Of course, if the system is known to be such that $\partial \mathbf{e}/\partial t = 0$ (that is, the camera observes a motionless object, as described in Sect. 24.1), no tracking error will appear with the most simple estimation given by $\widehat{\partial \mathbf{e}}/\partial t = 0$. Otherwise, a classical method in automatic control to cancel tracking errors consists of compensating the target motion through an integral term in the

control law. In this case, we have

$$\widehat{\frac{\partial \mathbf{e}}{\partial t}} = \mu \sum_j \mathbf{e}(j),$$

where μ is the integral gain that has to be tuned. This scheme allows the tracking errors to be canceled only if the target has a constant velocity. Other methods, based on feedforward control, estimate the term $\widehat{\partial \mathbf{e}}/\partial t$ directly through the image measurements and the camera velocity, when it is available. Indeed, from (24.28), we obtain

$$\widehat{\frac{\partial \mathbf{e}}{\partial t}} = \widehat{\mathbf{e}} - \widehat{\mathbf{L}_e} \widehat{\mathbf{v}_c},$$

where $\widehat{\mathbf{e}}$ can, for instance, be obtained as $\widehat{\mathbf{e}}(t) = [\mathbf{e}(t) - \mathbf{e}(t - \Delta t)]/\Delta t$, Δt being the duration of the control loop. A Kalman filter [24.54] or more-elaborate filtering methods [24.55] can then be used to improve the estimated values obtained. If some knowledge about the target velocity or the target trajectory is available, it can of course be used to smooth or predict the motion [24.56–58]. For instance, in [24.59], the periodic motion of the heart and of the breath are compensated for an application of visual servoing in medical robotics. Finally, other methods have been developed to remove the perturbations induced by the target motion as fast as possible [24.39], using for instance predictive controllers [24.60].

24.8 Eye-in-Hand and Eye-to-Hand Systems Controlled in the Joint Space

In the previous sections, we have considered the six components of the camera velocity as the input of the robot controller. As soon as the robot is not able to realize this motion, for instance, because it has fewer than six degrees of freedom, the control scheme must be expressed in the joint space. In this section, we describe how this can be done, and in the process develop a formulation for eye-to-hand systems.

In the joint space, the system equations for both the eye-to-hand and eye-in-hand configurations have the same form:

$$\dot{\mathbf{s}} = \mathbf{J}_s \dot{\mathbf{q}} + \frac{\partial \mathbf{s}}{\partial t}. \quad (24.32)$$

Here, $\mathbf{J}_s \in \mathbb{R}^{k \times n}$ is the feature Jacobian matrix, which can be linked to the interaction matrix, and n is the number of robot joints.

For an eye-in-hand system (Fig. 24.15a), $\partial \mathbf{s}/\partial t$ is the time variation of \mathbf{s} due to a potential object motion, and

\mathbf{J}_s is given by

$$\mathbf{J}_s = \mathbf{L}_s {}^c X_N \mathbf{J}(\mathbf{q}), \quad (24.33)$$

where

- ${}^c X_N$ is the spatial motion transform matrix (as defined in Chap. 1 and recalled in (24.15)) from the vision sensor frame to the end-effector frame. It is usually a constant matrix (as long as the vision sensor is rigidly attached to the end-effector). Thanks to the robustness of closed-loop control schemes, a coarse approximation of this transform matrix is sufficient in visual servoing. If needed, an accurate estimation is possible through classical hand–eye calibration methods [24.61].
- $\mathbf{J}(\mathbf{q})$ is the robot Jacobian expressed in the end-effector frame (as defined in Chap. 1)

For an eye-to-hand system (Fig. 24.15b), $\partial \mathbf{s}/\partial t$ is now the time variation of \mathbf{s} due to a potential vision

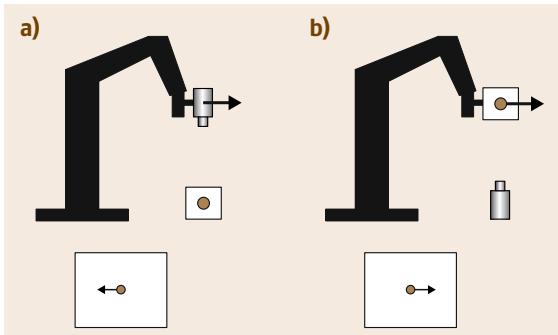

Fig. 24.15 (a) Eye-in-hand system, (b) eye-to-hand system: system schematic (*top*) and opposite image motion produced by the same robot motion (*bottom*)

sensor motion and J_s can be expressed as:

$$J_s = -L_s {}^c X_N {}^N J(\mathbf{q}), \quad (24.34)$$

$$= -L_s {}^c X_0 {}^0 J(\mathbf{q}). \quad (24.35)$$

In (24.34), the classical robot Jacobian ${}^N J(\mathbf{q})$ expressed in the end-effector frame is used but the spatial motion transform matrix ${}^c X_N$ from the vision sensor frame to the end-effector frame changes all along the servo, and it has to be estimated at each iteration of the control scheme, usually using pose-estimation methods.

In (24.35), the robot Jacobian ${}^0 J(\mathbf{q})$ is expressed in the robot reference frame, and the spatial motion transform matrix ${}^c X_0$ from the vision sensor frame to that reference frame is constant as long as the camera does not move. In this case, which is convenient in practice, a coarse approximation of ${}^c X_0$ is usually sufficient.

Once the modeling step is finished, it is quite easy to follow the procedure that has been used above to design a control scheme expressed in the joint space, and to determine the sufficient condition to ensure the stability of the control scheme. We obtain, considering

again $\mathbf{e} = \mathbf{s} - \mathbf{s}^*$, and an exponential decoupled decrease of \mathbf{e} :

$$\dot{\mathbf{q}} = -\lambda \widehat{J}_e^+ \mathbf{e} - \widehat{J}_e^+ \frac{\partial \widehat{\mathbf{e}}}{\partial t}. \quad (24.36)$$

If $k = n$, considering as in Sect. 24.1 the Lyapunov function $\mathcal{L} = \frac{1}{2} \|\mathbf{e}(t)\|^2$, a sufficient condition to ensure the global asymptotic stability is given by

$$\widehat{J}_e \widehat{J}_e^+ > 0. \quad (24.37)$$

If $k > n$, we obtain similarly to Sect. 24.1

$$\widehat{J}_e^+ \widehat{J}_e > 0 \quad (24.38)$$

to ensure the local asymptotic stability of the system. Note that the actual extrinsic camera parameters appear in J_e while the estimated ones are used in \widehat{J}_e^+ . It is thus possible to analyze the robustness of the control scheme with respect to the camera extrinsic parameters. It is also possible to estimate directly the numerical value of J_e or \widehat{J}_e^+ using the methods described in Sect. 24.2.8.

Finally, to remove tracking errors, we have to ensure that

$$J_e \widehat{J}_e^+ \frac{\partial \widehat{\mathbf{e}}}{\partial t} = \frac{\partial \mathbf{e}}{\partial t}.$$

Finally, let us note that, even if the robot has six degrees of freedom, it is generally not equivalent to first compute \mathbf{v}_c using (24.5) and then deduce $\dot{\mathbf{q}}$ using the robot inverse Jacobian, and to compute directly $\dot{\mathbf{q}}$ using (24.36). Indeed, it may occur that the robot Jacobian $J(\mathbf{q})$ is singular while the feature Jacobian J_s is not (that may occur when $k < n$). Furthermore, the properties of the pseudo-inverse ensure that using (24.5), $\|\mathbf{v}_c\|$ is minimal while using (24.36), $\|\dot{\mathbf{q}}\|$ is minimal. As soon as $J_e^+ \neq J^+(\mathbf{q}) {}^N X_c L_e^+$, the control schemes will be different and will induce different robot trajectories. The choice of the state space is thus important.

24.9 Conclusions

In this chapter we have only considered velocity controllers, which are convenient for most classical robot arms. However, the dynamics of the robot must of course be taken into account for high-speed tasks, or when we deal with mobile nonholonomic or underactuated robots. As for sensors, we have only considered geometrical features coming from a classical perspective camera. Features related to the image motion or coming from other vision sensors (fish-eye camera, catadioptric camera, echographic probes, etc.) necessitate reconsider-

eration of the modeling issues to select adequate visual features. Finally, fusing visual features with data coming from other sensors (force sensor, proximetry sensors, etc.) at the level of the control scheme will allow new research topics to be addressed. Numerous ambitious applications of visual servoing can also be considered, including mobile robots in indoor and outdoor environments, for aerial, space, and submarine robots, and in medical robotics. The end of fruitful research in the field of visual servo is thus nowhere yet in sight.

Multisensor Data Fusion

Hugh Durrant-Whyte, Thomas C. Henderson

Multisensor data fusion is the process of combining observations from a number of different sensors to provide a robust and complete description of an environment or process of interest. Data fusion finds wide application in many areas of robotics such as object recognition, environment mapping, and localization.

This chapter has three parts: methods, architectures, and applications. Most current data fusion methods employ probabilistic descriptions of observations and processes and use Bayes' rule to combine this information. This chapter surveys the main probabilistic modeling and fusion techniques including grid-based models, Kalman filtering, and sequential Monte Carlo techniques. This chapter also briefly reviews a number of non-probabilistic data fusion methods. Data fusion systems are often complex combinations of sensor devices, processing, and fusion algorithms. This chapter provides an overview of key principles in data fusion architectures from both a hardware and algorithmic viewpoint. The applications of data fusion are pervasive in robotics and underly the core problem of sensing, estimation, and perception. We highlight two example applications that bring out these features. The first describes a navigation or self-tracking application for an autonomous vehicle. The second describes an

application in mapping and environment modeling.

The essential algorithmic tools of data fusion are reasonably well established. However, the development and use of these tools in realistic robotics applications is still developing.

25.1 Multisensor Data Fusion Methods

The most widely used data fusion methods employed in robotics originate in the fields of statistics, estimation, and control. However, the application of these methods in robotics has a number of unique features and challenges. In particular, autonomy is most often the goal and so results must be presented and interpreted in

a form from which autonomous decisions can be made, for recognition or navigation, for example.

In this section we review the main data fusion methods employed in robotics. These are very often based on probabilistic methods, which are indeed now considered the standard approach to data fusion in all robotics

applications [25.1]. Probabilistic data fusion methods are generally based on Bayes' rule for combining prior and observation information. Practically, this may be implemented in a number of ways: through the use of the Kalman and extended Kalman filters, through sequential Monte Carlo methods, or through the use of functional density estimates. Each of these is reviewed. There are a number of alternatives to probabilistic methods. These include the theory of evidence and interval methods. Such alternative techniques are not as widely used as they once were, however they have some special features that can be advantageous in specific problems. These, too, are briefly reviewed.

25.1.1 Bayes' Rule

Bayes' rule lies at the heart of most data fusion methods. In general, Bayes' rule provides a means to make inferences about an object or environment of interest described by a state \mathbf{x} , given an observation \mathbf{z} .

Bayesian Inference

Bayes' rule requires that the relationship between \mathbf{x} and \mathbf{z} be encoded as a joint probability or joint probability distribution $P(\mathbf{x}, \mathbf{z})$ for discrete and continuous variables, respectively. The chain rule of conditional probabilities can be used to expand a joint probability in two ways

$$P(\mathbf{x}, \mathbf{z}) = P(\mathbf{x} | \mathbf{z})P(\mathbf{z}) = P(\mathbf{z} | \mathbf{x})P(\mathbf{x}). \quad (25.1)$$

Rearranging in terms of one of the conditionals, Bayes' rule is obtained

$$P(\mathbf{x} | \mathbf{z}) = \frac{P(\mathbf{z} | \mathbf{x})P(\mathbf{x})}{P(\mathbf{z})}. \quad (25.2)$$

The value of this result lies in the interpretation of the probabilities $P(\mathbf{x} | \mathbf{z})$, $P(\mathbf{z} | \mathbf{x})$, and $P(\mathbf{x})$. Suppose it is necessary to determine the various likelihoods of different values of an unknown state \mathbf{x} . There may be prior beliefs about what values of \mathbf{x} might be expected, encoded in the form of relative likelihoods in the *prior probability* $P(\mathbf{x})$. To obtain more information about the state \mathbf{x} an observation \mathbf{z} is made. These observations are modeled in the form of a conditional probability $P(\mathbf{z} | \mathbf{x})$ that describes, for each fixed state \mathbf{x} , the probability that the observation \mathbf{z} will be made, i. e., the probability of \mathbf{z} given \mathbf{x} . The new likelihoods associated with the state \mathbf{x} are computed from the product of the original prior information and the information gained by observation. This is encoded in the *posterior probability* $P(\mathbf{x} | \mathbf{z})$, which describes the likelihoods associated with \mathbf{x} given the observation \mathbf{z} . In this fusion process, the marginal probability $P(\mathbf{z})$ simply serves to normalize the posterior and

is not generally computed. The marginal $P(\mathbf{z})$ plays an important role in model validation or data association as it provides a measure of how well the observation is predicted by the prior, because $P(\mathbf{z}) = \int P(\mathbf{z} | \mathbf{x})P(\mathbf{x})d\mathbf{x}$. The value of Bayes' rule is that it provides a principled means of combining observed information with prior beliefs about the state of the world.

Sensor Models

and Multisensor Bayesian Inference

The conditional probability $P(\mathbf{z} | \mathbf{x})$ serves the role of a *sensor model* and can be thought of in two ways. First, in building a sensor model, the probability is constructed by fixing the value of $\mathbf{x} = \mathbf{x}$ and then asking what probability density $P(\mathbf{z} | \mathbf{x} = \mathbf{x})$ on \mathbf{z} results. Conversely, when this sensor model is used and observations are made, $\mathbf{z} = \mathbf{z}$ is fixed and a *likelihood function* $P(\mathbf{z} = \mathbf{z} | \mathbf{x})$ on \mathbf{x} is inferred. The likelihood function, while not strictly a probability density, models the relative likelihood that different values of \mathbf{x} gave rise to the observed value of \mathbf{z} . The product of this likelihood with the prior, both defined on \mathbf{x} , gives the posterior or observation update $P(\mathbf{x} | \mathbf{z})$. In a practical implementation of (25.2), $P(\mathbf{z} | \mathbf{x})$ is constructed as a function of both variables (or a matrix in discrete form). For each fixed value of \mathbf{x} , a probability density on \mathbf{z} is defined. Therefore, as \mathbf{x} varies, a family of likelihoods on \mathbf{z} is created.

The multisensor form of Bayes' rule requires conditional independence

$$\begin{aligned} P(\mathbf{z}_1, \dots, \mathbf{z}_n | \mathbf{x}) &= P(\mathbf{z}_1 | \mathbf{x}) \cdots P(\mathbf{z}_n | \mathbf{x}) \\ &= \prod_{i=1}^n P(\mathbf{z}_i | \mathbf{x}). \end{aligned} \quad (25.3)$$

so that

$$P(\mathbf{x} | \mathbf{Z}^n) = CP(\mathbf{x}) \prod_{i=1}^n P(\mathbf{z}_i | \mathbf{x}), \quad (25.4)$$

where C is a normalizing constant. Equation (25.4) is known as the *independent likelihood pool* [25.2]. This states that the posterior probability on \mathbf{x} given all observations \mathbf{Z}^n , is simply proportional to the product of prior probability and individual likelihoods from each information source.

The recursive form of Bayes' rule is

$$P(\mathbf{x} | \mathbf{Z}^k) = \frac{P(\mathbf{z}_k | \mathbf{x})P(\mathbf{x} | \mathbf{Z}^{k-1})}{P(\mathbf{z}_k | \mathbf{Z}^{k-1})}. \quad (25.5)$$

The advantage of (25.5) is that we need to compute and store only the posterior density $P(\mathbf{x} | \mathbf{Z}^{k-1})$, which contains a complete summary of all past information.

When the next piece of information $P(z_k | x)$ arrives, the previous posterior takes on the role of the current prior and the product of the two becomes, when normalized, the new posterior.

Bayesian Filtering

Filtering is concerned with the sequential process of maintaining a probabilistic model for a state which evolves over time and which is periodically observed

by a sensor. Filtering forms the basis for many problems in tracking and navigation. The general filtering problem can be formulated in Bayesian form. This is significant because it provides a common representation for a range of discrete and continuous data fusion problems without recourse to specific target or observation models.

Define x_t as the value of a state of interest at time t . This may, for example, describe a feature to be tracked, the state of a process being monitored, or the location

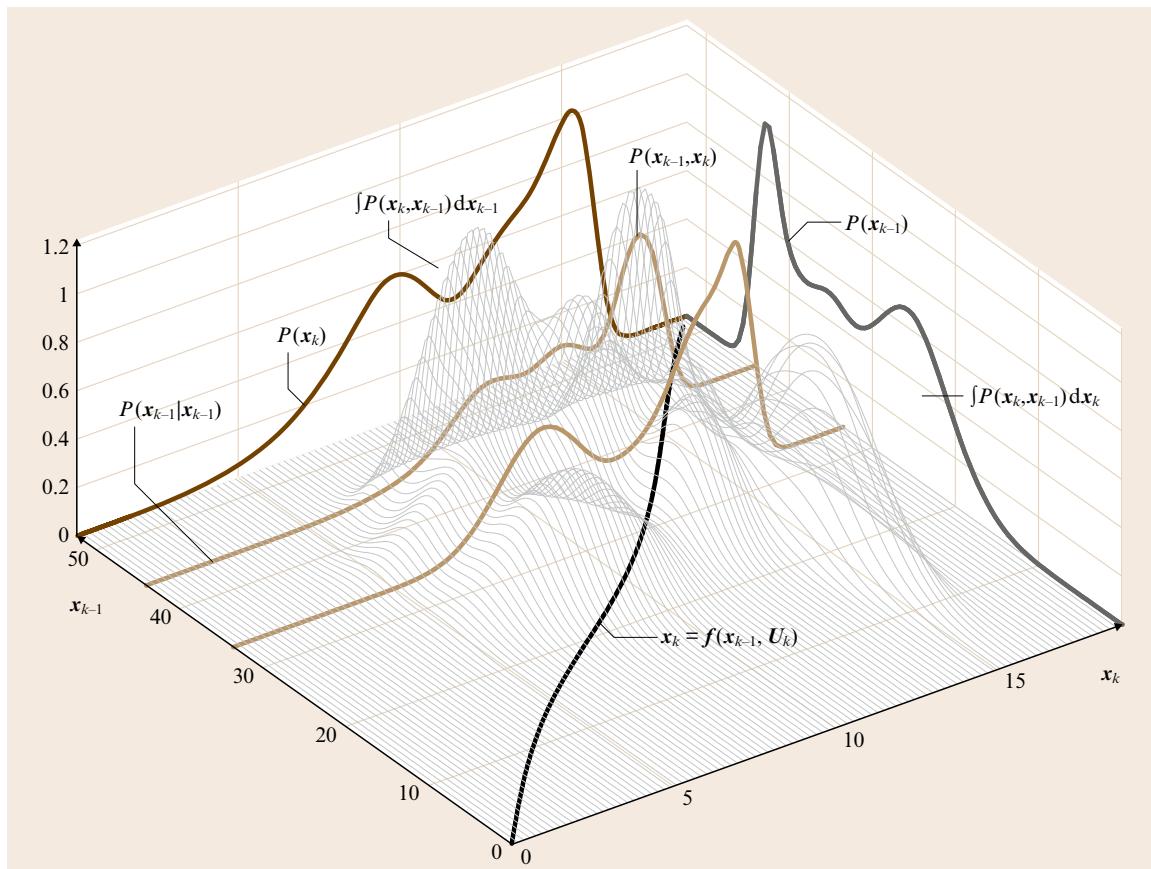

Fig. 25.1 Time update step for the full Bayes filter. At a time $k - 1$, knowledge of the state x_{k-1} is summarized in a probability distribution $P(x_{k-1})$. A vehicle model, in the form of a conditional probability density $P(x_k | x_{k-1})$, then describes the stochastic transition of the vehicle from a state x_{k-1} at a time $k - 1$ to a state x_k at a time k . Functionally, this state transition may be related to an underlying kinematic state model in the form $x_k = f(x_{k-1}, u_k)$. The figure shows two typical conditional probability distributions $P(x_k | x_{k-1})$ on the state x_k given fixed values of x_{k-1} . The product of this conditional distribution with the marginal distribution $P(x_{k-1})$, describing the prior likelihood of values of x_k , gives the joint distribution $P(x_k, x_{k-1})$ shown as the surface in the figure. The total marginal density $P(x_k)$ describes knowledge of x_k after state transition has occurred. The marginal density $P(x_k)$ is obtained by integrating (projecting) the joint distribution $P(x_k, x_{k-1})$ over all x_{k-1} . Equivalently, using the total probability theorem, the marginal density can be obtained by integrating (summing) all conditional densities $P(x_k | x_{k-1})$ weighted by the prior probability $P(x_{k-1})$ of each x_{k-1} . The process can equally be run in reverse (a retroverse motion model) to obtain $P(x_{k-1})$ from $P(x_k)$ given a model $P(x_{k-1} | x_k)$.

of a platform for which navigation data is required. For convenience, and without loss of generality, time is defined at discrete (asynchronous) times $t_k \triangleq k$. At a time instant k , the following quantities are defined:

- \mathbf{x}_k : the state vector to be estimated at time k
- \mathbf{u}_k : a control vector, assumed known, and applied at time $k - 1$ to drive the state from \mathbf{x}_{k-1} to \mathbf{x}_k at time k
- \mathbf{z}_k : an observation taken of the state \mathbf{x}_k at time k

In addition, the following sets are also defined.

- The history of states: $X^k = \{\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_k\} = \{X^{k-1}, \mathbf{x}_k\}$.
- The history of control inputs: $U^k = \{\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_k\} = \{U^{k-1}, \mathbf{u}_k\}$.
- The history of state observations: $Z^k = \{\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_k\} = \{Z^{k-1}, \mathbf{z}_k\}$.

In probabilistic form, the general data fusion problem is to find the posterior density

$$P(\mathbf{x}_k | Z^k, U^k, \mathbf{x}_0) \quad (25.6)$$

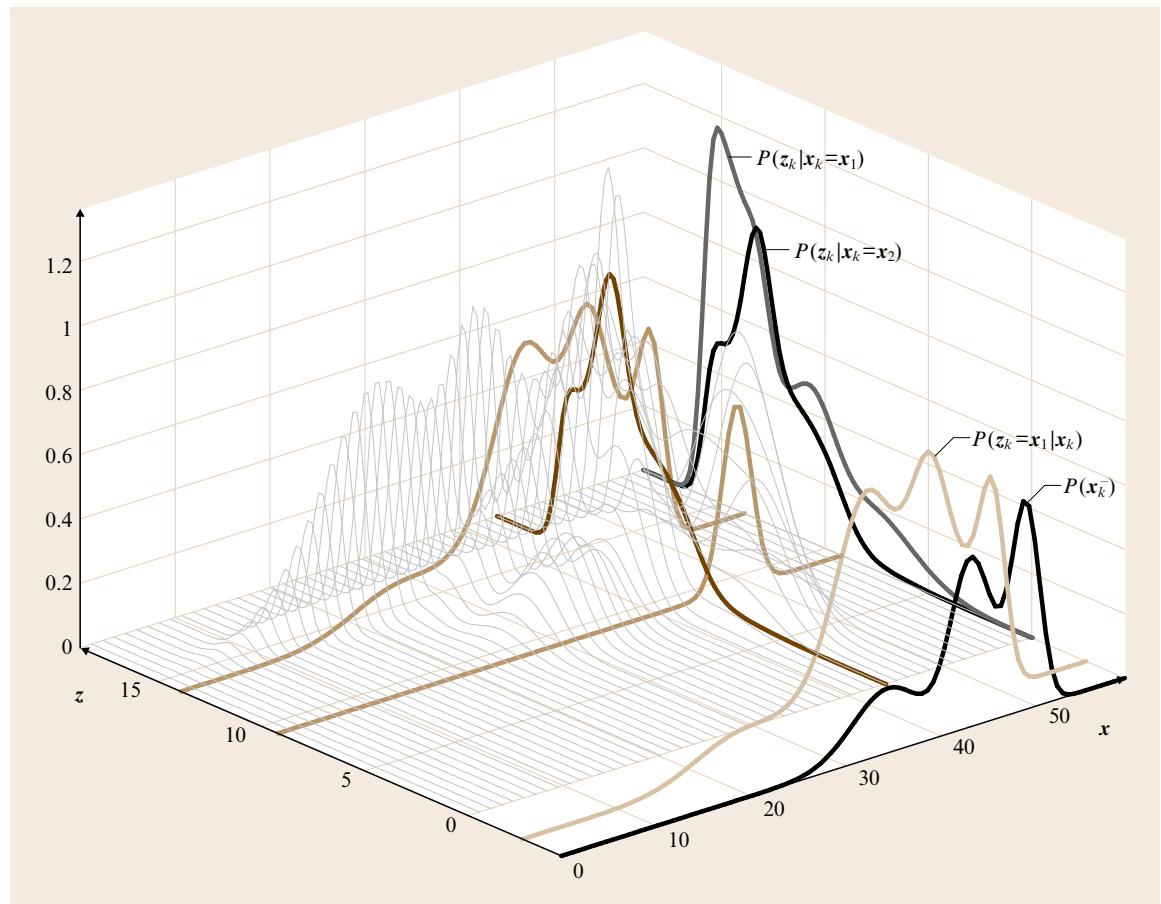

Fig. 25.2 Observation update for the full Bayes filter. Prior to observation, an observation model in the form of the conditional density $P(z_k | \mathbf{x}_k)$ is established. For a fixed value of \mathbf{x}_k , equal to \mathbf{x}_1 or \mathbf{x}_2 for example, a density function $P(z_k | \mathbf{x}_k = \mathbf{x}_1)$ or $P(z_k | \mathbf{x}_k = \mathbf{x}_2)$ is defined describing the likelihood of making the observation z_k . Together the density $P(z_k | \mathbf{x}_k)$ is then a function of both z_k and \mathbf{x}_k . This conditional density then defines the observation model. Now, in operation, a specific observation $z_k = \mathbf{x}_1$ is made and the resulting distribution $P(z_k = \mathbf{x}_1 | \mathbf{x}_k)$ defines a density function (now termed the likelihood function) on \mathbf{x}_k . This density is then multiplied by the prior density $P(\mathbf{x}_k^-)$ and normalized to obtain the posterior distribution $P(\mathbf{x}_k | z_k)$ describing knowledge in the state after observation

for all times k given the recorded observations and control inputs up to and including time k together (possibly) with knowledge of the initial state \mathbf{x}_0 . Bayes' rule can be used to write (25.6) in terms of a sensor model $P(z_k | \mathbf{x}_k)$ and a predicted probability density $P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0)$ based on observations up to time $k - 1$ as

$$\begin{aligned} P(\mathbf{x}_k | \mathbf{Z}^k, \mathbf{U}^k, \mathbf{x}_0) \\ = \frac{P(z_k | \mathbf{x}_k)P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0)}{P(z_k | \mathbf{Z}^{k-1}, \mathbf{U}^k)}. \end{aligned} \quad (25.7)$$

The denominator in (25.7) is independent of the state and following (25.4) can be set to some normalizing constant C . The sensor model makes use of the conditional independence assumption from (25.3).

The total probability theorem can be used to rewrite the second term in the numerator of (25.7) in terms of the state transition model and the joint posterior from time step $k - 1$ as

$$\begin{aligned} & P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) \\ &= \int P(\mathbf{x}_k, \mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) d\mathbf{x}_{k-1} \\ &= \int P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) \\ &\quad \times P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) d\mathbf{x}_{k-1} \\ &= \int P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k) \\ &\quad \times P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^{k-1}, \mathbf{x}_0) d\mathbf{x}_{k-1}, \end{aligned} \quad (25.8)$$

where the last equality implies that the future state depends only on the current state and the control exerted at this time. The state transition model is described in terms of a probability distribution in the form $P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k)$. That is, the state transition may reasonably be assumed to be a Markov process in which the next state \mathbf{x}_k depends only on the immediately preceding state \mathbf{x}_{k-1} and the applied control \mathbf{u}_k , and is independent of both the observations and preceding states.

Equations (25.7) and (25.8) define a recursive solution to (25.6). Equation (25.8) is the *time update* or prediction step for the full Bayes data fusion algorithm. A graphical description of this equation is shown in Fig. 25.1. Equation (25.7) is the *observation update* step for the full Bayes data fusion algorithm. A graphical description of this equation is shown in Fig. 25.2. The Kalman filter, grid-based methods, and sequential Monte Carlo methods, to be described, are specific implementations of these general equations.

25.1.2 Probabilistic Grids

Probabilistic grids are conceptually the simplest way of implementing Bayesian data fusion methods. They can be applied both to problems in mapping [25.3, 4] and tracking [25.5].

In mapping applications, the environment of interest is divided into a grid of equally sized spatial cells. Each cell is indexed and labeled with a property, thus the state \mathbf{x}_{ij} may describe a two-dimensional world indexed by ij and having the property x . Interest is focused on maintaining a probability distribution on possible state values $P(\mathbf{x}_{ij})$ at each grid cell. Typically, in navigation and mapping problems, the property of interest has only two values O and E , *occupied* and *empty*, respectively, and it is then usual to assume that $P(\mathbf{x}_{ij} = O) = 1 - P(\mathbf{x}_{ij} = E)$. However, there is no particular constraint on the property encoded by the state \mathbf{x}_{ij} which could have many values (green, red, blue, for example) and indeed be continuous (the temperature at a cell, for example).

Once the state has been defined, Bayesian methods require that a sensor model or likelihood function for the sensor be established. In theory, this requires specification of a probability distribution $P(z | \mathbf{x}_{ij} = x_{ij})$ mapping each possible grid state x_{ij} to a distribution on observations. Practically, however, this is implemented simply as another *observation* grid so that for a specific observation $z = z$ (taken from a specific location), a grid of likelihoods on the states \mathbf{x}_{ij} is produced in the form $P(z = z | \mathbf{x}_{ij}) = \Lambda(x_{ij})$. It is then trivial to apply Bayes' rule to update the property value at each grid cell as

$$P^+(\mathbf{x}_{ij}) = C \Lambda(x_{ij}) P(\mathbf{x}_{ij}), \quad \forall i, j, \quad (25.9)$$

where C is a normalizing constant obtained by summing posterior probabilities to one *at node ij only*. Computationally, this is a simple pointwise multiplication of two grids. Some care needs to be taken that the two grids appropriately overlap and align with each other at the right scale. In some instances it is also valuable to encode the fact that spatially adjacent cells will influence each other; that is, if we knew the value of the property (occupancy, temperature, for example) at ij we will have some belief also of the value of this property at adjacent nodes $i + 1, j, i, j + 1$, etc. Different sensors and the fusion of different sensor outputs is accommodated simply by building appropriate sensor models $\Lambda(x_{ij})$.

Grids can also be used for tracking and self-tracking (localization). The state \mathbf{x}_{ij} in this case is the location of the entity being tracked. This is a qualitatively different definition of state from that used in mapping. The probability $P(\mathbf{x}_{ij})$ must now be interpreted as the probability

that the object being tracked occupies the grid cell ij . In the case of mapping, the sum of property probabilities at each grid cell is one, whereas in the case of tracking, the sum of location probabilities over *the whole grid* must sum to one. Otherwise, the procedure for updating is very similar. An observation grid is constructed which, when instantiated with an observation value, provides a location likelihood grid $P(z = z \mid \mathbf{x}_{ij}) = \Lambda(\mathbf{x}_{ij})$. Bayes' rule is then applied to update the location probability at each grid cell in the same form as (25.9) except that now the normalization constant C is obtained by summing posterior probabilities over *all* ij grid cells. This can become computationally expensive, especially if the grid has three or more dimensions. One major advantage of grid-based tracking is that it is easy to incorporate quite complex prior information. For example, if it is known that the object being tracked is on a road, then the probability location values for all off-road grid cells can simply be set to zero.

Grid-based fusion is appropriate to situations where the domain size and dimension are modest. In such cases, grid-based methods provide straightforward and effective fusion algorithms. Grid-based methods can be extended in a number of ways; to hierarchical (quadtree) grids, or to irregular (triangular, pentagonal) grids. These can help reduce computation in larger spaces. Monte Carlo and particle filtering methods (Sect. 25.1.4) may be considered as grid-based methods, where the grid cells themselves are sample of the underlying probability density for the state.

25.1.3 The Kalman Filter

The Kalman filter is a recursive linear estimator that successively calculates an estimate for a continuous valued state, that evolves over time, on the basis of periodic observations of the state. The Kalman filter employs an explicit statistical model of how the parameter of interest $\mathbf{x}(t)$ evolves over time and an explicit statistical model of how the observations $z(t)$ that are made are related to this parameter. The gains employed in a Kalman filter are chosen to ensure that, with certain assumptions about the observation and process models used, the resulting estimate $\hat{\mathbf{x}}(t)$ minimizes mean-squared error and is thus the conditional mean $\hat{\mathbf{x}}(t) = E[\mathbf{x}(t) \mid \mathbf{Z}^t]$: an average, rather than a most likely value.

The Kalman filter has a number of features which make it ideally suited to dealing with complex multisensor estimation and data fusion problems. In particular, the explicit description of process and observations allows a wide variety of different sensor models to be

incorporated within the basic algorithm. In addition, the consistent use of statistical measures of uncertainty makes it possible to quantitatively evaluate the role each sensor plays in overall system performance. Further, the linear recursive nature of the algorithm ensures that its application is simple and efficient. For these reasons, the Kalman filter has found widespread application in many different data fusion problems [25.6–9].

In robotics, the Kalman filter is most suited to problems in tracking, localization, and navigation, and less so to problems in mapping. This is because the algorithm works best with well-defined state descriptions (positions, velocities, for example), and for states where observation and time-propagation models are also well understood.

Observation and Transition Models

The Kalman filter may be considered a specific instance of the recursive Bayesian filter of (25.7,25.8) for the case where the probability densities on states are Gaussian. The starting point for the Kalman Filter algorithm is to define a model for the states to be estimated in the standard state-space form:

$$\dot{\mathbf{x}}(t) = \mathbf{F}(t)\mathbf{x}(t) + \mathbf{B}(t)\mathbf{u}(t) + \mathbf{G}(t)\mathbf{v}(t), \quad (25.10)$$

where $\mathbf{x}(t)$ is the state vector of interest, $\mathbf{u}(t)$ is a known control input, $\mathbf{v}(t)$ is a random variable describing uncertainty in the evolution of the state, and $\mathbf{F}(t)$, $\mathbf{B}(t)$, and $\mathbf{G}(t)$ are matrices describing the contribution of states, controls, and noise to state transition [25.7]. An observation (output) model is also defined in standard state-space form:

$$\mathbf{z}(t) = \mathbf{H}(t)\mathbf{x}(t) + \mathbf{D}(t)\mathbf{w}(t), \quad (25.11)$$

where $\mathbf{z}(t)$ is the observation vector, $\mathbf{w}(t)$ is a random variable describing uncertainty in the observation, and where $\mathbf{H}(t)$ and $\mathbf{D}(t)$ are matrices describing the contribution of state and noise to the observation.

These equations define the evolution of a continuous-time system with continuous observations being made of the state. However, the Kalman Filter is almost always implemented in discrete time $t_k = k$. It is straightforward [25.8] to obtain a discrete-time version of (25.10) and (25.11) in the form

$$\mathbf{x}(k) = \mathbf{F}(k)\mathbf{x}(k-1) + \mathbf{B}(k)\mathbf{u}(k) + \mathbf{G}(k)\mathbf{v}(k), \quad (25.12)$$

$$\mathbf{z}(k) = \mathbf{H}(k)\mathbf{x}(k) + \mathbf{D}(k)\mathbf{w}(k). \quad (25.13)$$

A basic assumption in the derivation of the Kalman filter is that the random sequences $\mathbf{v}(k)$ and $\mathbf{w}(k)$ describing process and observation noise are all Gaussian,

temporally uncorrelated, and zero-mean

$$\mathbb{E}[\mathbf{v}(k)] = \mathbb{E}[\mathbf{w}(k)] = \mathbf{0}, \quad \forall k, \quad (25.14)$$

with known covariance

$$\mathbb{E}[\mathbf{v}(i)\mathbf{v}^\top(j)] = \delta_{ij}\mathbf{Q}(i), \quad \mathbb{E}[\mathbf{w}(i)\mathbf{w}^\top(j)] = \delta_{ij}\mathbf{R}(i). \quad (25.15)$$

It is also generally assumed that the process and observation noises are also uncorrelated

$$\mathbb{E}[\mathbf{v}(i)\mathbf{w}^\top(j)] = \mathbf{0}, \quad \forall i, j. \quad (25.16)$$

These are equivalent to a Markov property requiring observations and successive states to be conditionally independent. If the sequences $\mathbf{v}(k)$ and $\mathbf{w}(k)$ are temporally correlated, a shaping filter can be used to whiten the observations, again making the assumptions required for the Kalman filter valid [25.8]. If the process and observation noise sequences are correlated, then this correlation can also be accounted for in the Kalman filter algorithm [25.10]. If the sequence is not Gaussian, but is symmetric with finite moments, then the Kalman filter will still produce good estimates. If however, the sequence has a distribution which is skewed or otherwise pathological, results produced by the Kalman filter will be misleading and there will be a good case for using a more-sophisticated Bayesian filter [25.5].

Filtering Algorithm

The Kalman filter algorithm produces estimates that minimize mean-squared estimation error conditioned on a given observation sequence and so is the conditional mean

$$\hat{\mathbf{x}}(i | j) \triangleq \mathbb{E}[\mathbf{x}(i) | z(1), \dots, z(j)] \triangleq \mathbb{E}[\mathbf{x}(i) | \mathbf{Z}^j]. \quad (25.17)$$

The estimate variance is defined as the mean-squared error in this estimate

$$\mathbf{P}(i | j) \triangleq \mathbb{E}\{[\mathbf{x}(i) - \hat{\mathbf{x}}(i | j)][\mathbf{x}(i) - \hat{\mathbf{x}}(i | j)]^T | \mathbf{Z}^j\}. \quad (25.18)$$

The estimate of the state at a time k given all information up to time k is written $\hat{\mathbf{x}}(k | k)$. The estimate of the state at a time k given only information up to time $k-1$ is called a one-step-ahead prediction (or just a prediction) and is written $\hat{\mathbf{x}}(k | k-1)$.

The Kalman filter algorithm is now stated without proof. Detailed derivations can be found in many books on the subject, for example [25.7,8]. The state is assumed to evolve in time according to (25.12). Observations of this state are made at regular time intervals according

to (25.13). The noise processes entering the system are assumed to obey (25.14), (25.15), and (25.16). It is also assumed that an estimate $\hat{\mathbf{x}}(k-1 | k-1)$ of the state $\mathbf{x}(k-1)$ at time $k-1$ based on all observations made up to and including time $k-1$ is available, and that this estimate is equal to the conditional mean of the true state $\mathbf{x}(k-1)$ conditioned on these observations. The conditional variance $\mathbf{P}(k-1 | k-1)$ in this estimate is also assumed known. The Kalman filter then proceeds recursively in two stages (Fig. 25.3).

Prediction. A prediction $\hat{\mathbf{x}}(k | k-1)$ of the state at time k and its covariance $\mathbf{P}(k | k-1)$ is computed according to

$$\hat{\mathbf{x}}(k | k-1) = \mathbf{F}(k)\hat{\mathbf{x}}(k-1 | k-1) + \mathbf{B}(k)\mathbf{u}(k), \quad (25.19)$$

$$\mathbf{P}(k | k-1) = \mathbf{F}(k)\mathbf{P}(k-1 | k-1)\mathbf{F}^\top(k) + \mathbf{G}(k)\mathbf{Q}(k)\mathbf{G}^\top(k). \quad (25.20)$$

Update. At time k an observation $\mathbf{z}(k)$ is made and the updated estimate $\hat{\mathbf{x}}(k | k)$ of the state $\mathbf{x}(k)$, together with the updated estimate covariance $\mathbf{P}(k | k)$, is computed from the state prediction and observation according to

$$\hat{\mathbf{x}}(k | k) = \hat{\mathbf{x}}(k | k-1) + \mathbf{W}(k)[\mathbf{z}(k) - \mathbf{H}(k)\hat{\mathbf{x}}(k | k-1)], \quad (25.21)$$

$$\mathbf{P}(k | k) = \mathbf{P}(k | k-1) - \mathbf{W}(k)\mathbf{S}(k)\mathbf{W}^\top(k), \quad (25.22)$$

where the gain matrix $\mathbf{W}(k)$ is given by

$$\mathbf{W}(k) = \mathbf{P}(k | k-1)\mathbf{H}(k)\mathbf{S}^{-1}(k), \quad (25.23)$$

where

$$\mathbf{S}(k) = \mathbf{R}(k) + \mathbf{H}(k)\mathbf{P}(k | k-1)\mathbf{H}(k) \quad (25.24)$$

is the innovation covariance. The difference between the observation $\mathbf{z}(k)$ and the predicted observation $\mathbf{H}(k)\hat{\mathbf{x}}(k | k-1)$ is termed the *innovation* or residual $\mathbf{v}(k)$:

$$\mathbf{v}(k) = \mathbf{z}(k) - \mathbf{H}(k)\hat{\mathbf{x}}(k | k-1). \quad (25.25)$$

The innovation is an important measure of the deviation between the filter estimates and the observation sequence. Indeed, because the true states are not usually available for comparison with the estimated states, the innovation is often the only measure of how well the estimator is performing. The innovation is particularly important in data association.

The Extended Kalman Filter

The extended Kalman filter (EKF) is a form of the Kalman filter that can be employed when the state model

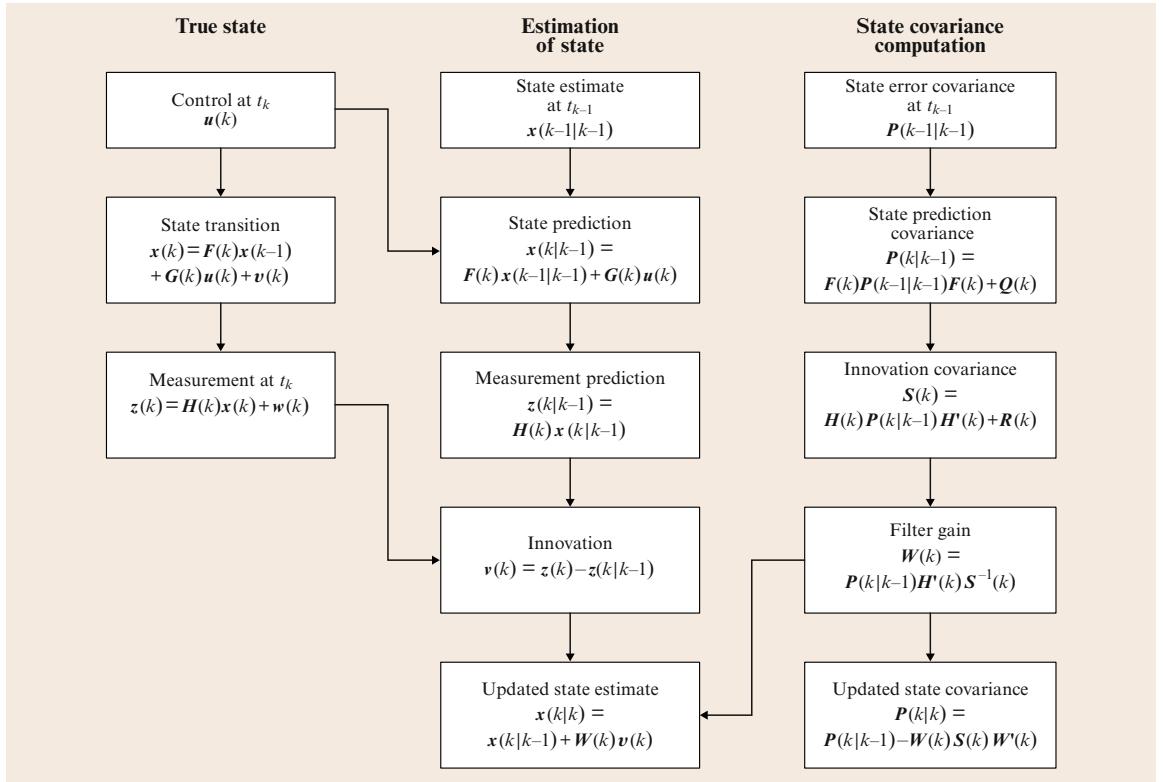

Fig. 25.3 Block diagram of the Kalman filter cycle (after Bar-Shalom and Fortmann [25.7])

and/or the observation model are nonlinear. The **EKF** is briefly described in this section.

The state models considered by the **EKF** are described in state-space notation by a first-order nonlinear vector differential equation or state model of the form

$$\dot{\mathbf{x}}(t) = f[\mathbf{x}(t), \mathbf{u}(t), \mathbf{v}(t), t], \quad (25.26)$$

where $f[\cdot, \cdot, \cdot, \cdot]$ is now a general nonlinear mapping of state and control input to state transition. The observation models considered by the **EKF** are described in state-space notation by a nonlinear vector function in the form

$$\mathbf{z}(t) = h[\mathbf{x}(t), \mathbf{u}(t), \mathbf{w}(t), t], \quad (25.27)$$

where $h[\cdot, \cdot, \cdot, \cdot]$ is now a general nonlinear mapping of state and control input to observations.

The **EKF**, like the Kalman filter, is almost always implemented in discrete time. By integration and with appropriate identification of discrete time states and observations, the state model is written

$$\mathbf{x}(k) = f[\mathbf{x}(k-1), \mathbf{u}(k), \mathbf{v}(k), k], \quad (25.28)$$

and the observation model as

$$\mathbf{z}(k) = h[\mathbf{x}(k), \mathbf{w}(k)]. \quad (25.29)$$

Like the Kalman filter, it is assumed that the noises $\mathbf{v}(k)$ and $\mathbf{w}(k)$ are all Gaussian, temporally uncorrelated, and zero-mean with known variance as defined in (25.14–25.16). The **EKF** aims to minimize the mean-squared error and thereby compute an approximation to the conditional mean. It is assumed therefore that an estimate of the state at time $k-1$ is available which is approximately equal to the conditional mean, $\hat{\mathbf{x}}(k-1|k-1) \approx E[\mathbf{x}(k-1) | Z^{k-1}]$. The **EKF** algorithm will now be stated without proof. Detailed derivations may be found in any number of books on the subject. The principle stages in the derivation of the **EKF** follow directly from those of the linear Kalman filter with the additional step that the process and observation models are linearized as a Taylor series about the estimate and prediction, respectively. The algorithm has two stages: prediction and update.

Prediction. A prediction $\hat{\mathbf{x}}(k|k-1)$ of the state at time k and its covariance $P(k|k-1)$ is computed according to

$$\hat{\mathbf{x}}(k | k-1) = f[\hat{\mathbf{x}}(k-1 | k-1), \mathbf{u}(k)], \quad (25.30)$$

$$\begin{aligned} \mathbf{P}(k | k-1) &= \nabla f_x(k) \mathbf{P}(k-1 | k-1) \nabla^T f_x(k) \\ &\quad + \nabla f_v(k) \mathbf{Q}(k) \nabla^T f_v(k). \end{aligned} \quad (25.31)$$

Update. At time k an observation $\mathbf{z}(k)$ is made and the updated estimate $\hat{\mathbf{x}}(k | k)$ of the state $\mathbf{x}(k)$, together with the updated estimate covariance $\mathbf{P}(k | k)$ is computed from the state prediction and observation according to

$$\begin{aligned} \hat{\mathbf{x}}(k | k) &= \hat{\mathbf{x}}(k | k-1) \\ &\quad + \mathbf{W}(k) \{ \mathbf{z}(k) - \mathbf{h}[\hat{\mathbf{x}}(k | k-1)] \}, \end{aligned} \quad (25.32)$$

$$\mathbf{P}(k | k) = \mathbf{P}(k | k-1) - \mathbf{W}(k) \mathbf{S}(k) \mathbf{W}^T(k), \quad (25.33)$$

where

$$\mathbf{W}(k) = \mathbf{P}(k | k-1) \nabla^T \mathbf{h}_x(k) \mathbf{S}^{-1}(k) \quad (25.34)$$

and

$$\begin{aligned} \mathbf{S}(k) &= \nabla \mathbf{h}_w(k) \mathbf{R}(k) \nabla^T \mathbf{h}_w(k) \\ &\quad + \nabla \mathbf{h}_x(k) \mathbf{P}(k | k-1) \nabla^T \mathbf{h}_x(k) \end{aligned} \quad (25.35)$$

and where the Jacobian $\nabla f(\cdot)$ is evaluated at $\mathbf{x}(k-1) = \hat{\mathbf{x}}(k-1 | k-1)$ and $\nabla \mathbf{h}(\cdot)$ is evaluated at $\mathbf{x}(k) = \hat{\mathbf{x}}(k | k-1)$.

A comparison of (25.19–25.24) with (25.30–25.35) makes it clear that the EKF algorithm is very similar to the linear Kalman filter algorithm, with the substitutions $\mathbf{F}(k) \rightarrow \nabla f_x(k)$ and $\mathbf{H}(k) \rightarrow \nabla \mathbf{h}_x(k)$ being made in the equations for the variance and gain propagation. Thus, the EKF is, in effect, a linear estimator for a state error which is described by a *linear* equation and which is being observed according to a *linear* equation of the form of (25.13).

The EKF works in much the same way as the linear Kalman filter with some notable caveats.

- The Jacobians $\nabla f_x(k)$ and $\nabla \mathbf{h}_x(k)$ are typically not constant, being functions of both state and time step. This means that unlike the linear filter, the covariances and gain matrix must be computed online as estimates and predictions are made available, and will not in general tend to constant values. This significantly increases the amount of computation which must be performed online by the algorithm.
- As the linearized model is derived by perturbing the true state and observation models around a predicted or nominal trajectory, great care must be taken to ensure that these predictions are always close enough to the true state that second order terms in the linearization are indeed insignificant. If the nominal trajectory is too far away from the true trajectory

then the true covariance will be much larger than the estimated covariance and the filter will become poorly matched. In extreme cases the filter may also become unstable.

- The EKF employs a linearized model that must be computed from an approximate knowledge of the state. Unlike the linear algorithm this means that the filter must be accurately initialized at the start of operation to ensure that the linearized models obtained are valid. If this is not done, the estimates computed by the filter will simply be meaningless.

The Information Filter

The information filter is mathematically equivalent to a Kalman filter. However, rather than generating state estimates $\hat{\mathbf{x}}(i | j)$ and covariances $\mathbf{P}(i | j)$ it uses information state variables $\hat{\mathbf{y}}(i | j)$ and information matrices $\mathbf{Y}(i | j)$, which are related to each other through the relationships

$$\begin{aligned} \hat{\mathbf{y}}(i | j) &= \mathbf{P}^{-1}(i | j) \hat{\mathbf{x}}(i | j), \\ \mathbf{Y}(i | j) &= \mathbf{P}^{-1}(i | j). \end{aligned} \quad (25.36)$$

The information filter has the same prediction–update structure as the Kalman filter.

Prediction. A prediction $\hat{\mathbf{y}}(k | k-1)$ of the information state at time k and its information matrix $\mathbf{Y}(k | k-1)$ is computed according to (Joseph form [25.8]):

$$\begin{aligned} \hat{\mathbf{y}}(k | k-1) &= (\mathbf{I} - \boldsymbol{\Omega} \mathbf{G}^T) \mathbf{F}^{-\top} \hat{\mathbf{y}}(k-1 | k-1) \\ &\quad + \mathbf{Y}(k | k-1) \mathbf{B} \mathbf{u}(k), \end{aligned} \quad (25.37)$$

$$\mathbf{Y}(k | k-1) = \mathbf{M}(k) - \boldsymbol{\Omega} \boldsymbol{\Sigma} \boldsymbol{\Omega}^T, \quad (25.38)$$

respectively, where

$$\begin{aligned} \mathbf{M}(k) &= \mathbf{F}^{-\top} \mathbf{Y}(k-1 | k-1) \mathbf{F}^{-1}, \\ \boldsymbol{\Sigma} &= \mathbf{G}^T \mathbf{M}(k) \mathbf{G} + \mathbf{Q}^{-1}, \end{aligned}$$

and

$$\boldsymbol{\Omega} = \mathbf{M}(t_k) \mathbf{G} \boldsymbol{\Sigma}^{-1}.$$

It should be noted that $\boldsymbol{\Sigma}$, whose inverse is required to compute $\boldsymbol{\Omega}$, has the same dimensionality as the process driving noise, which is normally considerably smaller than the state dimension. Further, the matrix \mathbf{F}^{-1} is the state-transition matrix evaluated backwards in time and so must always exist.

Update. At time k an observation $\mathbf{z}(k)$ is made and the updated information state estimate $\hat{\mathbf{y}}(k | k)$ together with

the updated information matrix $\mathbf{Y}(k | k)$ is computed from

$$\hat{\mathbf{y}}(k | k) = \hat{\mathbf{y}}(k | k - 1) + \mathbf{H}(k)\mathbf{R}^{-1}(k)\mathbf{z}(k), \quad (25.39)$$

$$\mathbf{Y}(k | k) = \mathbf{Y}(k | k - 1) + \mathbf{H}(k)\mathbf{R}^{-1}(k)\mathbf{H}^\top(k). \quad (25.40)$$

We emphasize that (25.38) and (25.37) are mathematically identical to (25.19) and (25.20), and that (25.39) and (25.40) are mathematically identical to (25.21) and (25.22). It will be noted that there is a duality between information and state space forms [25.10]. This duality is evident from the fact that Ω and Σ in the prediction stage of the information filter play an equivalent role to the gain matrix \mathbf{W} and innovation covariance \mathbf{S} in the update stage of the Kalman filter. Furthermore, the simple linear update step for the information filter is mirrored in the simple linear prediction step for the Kalman filter.

The main advantage of the information filter over the Kalman filter in data fusion problems is the relative simplicity of the update stage. For a system with n sensors, the fused information state update is *exactly* the linear sum of information contributions from all sensors as

$$\begin{aligned} \hat{\mathbf{y}}(k | k) &= \hat{\mathbf{y}}(k | k - 1) + \sum_{i=1}^n \mathbf{H}_i(k)\mathbf{R}_i^{-1}(k)\mathbf{z}_i(k), \\ \mathbf{Y}(k | k) &= \mathbf{Y}(k | k - 1) + \sum_{i=1}^n \mathbf{H}_i(k)\mathbf{R}_i^{-1}(k)\mathbf{H}_i^\top(k). \end{aligned} \quad (25.41)$$

The reason such an expression exists in this form is that the information filter is essentially a log-likelihood expression of Bayes' rule, where products of likelihoods (25.4) are turned into sums. No such simple expression for multisensor updates exists for the Kalman filter. This property of the information filter has been exploited for data fusion in robotic networks [25.11, 12] and more recently in robot navigation and localization problems [25.1]. One substantial disadvantage of the information filter is the coding of nonlinear models, especially for the prediction step.

When to Use a Kalman or Information Filter

Kalman or information filters are appropriate to data fusion problems where the entity of interest is well defined by a continuous parametric state. This would include estimation of the position, attitude, and velocity of a robot or other object, or the tracking of a simple geometric feature such as a point, line or curve. Kalman and information filters are inappropriate for estimating properties

such as spatial occupancy, discrete labels, or processes whose error characteristics are not easily parameterized.

25.1.4 Sequential Monte Carlo Methods

Monte Carlo (MC) filter methods describe probability distributions as a set of weighted samples of an underlying state space. MC filtering then uses these samples to simulate probabilistic inference usually through Bayes' rule. Many samples or simulations are performed. By studying the statistics of these samples as they progress through the inference process, a probabilistic picture of the process being simulated can be built up.

Representing Probability Distributions

In sequential Monte Carlo methods, probability distributions are described in terms of a set of support points (state-space values) \mathbf{x}^i , $i = 1, \dots, N$, together with a corresponding set of normalized weights w^i , $i = 1, \dots, N$, where $\sum_i w^i = 1$. The support points and weights can be used to define a probability density function in the form

$$P(\mathbf{x}) \approx \sum_{i=1}^N w^i \delta(\mathbf{x} - \mathbf{x}^i). \quad (25.42)$$

A key question is how these support points and weights are selected to obtain a faithful representation of the probability density $P(\mathbf{x})$. The most general way of selecting support values is to use an *importance density* $q(\mathbf{x})$. The support values \mathbf{x}^i are drawn as samples from this density; where the density has high probability, more support values are chosen, and where the density has low probability, few support vectors are selected. The weights in (25.42) are then computed from

$$w^i \propto \frac{P(\mathbf{x}^i)}{q(\mathbf{x}^i)}. \quad (25.43)$$

Practically, a sample \mathbf{x}^i is drawn from the importance distribution. The sample is then instantiated in the underlying probability distribution to yield the value $P(\mathbf{x} = \mathbf{x}^i)$. The ratio of the two probability values, appropriately normalized, then becomes the weight.

There are two instructive extremes of the importance sampling method.

- At one extreme, the importance density could be taken to be a uniform distribution, so the support values \mathbf{x}^i are uniformly distributed on the state space in a close approximation to a grid. The probabilities $q(\mathbf{x}^i)$ are also therefore equal. The weights computed from (25.43) are then simply proportional to the

probabilities $w^i \propto P(\mathbf{x} = \mathbf{x}^i)$. The result is a model for the distribution which looks very like the regular grid model.

- At the other extreme, we could choose an importance density equal to the probability model $q(\mathbf{x}) = P(\mathbf{x})$. Samples of the support values \mathbf{x}^i are now drawn from this density. Where the density is high there will be many samples, where the density is low there will be few samples. However, if we substitute $q(\mathbf{x}^i) = P(\mathbf{x}^i)$ into (25.43), it is clear that the weights all become equal $w^i = 1/N$. A set of samples with equal weights is known as a *particle* distribution.

It is, of course, possible to mix these two representations to describe a probability distribution both in terms of a set of weights and in terms of a set of support values. The complete set of samples and weights describing a probability distribution $\{\mathbf{x}^i, w^i\}_{i=1}^N$ is termed a *random measure*.

The Sequential Monte Carlo Method

Sequential Monte Carlo (SMC) filtering is a simulation of the recursive Bayes update equations using sample support values and weights to describe the underlying probability distributions.

The starting point is the recursive or sequential Bayes observation update given in (25.7) and (25.8). The SMC recursion begins with an a posterior probability density represented by a set of support values and weights $\{\mathbf{x}_{k-1}^i, w_{k-1|k-1}^i\}_{i=1}^{N_{k-1}}$ in the form

$$P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}) = \sum_{i=1}^{N_{k-1}} w_{k-1}^i \delta(\mathbf{x}_{k-1} - \mathbf{x}_{k-1}^i). \quad (25.44)$$

The prediction step requires that (25.44) is substituted into (25.8) where the joint density is marginalized. Practically however, this complex step is avoided by implicitly assuming that the importance density is exactly the transition model as

$$q_k(\mathbf{x}_k^i) = P(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i). \quad (25.45)$$

This allows new support values \mathbf{x}_k^i to be drawn on the basis of old support values \mathbf{x}_{k-1}^i while leaving the weights unchanged $w_k^i = w_{k-1}^i$. With this, the prediction becomes

$$P(\mathbf{x}_k | \mathbf{Z}^{k-1}) = \sum_{i=1}^{N_k} w_{k-1}^i \delta(\mathbf{x}_k - \mathbf{x}_k^i). \quad (25.46)$$

The SMC observation update step is relatively straightforward. An observation model $P(z_k | \mathbf{x}_k)$ is defined.

This is a function on both variables, \mathbf{z}_k and \mathbf{x}_k , and is a probability distribution on \mathbf{z}_k (integrates to unity). When an observation or measurement is made, $\mathbf{z}_k = \mathbf{x}_k$, the observation model becomes a function of state \mathbf{x}_k only. If samples of the state are taken $\mathbf{x}_k = \mathbf{x}_k^i$, $i = 1 \dots, N_k$, the observation model $P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i)$ becomes a set of scalars describing the likelihood that the sample \mathbf{x}_k^i could have given rise to the observation z_k . Substituting these likelihoods and (25.46) into (25.7) gives:

$$\begin{aligned} & P(\mathbf{x}_k | \mathbf{Z}^k) \\ &= C \sum_{i=1}^{N_k} w_{k-1}^i P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i) \delta(\mathbf{x}_k - \mathbf{x}_k^i). \end{aligned} \quad (25.47)$$

This is normally implemented in the form of an updated set of normalized weights

$$w_k^i = \frac{w_{k-1}^i P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i)}{\sum_{j=1}^{N_k} w_{k-1}^j P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^j)} \quad (25.48)$$

and so

$$P(\mathbf{x}_k | \mathbf{Z}^k) = \sum_{i=1}^{N_k} w_k^i \delta(\mathbf{x}_k - \mathbf{x}_k^i). \quad (25.49)$$

Note that the support values in (25.49) are the same as those in (25.46), only the weights have been changed by the observation update.

The implementation of the SMC method requires the enumeration of models for both the state transition $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ and the observation $P(z_k | \mathbf{x}_k)$. These need to be presented in a form that allows instantiation of values for \mathbf{z}_k , \mathbf{x}_k , and \mathbf{x}_{k-1} . For low-dimensional state spaces, interpolation in a lookup table is a viable representation. For high-dimensional state spaces, the preferred method is to provide a representation in terms of a function.

Practically, (25.46) and (25.49) are implemented as follows.

Time Update. A process model is defined in the usual state-space form as $\mathbf{x}_k = f(\mathbf{x}_{k-1}, \mathbf{w}_k, k)$, where \mathbf{w}_k is an independent noise sequence with known probability density $P(\mathbf{w}_k)$. The prediction step is now implemented as follows: N_k samples \mathbf{w}_k^i , $i = 1, \dots, N_k$ are drawn from the distribution $P(\mathbf{w}_k)$. The N_k support values \mathbf{x}_{k-1}^i together with the samples \mathbf{w}_k^i are passed through the process model as

$$\mathbf{x}_k^i = f(\mathbf{x}_{k-1}^i, \mathbf{w}_k^i, k), \quad (25.50)$$

yielding a new set of support vectors \mathbf{x}_k^i . The weights for these support vectors w_{k-1}^i are not changed. In effect, the process model is simply used to do N_k simulations of state propagation.

Observation Update. The observation model is also defined in the usual state-space form as $z_k = \mathbf{h}(\mathbf{x}_k, \mathbf{v}_k, k)$, where \mathbf{v}_k is an independent noise sequence with known probability density $P(\mathbf{v}_k)$. The observation step is now implemented as follows. A measurement $z_k = z_k$ is made. For each support value \mathbf{x}_k^i , a likelihood is computed as

$$A(\mathbf{x}_k^i) = P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i). \quad (25.51)$$

Practically, this requires that the observation model be in an equational form (such as a Gaussian) which allows computation of the likelihood in the error between the measured value z_k and the observations predicted by each particle $\mathbf{h}(\mathbf{x}_k^i, k)$. The updated weights after observation are just

$$w_k^i \propto w_{k-1}^i P(z_k = z_k | \mathbf{x}_k^i). \quad (25.52)$$

Resampling

After the weights are updated it is usual to resample the measure $\{\mathbf{x}_k^i, w_k^i\}_{i=1}^N$. This focuses the samples in on those areas that have most probability density. The decision to resample is made on the basis of the *effective number*, N_{eff} of particles in the sample, approximately estimated from $N_{\text{eff}} = 1 / \sum_i (w_k^i)^2$. The sampling importance resampling (**SIR**) algorithm resamples at every cycle so that the weights are always equal. One of the key problems with resampling is that the sample set fixates on a few highly likely samples. This problem of fixating on a few highly likely particles during resampling is known as *sample impoverishment*. Generally, it is good to resample when N_{eff} falls to some fraction of the actual samples (say 1/2).

When to Use Monte Carlo Methods

Monte Carlo (**MC**) methods are well suited to problems where state-transition models and observation models are highly nonlinear. This is because sample-based methods can represent very general probability densities. In particular multimodal or multiple hypothesis density functions are well handled by Monte Carlo techniques. One caveat to note however is that the models $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ and $P(z_k | \mathbf{x}_k)$ must be enumerable in all cases and must typically be in a simple parametric form. **MC** methods also span the gap between parametric and grid-based data fusion methods.

Monte Carlo methods are inappropriate for problems where the state space is of high dimension. In general the number of samples required to faithfully model a given density increases exponentially with state-space dimension. The effects of dimensionality can be limited by marginalizing out states that can be modeled without sampling, a procedure known as Rao–Blackwellization.

25.1.5 Alternatives to Probability

The representation of uncertainty is so important to the problem of information fusion that a number of alternative modeling techniques have been proposed to deal with perceived limitations in probabilistic methods.

There are three main perceived limitations of probabilistic modeling techniques.

1. Complexity: the need to specify a large number of probabilities to be able to apply probabilistic reasoning methods correctly.
2. Inconsistency: the difficulties involved in specifying a consistent set of beliefs in terms of probability and using these to obtain consistent deductions about states of interest.
3. Precision of models: the need to be precise in the specification of probabilities for quantities about which little is known.
4. Uncertainty about uncertainty: the difficulty in assigning probability in the face of uncertainty, or ignorance about the source of information.

There are three main techniques put forward to address these issues: interval calculus, fuzzy logic, and the theory of evidence (Dempster–Shafer methods). We briefly discuss each of these in turn.

Interval Calculus

The representation of uncertainty using an interval to bound true parameter values has a number of potential advantages over probabilistic techniques. In particular, intervals provide a good measure of uncertainty in situations where there is a lack of probabilistic information, but in which sensor and parameter error is known to be bounded. In interval techniques, the uncertainty in a parameter x is simply described by a statement that the true value of the state x is known to be bounded from below by a , and from above by b ; $x \in [a, b]$. It is important that no other additional probabilistic structure is implied; in particular the statement $x \in [a, b]$ does not necessarily imply that x is equally probable (uniformly distributed) over the interval $[a, b]$.

There are a number of simple and basic rules for the manipulation of interval errors. These are described in detail in the book by Moore [25.13] (whose analysis was originally aimed at understanding limited-precision computer arithmetic). Briefly, with $a, b, c, d \in \mathbb{R}$, addition, subtraction, multiplication, and division are defined by the following algebraic relations

$$\begin{aligned}[a, b] + [c, d] &= [a+c, b+d], \\ [a, b] - [c, d] &= [a-d, b-c],\end{aligned}\quad (25.53)$$

$$\begin{aligned}[a, b] \times [c, d] &= [\min(ac, ad, bc, bd), \\ &\quad \max(ac, ad, bc, bd)],\end{aligned}\quad (25.54)$$

$$\frac{[a, b]}{[c, d]} = [a, b] \times \left[\frac{1}{d}, \frac{1}{c} \right], \quad 0 \notin [c, d].\quad (25.55)$$

It can be shown that interval addition and multiplication are both associative and commutative. Interval arithmetic admits an obvious metric distance measure:

$$d([a, b], [c, d]) = \max(|a - c|, |b - d|).\quad (25.56)$$

Matrix arithmetic using intervals is also possible, but substantially more complex, particularly when matrix inversion is required.

Interval calculus methods are sometimes used for detection. However, they are not generally used in data fusion problems since:

1. it is difficult to get results that converge to anything of value (it is too pessimistic), and
2. it is hard to encode dependencies between variables which are at the core of many data fusion problems.

Fuzzy Logic

Fuzzy logic has found widespread popularity as a method for representing uncertainty particularly in applications such as supervisory control and high-level data fusion tasks. It is often claimed that fuzzy logic provides an ideal tool for inexact reasoning, particularly in rule-based systems. Certainly, fuzzy logic has had some notable success in practical application.

A great deal has been written about fuzzy sets and fuzzy logic (see, for example, [25.14] and the discussion in [25.15, Chap. 11]). Here we briefly describe the main definitions and operations without any attempt to consider the more advanced features of fuzzy-logic methods.

Consider a universal set consisting of the elements $x; \mathcal{X} = \{x\}$. Consider a proper subset $\mathcal{A} \subseteq \mathcal{X}$ such that

$$\mathcal{A} = \{x \mid x \text{ has some specific property}\}.$$

In conventional logic systems, we can define a membership function $\mu_A(x)$ (also called the *characteristic function*) which reports if a specific element $x \in \mathcal{X}$ is a member of this set:

$$\mathcal{A} \Leftrightarrow \mu_A(x) = \begin{cases} 1 & \text{if } x \in \mathcal{A} \\ 0 & \text{if } x \notin \mathcal{A} \end{cases}.$$

For example \mathcal{X} may be the set of all aircraft. The set \mathcal{A} may be the set of all supersonic aircraft. In the fuzzy logic literature, this is known as a *crisp* set. In contrast, a fuzzy set is one in which there is a *degree of membership*, ranging between 0 and 1. A fuzzy membership function $\mu_A(x)$ then defines the degree of membership of an element $x \in \mathcal{X}$ to the set \mathcal{A} . For example, if \mathcal{X} is again the set of all aircraft, \mathcal{A} may be the set of all *fast* aircraft. Then the fuzzy membership function $\mu_A(x)$ assigns a value between 0 and 1 indicating the degree of membership of every aircraft x to this set. Formally

$$\mathcal{A} \Leftrightarrow \mu_A \mapsto [0, 1].$$

Composition rules for fuzzy sets follow the composition processes for normal crisp sets, for example,

$$\begin{aligned}\mathcal{A} \cap \mathcal{B} &\Leftrightarrow \mu_{A \cap B}(x) = \min[\mu_A(x), \mu_B(x)], \\ \mathcal{A} \cup \mathcal{B} &\Leftrightarrow \mu_{A \cup B}(x) = \max[\mu_A(x), \mu_B(x)].\end{aligned}$$

The normal properties associated with binary logic now hold: commutativity, associativity, idempotence, distributivity, De Morgan's law, and absorption. The only exception is that the law of the excluded middle is no longer true

$$\mathcal{A} \cup \overline{\mathcal{A}} \neq \mathcal{X}, \quad \mathcal{A} \cap \overline{\mathcal{A}} \neq \emptyset.$$

Together these definitions and laws provide a systematic means of reasoning about inexact values.

The relationship between fuzzy set theory and probability is still hotly debated.

Evidential Reasoning

Evidential reasoning (often called the Dempster–Shafer theory of evidence after the originators of these ideas) has seen intermittent success particularly in automated reasoning applications. Evidential reasoning is qualitatively different from either probabilistic methods or fuzzy set theory in the following sense. Consider a universal set \mathcal{X} . In probability theory or fuzzy set theory, a belief mass may be placed on any element $x_i \in \mathcal{X}$

and indeed on any subset $\mathcal{A} \subseteq \mathcal{X}$. In evidential reasoning, belief mass can not only be placed on elements and sets, but also sets of sets. Specifically, while the domain of probabilistic methods is all possible subsets \mathcal{X} , the domain of evidential reasoning is the power set $2^{\mathcal{X}}$.

As an example, consider the mutually exclusive set $\mathcal{X} = \{\text{occupied}, \text{empty}\}$. In probability theory we might assign a probability to each possible event, for example, $P(\text{occupied}) = 0.3$, and thus $P(\text{empty}) = 0.7$. In evidential reasoning, we construct the set of all subsets

$2^{\mathcal{X}} = \{\{\text{occupied}, \text{empty}\}, \{\text{occupied}\}, \{\text{empty}\}, \emptyset\}$, and belief mass is assigned to all elements of this set as

$$\begin{aligned} m(\{\text{occupied}, \text{empty}\}) &= 0.5, \\ m(\{\text{occupied}\}) &= 0.3, \\ m(\{\text{empty}\}) &= 0.2, \\ m(\emptyset) &= 0.0, \end{aligned}$$

(the null set \emptyset is assigned a belief mass of zero for normalization purposes). The interpretation of this is that there is a 30% chance of occupied, a 20% chance of empty, and a 50% chance of either occupied or empty. In effect, the measure placed on the set containing both occupied and empty is a measure of ignorance or inability to distinguish between the two alternatives. See [25.16] for a more-detailed example of applying the evidential method to certainty-grid navigation.

Evidential reasoning thus provides a method of capturing ignorance or an inability to distinguish between alternatives. In probability theory, this would be dealt with in a very different manner by assigning an equal or uniform probability to each alternative. Yet, stating that there is a 50% chance of occupancy is clearly *not* the same as saying that it is unknown whether it will occupied or not. The use of the power set as the *frame of discernment* allows a far richer representation of beliefs. However, this comes at the cost of a substantial increase in complexity. If there are n elements in the original set \mathcal{X} , then there will be 2^n possible subsets on which a belief mass will be assigned. For large n , this is clearly intractable. Further, when the set is continuous, the set of all subsets is not even measurable.

Evidential reasoning methods provide a means of assigning, and combining belief masses on sets. Methods also exist for obtaining related measures called *support* and *plausibility* which, in effect, provide upper and lower probability bounds in agreement with Dempster's original formulation of this method.

Evidential reasoning can play an important role in discrete data fusion systems, particularly in areas such as attribute fusion and situation assessment, where information may be unknown or ambiguous. Its use in lower-level data fusion problems is challenging as the assignment of belief mass to the power set scales exponentially with state cardinality.

25.2 Multisensor Fusion Architectures

The multisensor fusion methods described in the previous section provide the algorithmic means by which sensor data and their associated uncertainty models can be used to construct either implicit or explicit models of the environment. However, a multisensor fusion system must include many other functional components to manage and control the fusion process. The organization of these is termed a *multisensor fusion architecture*.

25.2.1 Architectural Taxonomy

Multisensor systems architectures can be organized in various ways. The military community has developed a layout of functional architectures based on the joint directors of the laboratories (**JDL**) model for multisensor systems. This approach views multisensor fusion in terms of signal, feature, threat and situation analysis levels (so-called **JDL** levels). The assessment of such

systems is specified in terms of tracking performance, survivability, efficiency and bandwidth. Such measures are not generally appropriate in robotics applications and so the **JDL** model is not discuss this further here (see [25.17, 18] for details). Other classification schemes distinguish between low- and high-level fusion [25.19], or centralized versus decentralized processing or data versus variable [25.20].

A general architectural framework for multisensor robotic systems has been developed and described in detail by *Makarenko* [25.21], and we will base our discussion on this approach. A system architecture is defined as follows.

Meta-architecture. A set of high-level considerations that strongly characterize the system structure. The selection and organization of the system elements may be guided by aesthetics, efficiency, or other design cri-

teria and goals (for example, system and component comprehensibility, modularity, scalability, portability, interoperability, (de)centralization, robustness, fault tolerance).

Algorithmic Architecture. A specific set of information fusion and decision-making methods. These methods address data heterogeneity, registration, calibration, consistency, information content, independence, time interval and scale, and relationships between models and uncertainty.

Conceptual Architecture. The granularity and functional roles of components (specifically, mappings from algorithmic elements to functional structures).

Logical Architecture. Detailed canonical component types (i.e., object-oriented specifications) and interfaces to formalize intercomponent services. Components may be ad hoc or regimented, and other concerns include granularity, modularity, reuse, verification, data structures, semantics, etc. Communication issues include hierarchical versus heterarchical organization, shared memory versus message passing, information-based characterizations of subcomponent interactions, pull/push mechanisms, subscribe–publish mechanisms, etc. Control involves both the control of actuation systems within the multisensor fusion system, as well as control of information requests and dissemination within the system, and any external control decisions and commands.

Execution Architecture. Defines mapping of components to execution elements. This includes internal or external methods of ensuring correctness of the code (i.e., that the environment and sensor models have been correctly transformed from mathematical or other formal descriptions into computer implementations), and also validation of the models (i.e., ensure that the formal descriptions match physical reality to the required extent).

In any closed-loop control system, sensors are used to provide the feedback information describing the current status of the system and its uncertainties. Building a sensor system for a given application is a system engineering process that includes the analysis of system requirements, a model of the environment, the determination of system behavior under different conditions, and the selection of suitable sensors [25.22]. The next step in building the sensor system is to assemble the hardware components and develop the necessary

software modules for data fusion and interpretation. Finally, the system is tested, and the performance is analyzed. Once the system is built, it is necessary to monitor the different components of the system for the purpose of testing, debugging, and analysis. The system also requires quantitative measures in terms of time complexity, space complexity, robustness, and efficiency.

In addition, designing and implementing real-time systems are becoming increasingly complex owing to many added features such as graphical user interfaces (GUIs), visualization capabilities, and the use of many sensors of different types. Therefore, many software engineering issues such as reusability and the use of commercial off-the-shelf (COTS) components [25.23], real-time issues [25.24–26], sensor selection [25.27], reliability [25.28–30], and embedded testing [25.31] are now receiving more attention from system developers.

Each sensor type has different characteristics and functional descriptions. Consequently, some approaches aim to develop general methods of modeling sensor systems in a manner that is independent of the physical sensors used. In turn, this enables the performance and robustness of multisensor systems to be studied in a general way. There have been many attempts to provide the general model, along with its mathematical basis and description. Some of these modeling techniques concern error analysis and fault tolerance of multisensor systems [25.32–37]. Other techniques are model based, and require a priori knowledge of the sensed object and its environment [25.38–40]. These help fit data to a model, but do not always provide the means to compare alternatives. Task-directed sensing is another approach to devising sensing strategies [25.41–43]. General sensor modeling work has had a considerable influence on the evolution of multisensor fusion architectures.

Another approach to modeling sensor systems is to define sensori-computational systems associated with each sensor to allow design, comparison, transformation, and reduction of any sensory system [25.44]. In this approach, the concept of an information invariant is used to define a measure of information complexity. This provides a computational theory allowing analysis, comparison, and reduction of sensor systems.

In general terms, multisensor fusion architectures may be classified according to the choice along four independent design dimensions:

1. centralized–decentralized,
2. local–global interaction of components,

3. modular–monolithic, and
4. heterarchical–hierarchical.

The most prevalent combinations are:

- centralized, global interaction, and hierarchical,
- decentralized, global interaction, and heterarchical,
- decentralized, local interaction, and hierarchical,
- decentralized, local interaction, and heterarchical.

In some cases explicit modularity is also desirable. Most existing multisensor architectures fit reasonably well into one of these categories. These categories make no general commitment to the algorithmic architecture. If the algorithmic architecture is the predominant feature of a system, it will be characterized as part of multisensor fusion theory in Sect. 25.1; otherwise, it merely differentiates methods within one of the four meta-architectures.

25.2.2 Centralized, Local Interaction, and Hierarchical

Centralized, local interaction and hierarchical architectures encompass a number of system philosophies. Least representationally demanding is the *subsumption architecture* initially proposed by *Braitenberg* [25.45] and popularized by *Brooks* [25.46]. The subsumption multisensor architecture defines behaviors as the basic components, and employs a layered set of behaviors to embody one program (monolithic). Any behavior may utilize the output of other behaviors, and may also inhibit other behaviors. The hierarchy is defined by the layers, although this is not always clear-cut. The major design philosophy is to develop behaviors directly from perception–action loops without recourse to brittle, environment representations. This leads to robustness in operation, but a lack of composite behavior predictability.

A more sophisticated (representationally) behavior-based system is the *distributed field robot architecture (DFRA)* [25.47]. This is a generalization of the sensor fusion effects (**SFX**) architecture [25.48]. This approach exploits modularity, and aims to achieve both behavior-based and deliberative action, reconfigurability and interoperability through the use of Java, Jini, and **XML**, fault tolerance, adaptability, longevity, consistent interfaces, and dynamic components. The algorithmic architecture is based on fuzzy logic controllers. Experiments have been demonstrated on outdoor mobile robot navigation.

Other similar architectures of this type include perception action networks *Lee* [25.49, 50], while *Draper* [25.51] focuses on types of information needed to perform tasks (higher-level integration); see also [25.52].

Another approach to this type of sensor fusion is to use artificial neural networks. The advantage is that the user, at least in principle, does not need to understand how sensor modalities relate, nor model the uncertainties, nor in fact determine the structure of the system more than to specify the number of layers in the network and the number of nodes per layer. The neural network is presented with a set of training examples, and must determine through the weights on the neuron connections the optimal mapping from inputs to desired outputs (classifications, control signals, etc.) [25.53, 54].

Various other methods exist; for example, *Hager* [25.42, 43] defines a task-oriented approach to sensor fusion based on Bayesian decision theory and develops an object-oriented programming framework. *Joshi* and *Sanderson* [25.55] describe a

“methodology for addressing model selection and multisensor fusion issues using representation size (description length) to choose (1) model class and number of parameters, (2) model parameter resolution (3) subset of observed features to model, and (4) correspondence to map features to models.”

Their approach is broader than an architecture and uses a minimization criterion to synthesize a multisensor fusion system to solve specific two-dimensional (2-D) and three-dimensional (3-D) object recognition problems.

25.2.3 Decentralized, Global Interaction, and Heterarchical

The major example of the decentralized, global interaction meta-architecture is the blackboard system. There have been many examples of blackboard systems developed for data fusion applications. For example, the SEPIA system of *Cherfaoui* and *Vachon* [25.56] uses logical sensors (see below) in the form of modular agents that post results to a blackboard. The overall architectural goals for blackboards include efficient collaboration and dynamic configuration. Experiments are reported on an indoor robot moving from room to room.

The MESSIE (Multi Expert System for Scene Interpretation and Evaluation) system [25.57] is a scene interpretation system based on multisensor fusion; it has been applied to the interpretation of remotely sensed im-

ages. A typology of the multisensor fusion concepts is presented, and the consequences of modeling problems for objects, scene, and strategy are derived. The proposed multispecialist architecture generalized the ideas of their previous work by taking into account the knowledge of sensors, the multiple viewing notion (shot), and the uncertainty and imprecision of models and data modeled with possibility theory. In particular, generic models of objects are represented by concepts independent of sensors (geometry, materials, and spatial context). Three kinds of specialists are present in the architecture: generic specialists (scene and conflict), semantic object specialists, and low-level specialists. A blackboard structure with a centralized control is used. The interpreted scene is implemented as a matrix of pointers enabling conflicts to be detected very easily. Under the control of the scene specialist, the conflict specialist resolves conflicts using the spatial context knowledge of objects. Finally, an interpretation system with SAR (synthetic aperture radar)/SPOT sensors is described, and an example of a session concerned with bridge, urban area, and road detection is shown.

25.2.4 Decentralized, Local Interaction, and Hierarchical

One of the earliest proposals for this type of architecture is the real-time control system (**RCS**) [25.58]. **RCS** is presented as a cognitive architecture for intelligent control, but essentially uses multisensor fusion to achieve complex control. **RCS** focuses on task decomposition as the fundamental organizing principle. It defines a set of nodes, each comprised of a sensor processor, a world model, and a behavior generation component. Nodes communicate with other nodes, generally in a hierarchical manner, although across-layer connections are allowed. The system supports a wide variety of algorithmic architectures, from reactive behavior to semantic networks. Moreover, it maintains signals, images, and maps, and allows tight coupling between iconic and symbolic representations. The architecture does not generally allow dynamic reconfiguration, but maintains the static module connectivity structure of the specification. **RCS** has been demonstrated in unmanned ground vehicles [25.59]. Other object-oriented approaches have been reported [25.34, 60].

An early architectural approach which advocated strong programming semantics for multisensor systems is the logical sensor system (**LSS**). This approach exploits functional (or applicative) language theory to achieve that.

The most developed version of **LSS** is instrumented **LSS** (**ILSS**) [25.22]. The **ILSS** approach is based on the **LSS** introduced by *Shilcrat* and *Henderson* [25.61]. The **LSS** methodology is designed to specify any sensor in a way that hides its physical nature. The main goal behind **LSS** was to develop a coherent and efficient presentation of the information provided by many sensors of different types. This representation provides a means for recovery from sensor failure, and also facilitates reconfiguration of the sensor system when adding or replacing sensors [25.62].

ILSS is defined as an extension to **LSS**, and is comprised of the following components (Fig. 25.4):

1. *ILSS name*: uniquely identifies a module
2. *Characteristic output vector (COV)*: strongly typed output structure, with one output vector and zero or more input vectors
3. *Commands*: input commands to the module, and output commands to the other modules
4. *Select function*: a selector that detects the failure of an alternate and switches to another alternate if possible
5. *Alternate subnets*: alternative ways of producing the COV_{out} ; it is these implementations of one or more algorithms that carry the main functions of the module
6. *Control command interpreter (CCI)*: interpreter of the commands to the module
7. *Embedded tests*: self-testing routines that increase robustness and facilitate debugging

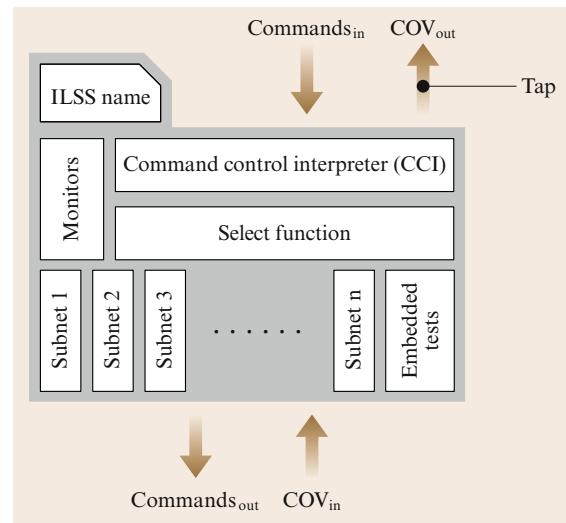

Fig. 25.4 Instrumented logical sensor module

8. *Monitors*: modules that check the validity of the resulting COVs
9. *Taps*: hooks on the output lines to view different COV values

These components identify the system behavior and provide mechanisms for online monitoring and debugging. In addition, they provide handles for measuring the runtime performance of the system. Monitors are validity check stations that filter the output and alert the user to any undesired results. Each monitor is equipped with a set of rules (or constraints) that governs the behavior of the COV under different conditions.

Embedded testing is used for online checking and debugging purposes. *Weller* proposed a sensor-processing model with the ability to detect measurement errors and to recover from these errors [25.31]. This method is based on providing each system module with verification tests to verify certain characteristics in the measured data, and to verify the internal and output data resulting from the sensor-module algorithm. The recovery strategy is based on rules that are local to the different sensor modules. ILSS uses a similar approach called *local embedded testing*, in which each module is equipped with a set of tests based on the semantic definition of that module. These tests generate input data to check different aspects of the module, then examine the output of the module using a set of constraints and rules defined by the semantics. These tests can also take input from other modules to check the operation of a group of modules. Examples are given of a wall-posed estimation system comprised of a Labmate platform with a camera and sonars. Many extensions have been proposed for LSS [25.63, 64].

Table 25.1 Canonical components and the roles they play. Multiple X's in the same row indicate that some interrole relationships are internalized within a component. ‘Frame’ does not participate in information fusion or decision making but is required for localization and other platform-specific tasks (from [25.21])

| Component Type | Belief | | | Plan | | | Action | |
|----------------|--------|-----------|------|--------|-----------|------|--------|------|
| | Source | Fuse/Dist | Sink | Source | Fuse/Dist | Sink | Source | Sink |
| Sensor | x | | | | | | | |
| Node | | x | | | x | | | |
| Actuator | | | | | | | | x |
| Planner | | | x | x | | x | x | |
| UI | x | | x | | | x | x | |
| Frame | | | | | | | | |

25.2.5 Decentralized, Local Interaction, and Heterarchical

The best example of this meta-architecture is the active sensor network ([ASN](#)) framework for distributed data fusion developed by *Makarenko* [25.21, 65]. The distinguishing features of the various architectures are now described.

Meta-architecture

The distinguishing features of [ASN](#) are its commitment to decentralization, modularity, and strictly local interactions (this may be physical or by type). Thus, these are communicating processes. Decentralized means that no component is central to operation of the system, and the communication is peer to peer. Also, there are no central facilities or services (e.g., for communication, name and service lookup or timing). These features lead to a system that is scalable, fault tolerant, and reconfigurable.

Local interactions mean that the number of communication links does not change with the network size. Moreover, the number of messages should also remain constant. This makes the system scalable as well as reconfigurable.

Modularity leads to interoperability derived from interface protocols, reconfigurability, and fault tolerance: failure may be confined to individual modules.

Algorithmic Architecture

There are three main algorithmic components: belief fusion, utility fusion, and policy selection. Belief fusion is achieved by communicating all beliefs to neighboring platforms. A belief is defined as a probability distribution of the world state space.

Utility fusion is handled by separating the individual platform's partial utility into the team utility of belief quality and local utilities of action and communication. The downside is that the potential coupling between individual actions and messages is ignored because the utilities of action and communication remain local.

The communication and action policies are chosen by maximizing expected values. The selected approach is to achieve point maximization for one particular state and follows the work of *Manyika* and *Grocholsky* [25.11, 66].

Conceptual Architecture

The data types of the system include

1. *beliefs*: current world beliefs
2. *plans*: future planned world beliefs
3. *actions*: future planned actions

The definition of component roles leads to a natural partition of the system.

The information fusion task is achieved through the definition of four component roles for each data type: *source*, *sink*, *fuser*, and *distributor*. (Note that the data type action does not have fuser or distributor component roles.)

Connections between distributors form the backbone of the [ASN](#) framework, and the information exchanged is in the form of their local beliefs. Similar consider-

ations are used to determine component roles for the decision-making and system configuration tasks.

Logical Architecture

A detailed architecture specification is determined from the conceptual architecture. It is comprised of six canonical component types as described in Table 25.1 [25.21].

Makarenko then describes how to combine the components and interfaces to realize the use cases of the problem domain in [ASN](#).

Execution Architecture

The execution architecture traces the mapping of logical components to runtime elements such as processes and shared libraries. The deployment view shows the mapping of physical components onto the nodes of the physical system. The source code view explains how the software implementing the system is organized. At the architectural level, three items are addressed: execution, deployment, and source code organization.

The experimental implementation of the [ASN](#) framework has proven to be flexible enough to accommodate a variety of system topologies, platform, and sensor hardware, and environment representations. Several examples are given with a variety of sensors, processors, and hardware platforms.

25.3 Applications

Multisensor fusion systems have been applied to a wide variety of problems in robotics (see the references for this chapter), but the two most general areas are *dynamic system control* and *environment modeling*. Although there is some overlap between these, they may generally be characterized as

- *Dynamic system control*: the problem is to use appropriate models and sensors to control the state of a dynamic system (e.g., industrial robot, mobile robot, autonomous vehicle, surgical robot). Usually such systems involve real-time feedback control loops for steering, acceleration, and behavior selection. In addition to state estimation, uncertainty models are required. Sensors may include force/torque sensors, gyros, global positioning system ([GPS](#)), position encoders, cameras, range finders, etc.;

- *environment modeling*: the problem is to use appropriate sensors to construct a model of some aspect of the physical environment. This may be a particular object, e.g., a cup, a physical part, a face, or a larger part of the surroundings, e.g., the interior of a building, part of a city or an extended remote or underground area. Typical sensors include cameras, radar, 3-D range finders, infrared (IR), tactile sensors and touch probes (CMMs), etc. The result is usually expressed as geometry (points, lines, surfaces), features (holes, sinks, corners, etc.), or physical properties. Part of the problem includes the determination of optimal sensor placement.

25.3.1 Dynamic System Control

The [EMS](#)-Vision system [25.67] is an outstanding exemplar of this application domain. The goal is to develop

Fig. 25.5 First fully autonomous vehicle on German autobahn

a robust and reliable perceptual system for autonomous vehicles. The development goals, as stated by the EMS-Vision team, are:

- COTS components
- wide variety of objects modeled and incorporated into behaviors
- inertial sensors for ego-state estimation
- peripheral/foveal/saccadic vision

- knowledge and goal driven behavior
- state tracking for objects
- 25 Hz real-time update rate

The approach has been in development since the 1980s. Figure 25.5 shows the first vehicle to drive fully autonomously on the German autobahn for 20 km and at speeds up to 96 km/h.

Information from inertial and vision sensors is combined to produce a road scene tree (Fig. 25.6). A four-dimensional (4-D) generic object representation is built which includes background knowledge of the object (e.g., roads), its behavioral capabilities, object state and variances, and shape and aspect parameters. Figure 25.7 shows the 4-D inertial/vision multisensor guidance system, while Fig. 25.8 shows the hardware aspects.

In summary, the EMS-Vision system is an interesting and powerful demonstration of multisensor fusion for dynamic system control.

25.3.2 ANSER II: Decentralized Data Fusion

Decentralized data fusion (DDF) methods were initially motivated by the insight that the *information* or canonical form of the conventional Kalman filter data fusion algorithm could be implemented by simply adding information contributions from observations as shown in (25.41). As these (vector and

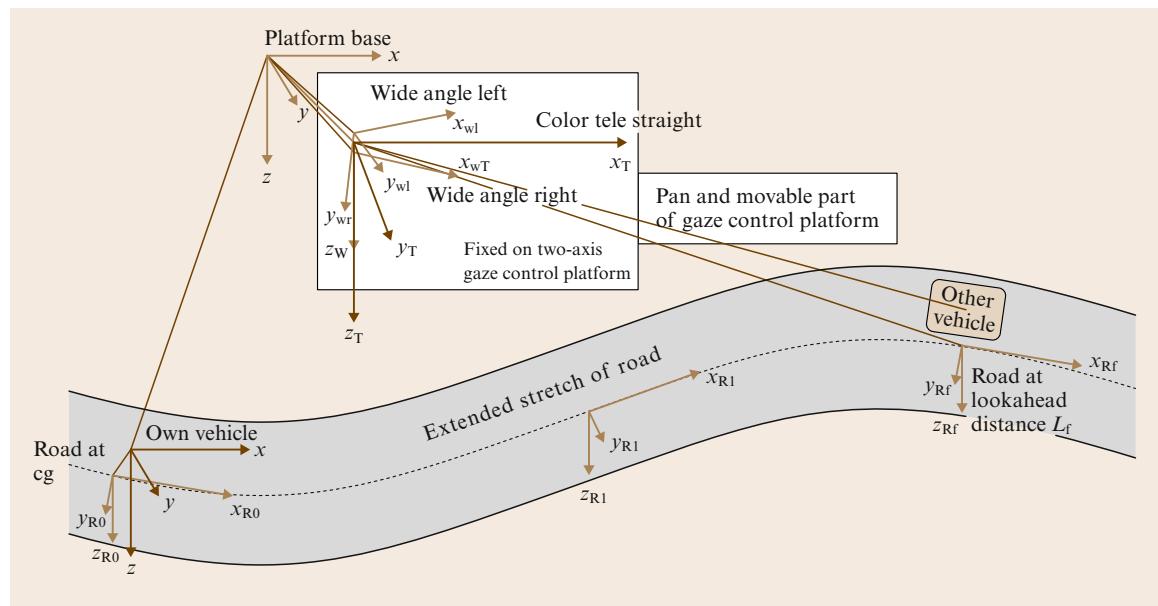

Fig. 25.6 EMS-Vision road scene tree

matrix) additions are commutative, the update or data fusion process can be optimally distributed amongst a network of sensors [25.11, 12, 68]. The aim of the ANSER II project was to generalize the DDF method to deal with non-Gaussian probabilities for observations and states, and to incorporate information from a diversity of sources including uninhabited air and ground vehicles, terrain databases, and human operatives.

The mathematical structure of a DDF sensor node is shown in Fig. 25.9. The sensor is modeled directly in the form of a likelihood function. Once instantiated with an observation, the likelihood function is input to a local fusion loop which implements a local form of the Bayesian time and observation update of (25.7) and (25.8). Network nodes accumulate probabilistic information from observation or communication and exchange mutual information (information gain) with other nodes in the network [25.21]. This mutual information is transmitted

to and assimilated by other nodes in the network in an ad hoc manner. The result is that all nodes in the network obtain a single integrated posterior-probability-based all-node observations.

The ANSER II system consists of a pair of autonomous air vehicles equipped with infrared and visual sensors, a pair of unmanned ground vehicles equipped with visual and radar sensors, and additional information provided by geometric and hyperspectral databases, along with information input by human operatives [25.69]. The likelihood functions for single-sensor features are obtained through a semisupervised machine learning method [25.70]. The resulting probabilities are modeled in the form of a mixture of Gaussians. Each platform then maintains a bank of decentralized, non-Gaussian Bayesian filters for the observed features, and transmits this information to all other platforms. The net result is that each platform maintains a complete map of all features observed by all nodes in the

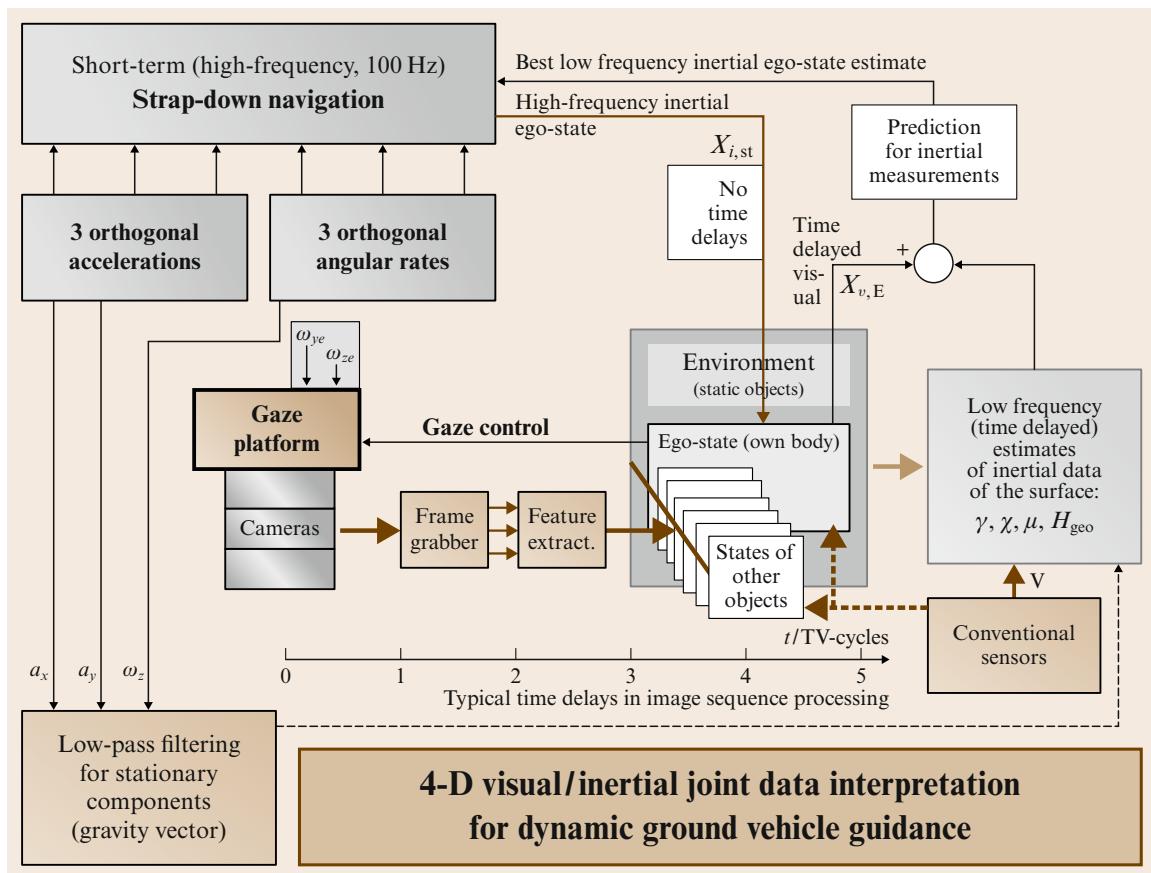

Fig. 25.7 EMS-Vision guidance system

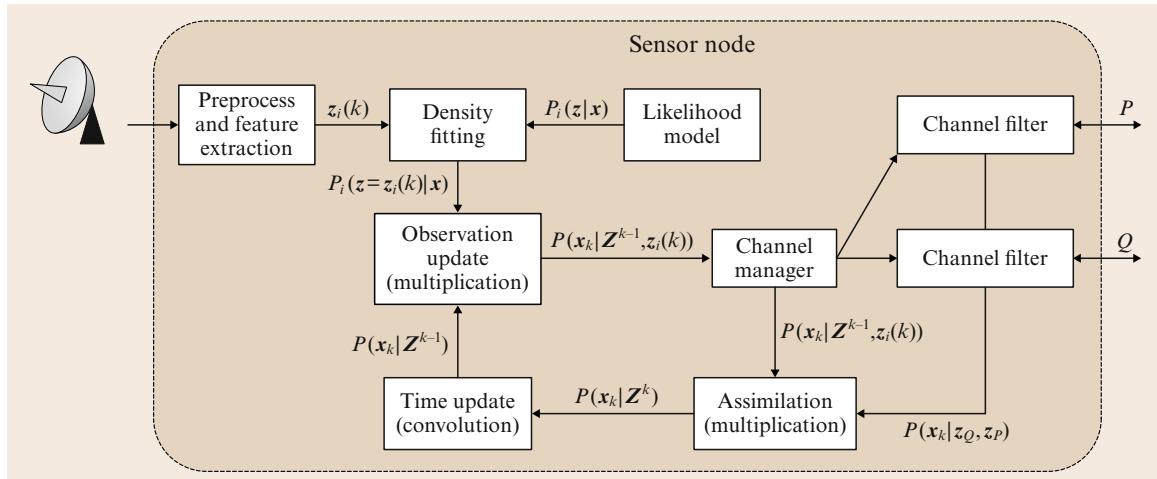

Fig. 25.9 Mathematical structure of a decentralized data fusion node

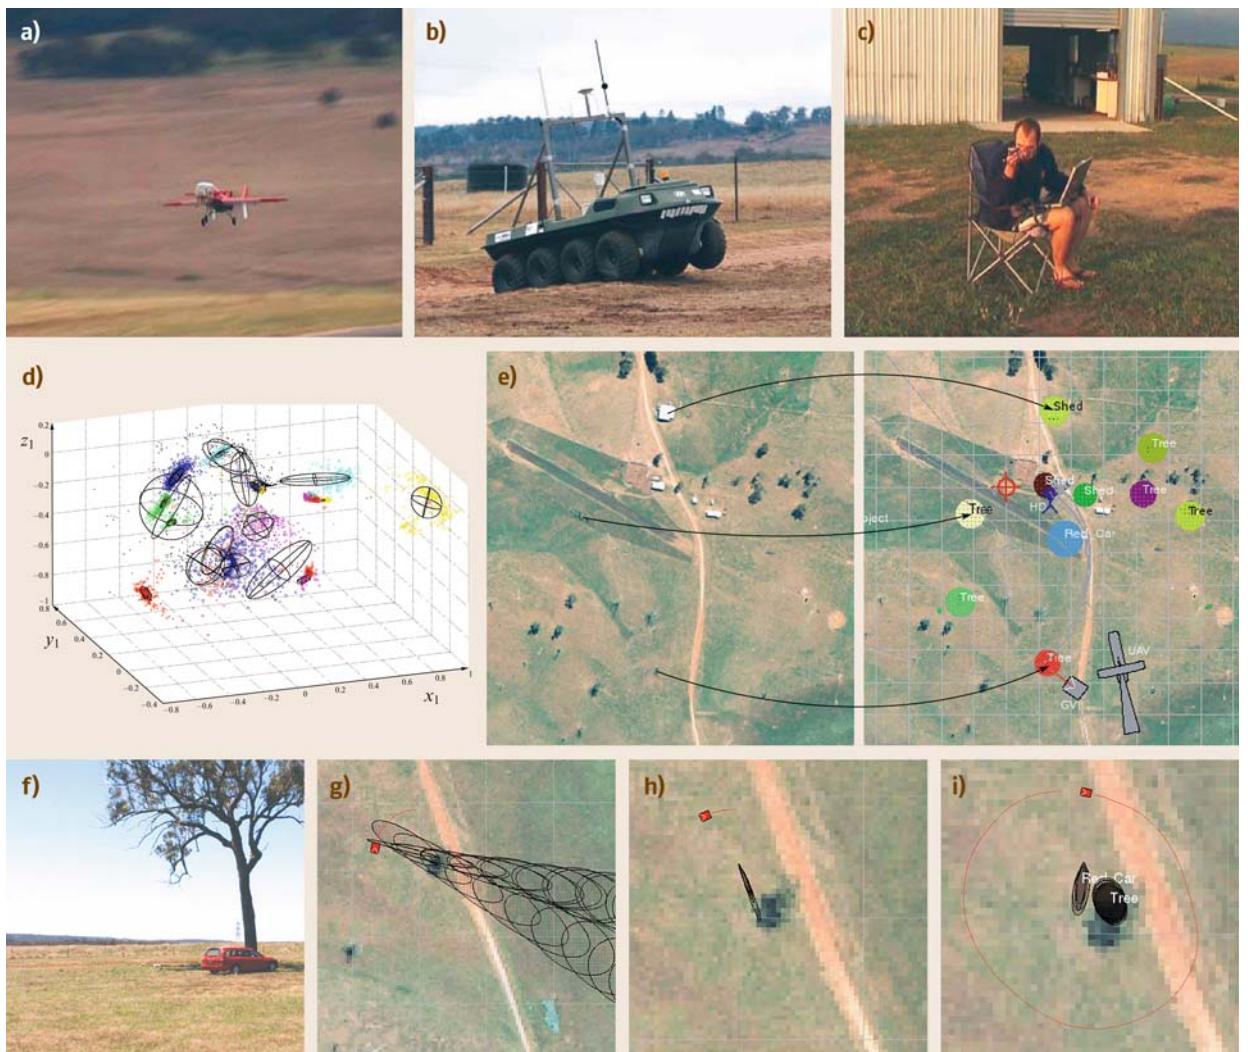

Fig. 25.10a–i A synopsis of the ANSER II autonomous network and its operation. **(a–c)** Main system components: **(a)** air vehicle, **(b)** ground vehicle, **(c)** human operative. **(d–e)** The perception process: **(d)** top three dimensions of features discovered from ground-based visual sensor data along with the derived mixture model describing these feature properties, **(e)** sector of the overall picture obtained from fusing air vehicle (UAV), ground vehicle (GV), and human operator (HO) information. Each set of ellipses corresponds to a particular feature and the labels represent the identity state with highest probability. **(f–i)** Sequential fusion process for two close landmarks: **(f)** a tree and a red car, **(g)** bearing-only visual observations of these landmarks are successively fused, **(h)** to determine location and identity **(i)**. Note the Gaussian mixture model for the bearing measurement likelihood

network. Multiple observations of the same feature, possibly by different platforms, result in an increasingly accurate estimate of the feature location for all nodes. A corresponding discrete probability measure is used for Fig. 25.10 shows a synopsis of the operation of the ANSER II system.

The ANSER II system demonstrates a number of general principles in Bayesian data fusion methods, specifically the need to model sensors appropriately through the likelihood function, and the possibility of building very different data fusion architectures from the essential Bayesian form.

25.4 Conclusions

Multisensor data fusion has progressed greatly in the last few decades; further advances in the field will be documented in the robotics and multisensor fusion and integration conference and journal literature. Robust applications are being fielded based on the body of theory and experimental knowledge produced by the research community. Current directions of interest include:

1. large-scale, ubiquitous sensor systems
2. bio-based or biomimetic systems
3. medical in situ applications
4. wireless sensor networks

Representative large-scale examples include intelligent vehicle and road systems, as well as instrumented contexts such as cities. Biological principles may provide fundamentally distinct approaches to the exploitation of dense, redundant, correlated, noisy sensors, especially when considered as part of a Gibbsian framework for behavioral response to environmen-

tal stimuli. Another issue here is the development of a theoretical understanding of sensor system development, adaptivity, and learning with respect to the particular context in which the system is deployed.

Further pushing the envelope of both technology and theory will permit the introduction of micro- and nanosensors into the human body and allow the monitoring and locally adaptive treatment of various illnesses. Finally, a more-complete theoretical framework that encompasses system models for wireless sensor networks is still required. This should include models of the physical phenomena being monitored, as well as operational and network issues. Finally, numerical analysis of the algorithmic properties of data-driven systems with sensor data error sources must be unified with the analysis of truncation, roundoff, and other errors.

A firm foundation exists upon which to build these new theories, systems, and applications. It will be a vibrant area of research for years to come.

Part D Manipulation and Interfaces, is separated into two subparts; the first half is concerned with manipulation where frameworks of modeling, motion planning, and control of grasp and manipulation of an object are addressed, and the second half is concerned with interfaces where physical human–robot interactions are handled. Humans can achieve grasping and manipulation of an object dexterously through hand–arm coordination. An optimum control skill for such a redundant system is naturally and gradually acquired through experience in our daily life. Especially, fingers play an important role for expressing human dexterity. Without dexterous fingers, it is hard for us to handle any daily tool, such as a pencil, keyboard, cup, knife, or fork. This dexterity is supported with active and passive compliance as well as the multiple sensory organs existing at the fingertip. Such dexterous manipulation enables us to clearly differentiate humans from other animals. Thus, manipulation is one of the most important functions for humans. We eventually acquired the current shape of finger, the sensory organs, and skill for manipulation, through a long history of evolution, over more than six million years. While both humans and robots are largely different in terms of actuators, sensors, and mechanisms, achieving dexterous manipulation like that of a human in a robot is a challenging subject in robotics. As we overview current robot technology, however, we observe that the dexterity of robots is still far behind that of humans. With this overview, we now provide a brief synopsis of each chapter in the first half of Part D.

Chapter 26, Motion for Manipulation Tasks, discusses algorithms that generate motion for manipulation tasks at the arm level, especially in an environment, by using the configuration space formalism. While in previous chapters (6 and 7) the focus was on specific algorithmic techniques for robot motion, this chapter is focused on a specific application for robot manipulation.

Chapter 27, Contact Modeling and Manipulation, provides contact modeling based on soft as well as rigid contacts. Kinematics and mechanics with friction are precisely handled under rigid-body contact. The selection matrix H is introduced to understand the force and velocity constraints at the contact interface. Pushing manipulation is also addressed by using the concept of the friction limit surface.

Chapter 28, Grasping, discusses, based on the closure property, grasping with many examples, supposing multifingered robotic hands. A strong constraint for grasping is the unilateral characteristic, where a fingertip can push but not pull an object through a contact point.

Kinematics and closure issues are addressed under this unilateral constraint.

Chapter 29, Cooperative Manipulators, addresses the strategies for controlling both the motion of cooperative system and the interaction forces between the manipulators and the grasped object when two manipulator arms firmly grasp a common object. It should be noted that this chapter allows the bilateral constraint where both directional force and moment are permissible.

Without dexterity like that of humans, future robots will not be able to work instead of humans in environments where human cannot enter. In this sense, the implementation of dexterity into robots is one of the highlights of future robot design. Chapters 26–29 provide a good hint for enhancing dexterity for robots.

The second half of Part D addresses interfaces where humans control a robot or multiple robots through direct or indirect contact with robot(s). We now provide a brief synopsis of each chapter in the second half of Part D.

Chapter 30, Haptics, discusses robotics devices that allow human operators to experience the sense of touch in remote or virtual environment. In haptic device design, two classes of haptic devices are discussed. One is an admittance haptic device that senses the force applied by the operator and constrains the operator's position to match the appropriate deflection of a simulated object or surface; the other is an impedance haptic device that senses the position of the operator and then applies a force vector to the operator according to the computed behavior of the simulated object or surface.

Chapter 31, Telerobotics, starts with a discussion on the classification of three different concepts: direct control where all slave motions are directly controlled by the user via the master interface, shared control where task execution is shared between direct control and local sensory control, and supervisory control where the user and slave are connected loosely with strong local autonomy. Various control issues such as time delay are also addressed.

Chapter 32, Networked Telerobotics, includes three components: a user, where anyone with an Internet connection is allowed, a web server on which an Internet-compatible server software can run, and a robot including a robot manipulator, mobile robot, or any device that can change its environment. The Internet is a powerful tool for controlling a robot (or robots), since it is the most popular communication media. We may see an enormous market for this in the future, and great care is required to ensure security.

Chapter 33, Exoskeletons for Human Performance Augmentation, deals with power-assist systems where human power is enhanced by wearing a robotic suit. In a human–robot system, we can consider that the distance between the human and the robot is zero as an extreme case. Design of hardware and control issues are precisely discussed by taking the Berkeley Lower Extremity Exoskeleton (**BLEEX**) as an example.

In both Telerobotics (Chap. 31) and Networked Telerobotics (Chap. 32), an appropriate distance between the human and robot is kept, while in both Haptics (Chap. 30) and Exoskeletons (Chap. 33), direct contact between human and robot is made. One of the main issues is how to maintain appropriate control performance of the system in the presence of humans or a time lag between humans and robots.

Motion for Manipulation Tasks

Oliver Brock, James Kuffner, Jing Xiao

This chapter serves as an introduction to Part D by giving an overview of motion generation and control strategies in the context of robotic manipulation tasks. Automatic control ranging from the abstract, high-level task specification down to fine-grained feedback at the task interface are considered. Some of the important issues include modeling of the interfaces between the robot and the environment at the different time scales of motion and incorporating sensing and feedback. Manipulation planning is introduced as an extension to the basic motion planning problem, which can be modeled as a hybrid system of continuous configuration spaces arising from the act of grasping and moving parts in the environment. The important example of assembly motion is discussed through the analysis of contact states and compliant motion control. Finally, methods aimed at integrating global planning with state feedback control are summarized.

26.1 Overview

Part D of this handbook is concerned with the interfaces that connect robots to their environment. We differentiate three such interfaces, depicted in Fig. 26.1. The first interface, between the robot and the computer, is primarily concerned with the automatic generation of motion for performing a task. The second interface is concerned with the physical interaction between the robot and the environment. This chapter relates both interfaces in the context of manipulation tasks. It is focused on automatic specification, planning, and execution of

motion of the robot manipulator or the manipulated object to meet a task goal under the constraints of the physical environment. Chapters 27–29 address other important issues pertaining to the second interface, such as the physical characteristics of contacts between the robot and the environment, grasping (i.e., the interaction between the robot and the object for manipulation), and the interaction between cooperative manipulators. The third interface, described in Chaps. 30–33, lies between humans and robots. Key issues that need to be

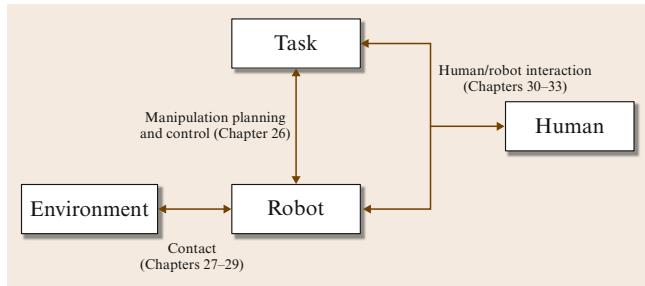

Fig. 26.1 Overview of Part D

addressed involve displaying appropriate sensor information to humans, or permitting humans to interactively specify the task or motion a robot is supposed to perform.

Manipulation refers to the process of moving or rearranging objects in the environment [26.1]. To perform a *manipulation task*, a robot establishes physical contact with objects in the environment and subsequently moves these objects by exerting forces and moments. The object to be manipulated can be large or small, and may serve various purposes in relation to the manipulation task (e.g., flipping a switch, opening a door, polishing a surface). In the context of automated assembly and industrial manipulation, the object to be manipulated is often referred to as a *part*. The *end-effector* generally refers to the link of the *manipulator* that makes contact and applies forces to the *part*. The *end-effector* is so named as it is often the end link in a serial kinematic chain. However, complex manipulation tasks may require the simultaneous exertion of multiple forces and moments at different contact points as well

as the execution of sequences of force applications to several objects.

To understand the challenge of generating the motion required for the execution of a manipulation task, we will consider the classic example of inserting a peg into a hole. The mobile manipulator shown in Fig. 26.2 is commanded to perform the peg insertion *manipulation task*, whose general problem structure arises in a number of contexts such as compliant assembly. For simplicity, we will only consider the *transfer motion* (see Sect. 26.3) and assume that the robot has already established a stable grasp (see Chap. 28) and is holding the peg. If the clearance between the peg and the hole is very small, the peg may not be able to enter the hole easily, and often some contact occurs. In order to guide the peg successfully into the hole, the robot has to deal with the possible contact states between the peg and the hole (Sect. 26.4) and select an appropriate sequence of control strategies that will result in successful completion of the task.

The peg-and-hole example illustrates that successful robotic manipulation involves dealing with models of object geometry and contact in the presence of uncertainty. There are various kinds of uncertainty, including modeling, actuation, and sensing uncertainty. To plan motion strategies in the presence of uncertainty poses difficult computational challenges. Historically, motion planning for manipulation has been divided into *gross motion planning* and *fine motion planning*. The former involves reasoning about the manipulator motion on the macro scale and considers its overall global movement strategy, while the latter considers how to deal with uncertainty to accomplish a task requiring high precision robustly. The primary reason for the historical division stems from attempts to simplify the various aspects of the problem into something computationally tractable. Assuming that the uncertainty in actuator position, object models, and environment obstacle shapes can be bounded, gross motion planning can be formulated primarily in terms of geometry (Sect. 26.3). As the robot or the manipulated object makes contact with the environment, such as in the example of the insertion task, fine motion planning techniques are employed to take into account contact geometry, forces, friction, and uncertainty effectively (see Mason's book [26.1] and [26.2, 3] for an overview and historical perspective on fine motion strategies for manipulation tasks).

This peg-and-hole insertion example also illustrates that motion in the context of manipulation tasks is subject to *constraints*. These constraints have to be maintained to perform the task successfully. The specific

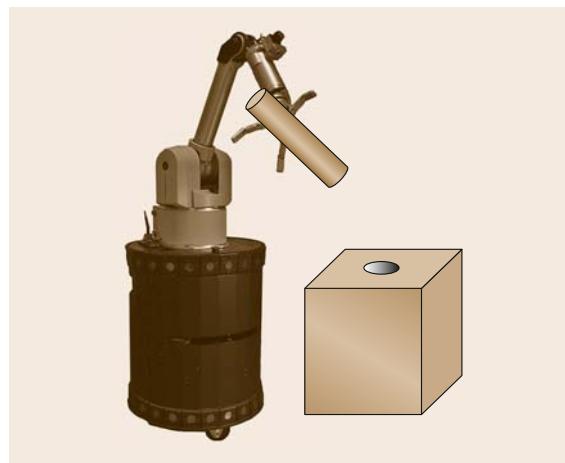

Fig. 26.2 A mobile manipulator inserting a peg into a hole

constraints depend on the type of manipulation task, but they may include contact constraints, position, and force constraints for the point at which the manipulator makes contact with the environment, kinematic and dynamic constraints imposed by the mechanism and its actuation capabilities, posture constraints that specify behavior to be performed in addition to the manipulation task, reactive obstacle avoidance in an unpredictably changing environment, and global motion constraints to ensure that a specific goal location is attained. These motion constraints are imposed by the task, by the kinematics of the mechanism performing the task, by the actuation capabilities of the mechanism, and by the environment.

To ensure that constraints are satisfied in spite of uncertainty, sensory information (see Part C – Sensing and Perception) is considered in the context of feedback control loops (Chaps. 6 and 35). Depending on the type of constraint, this feedback has to be considered at various time scales. For example, the exertion of a constant force on an object in the environment requires high-frequency feedback at rates up to 1000 Hz. At the other end of the time scale, we consider changes to the global connectivity of the environment. These changes, resulting from opening doors or moving obstacles, for example, occur relatively slowly or infrequently and feedback about these changes only has to be considered a few times per second. Figure 26.3 graphically illustrates a task-dependent ordering of motion constraints encountered in manipulation tasks and their associated feedback requirements.

This chapter is concerned with algorithms that generate motion for manipulation tasks. Previous chapters already discussed planning algorithms (Chap. 5) and control methods (Chap. 6). While in these two former chapters the focus was on specific algorithmic techniques for robot motion, the current chapter is focused on a specific application, namely robotic manipulation. This application dictates motion constraints and their feedback requirements that will have to be satisfied during the motion for a manipulation task. In contrast, the methods discussed in the two aforementioned chapters each only address a subset of the motion constraints, as indicated in Fig. 26.3.

This chapter first discusses task-level control in Sect. 26.2. Task-level control describes a set of techniques to control a robotic mechanism in terms of its contact points with the environment. These contact points are controlled to perform motion that accomplishes a specific manipulation task. This means that, instead of directly controlling the mechanism, task-

relevant points on the mechanism, so-called *operational points*, are controlled. This indirect control provides an intuitive means to specify desired motion for manipulation tasks.

Section 26.3 gives an overview of the configuration space formalization for manipulation planning, and how it can be cast as a classical motion planning problem (Chap. 5). Through this formalism, we can gain an understanding and intuition regarding how the geometry and relative positions of the manipulator, the manipulated objects, and the obstacles in the workspace determine both the geometry and topological structure of the manipulation configuration space. As we shall see, there are often an infinite number of possible ways to accomplish a manipulation task. Thus, the challenge in manipulation planning is to develop methods that deal effectively with the combinatorics of the search over all possible motions.

Section 26.4 addresses planning motion for assembly tasks, for which the peg-in-hole insertion is a typical example. The focus will be on motion constrained by contact, called *compliant motion*. There are two broad classes of assembly strategies involving compliant motion; one class is through special mechanism or control, called *passive compliance*, and the other is through active reasoning of contact states, called *active compliant motion*. Fine motion planning is discussed within the class of active compliant motion.

Methods from task-level control and manipulation planning address aspects of motion in a complementary fashion. While control methods are able to satisfy the feedback requirements of manipulation tasks, they often do not account for the overall global progress in accomplishing the manipulation task. Manipulation planners, on the other hand, reason about the global nature of the task at the high level, but are often computa-

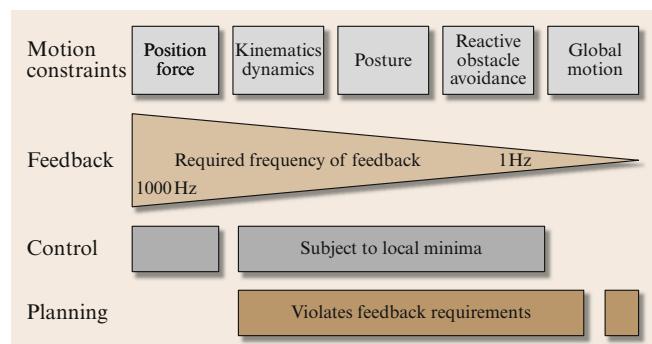

Fig. 26.3 Examples of motion constraints encountered in manipulation tasks and their feedback requirements

ally too expensive to deal with uncertainty or satisfy the high-frequency feedback requirements of manipulation tasks. A robust and skillful manipulator must satisfy all feedback requirements while at the same time en-

suring the accomplishment of the manipulation task. Section 26.5 discusses various techniques that offer a unified view of planning and control for manipulation tasks.

26.2 Task-Level Control

To perform a manipulation task, a robot has to establish contact with the environment. Through contact points the robot is able to apply forces and moments to objects. By controlling the position and velocity of the contact points as well as the forces acting at them, the robot causes the desired motion of objects, thereby performing the manipulation task. The programming of such a task is most conveniently accomplished by directly specifying positions, velocities, and forces at the contact points, rather than by specifying the joint positions and velocities required to achieve them.

Consider the manipulation task of serving a cup of water shown in Fig. 26.2. This task can easily be specified by providing a trajectory for the cup's motion. To determine a joint space trajectory that achieves the same motion, however, would be much more complex. One would have to rely on inverse kinematics (Sect. 1.9), which can be computationally challenging. More importantly, the task constraints imposed on the cup's motion do not uniquely specify the cup's trajectory. For example, while the cup is not allowed to tilt, it can be delivered to the goal location in any vertical orientation. Such task constraints can easily be specified in terms of the object motion – at the task level – but would be very difficult to characterize in terms of joint trajectories. Operational space control is therefore a natural choice for performing manipulation tasks. We will see in Sect. 26.2.3 that the operational space framework provides important additional advantages over joint space control in the context of redundant manipulators.

The advantages associated with task-level control come at the cost of depending on the manipulator Jacobian. For singular configurations of the manipulator (see Chap. 3), the manipulator Jacobian is not well defined. In these configurations, task-level control of a manipulator becomes unstable. Special care has to be applied to prevent the manipulator from entering these configurations, or to resort to specialized controllers in the proximity of these configurations. Most commonly, the manipulator is controlled so as to avoid singular configurations.

26.2.1 Operational Space Control

Task-level control – also called operational space control [26.4,5] (Sect. 6.2) – specifies the behavior of a robot in terms of operational points rather than joint positions and velocities. An operational point is an arbitrary point on the robot that is required to perform a particular motion or to exert a specified force to accomplish a manipulation task. In a serial-chain manipulator arm the operational point is most commonly chosen to coincide with the end-effector. More complex, branching mechanisms, such as humanoid robots, but also redundant serial-chain mechanisms, can have several operational points. To specify positions, velocities, accelerations, forces, and moments at the operational point, it is convenient to define a coordinate system with an origin that coincides with the operation point. This coordinate frame is called the operational frame. The orientation of the frame should be chosen in accordance with the task. For now we will ignore the orientation, however, and only consider tasks that require positioning of the operational point. In Sect. 26.2.2, we will consider more general tasks, combining position and force control.

Let us consider an operational point \mathbf{x} on a robot. The relationship between the joint velocities $\dot{\mathbf{q}}$ and the velocity of the operational point, $\dot{\mathbf{x}}$, is given by the Jacobian matrix of the mechanism (Sect. 1.8) at the operational point \mathbf{x} :

$$\dot{\mathbf{x}} = \mathbf{J}_x(\mathbf{q})\dot{\mathbf{q}} . \quad (26.1)$$

Note that the Jacobian \mathbf{J} depends on the placement of the operational point \mathbf{x} , and on the current configuration \mathbf{q} of the robot. For simplicity, we will omit this dependency from our notation and just write $\dot{\mathbf{x}} = \mathbf{J}\dot{\mathbf{q}}$. From (26.1) we can derive an expression for the instantaneous torques $\boldsymbol{\tau}$ acting at the joints when the forces and moments described by \mathbf{F} is applied at the operational point \mathbf{x} :

$$\boldsymbol{\tau} = \mathbf{J}^\top(\mathbf{q})\mathbf{F}_x . \quad (26.2)$$

The vector \mathbf{F} captures the task to be performed at operational point \mathbf{x} . If the task specifies the complete position and orientation of the operational frame, \mathbf{F} will be given by $\mathbf{F} = (f_x, f_y, f_z, u_x, u_y, u_z)$, where f and u designate forces along and moments about the respective axes. (For ease of presentation, we will refer to \mathbf{F} as a force vector, even if it describes forces and moments.) The execution of such a task requires a manipulator with at least six degrees of freedom. If a task does not specify one of the components of \mathbf{F} , this component can be omitted and the corresponding column of the Jacobian matrix is dropped (or a manipulator with fewer than six degrees of freedom can be used to accomplish the task). For example, dropping u_z would indicate that the orientation about the z -axis is not specified by the task. The motion behavior in the dimensions of the task space that have been dropped is unspecified and the robot will float in these dimensions [26.4]. In Sect. 26.2.3 we will discuss how additional behavior can be performed in these unspecified dimensions of the task space.

Similarly to joint space control, we have to account for manipulator dynamics to achieve acceptable performance in operational space control. Using (26.1), we can project the joint space dynamics into operational space to obtain

$$\mathbf{F}_x = \Lambda(\mathbf{q})\ddot{\mathbf{x}} + \Gamma(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \eta(\mathbf{q}), \quad (26.3)$$

where Λ is the operational space inertial matrix, Γ captures centrifugal and Coriolis forces in operational space, and η compensates for gravity forces. This equation pertains to a particular operational point. Intuitively speaking, the operational space inertia matrix Λ captures the resistance of the operational point to acceleration along and about different axes. More details about operational space control and its relationship to joint space control are provided in Sect. 6.2 (motion control, joint space versus operational space control).

26.2.2 Combined Force and Position Control

Let us consider the example task of controlling the motion of a peg inside a hole. We assume the peg is already inserted into the hole and rigidly connected to the robot's end-effector. We attach the operational frame to a point on the peg so that its z -axis is aligned with the desired direction of motion of the peg inside the hole. To perform this task, the robot has to control the position of the peg along the z -axis of the operational frame and it also has to control contact forces between the peg and the hole to avoid jamming. Thus, the task of moving a peg

inside a hole requires that position and force control be seamlessly integrated.

To address contact forces within the operational space framework, we rewrite (26.3) as

$$\mathbf{F}_x = \mathbf{F}_c + \Lambda(\mathbf{q})\mathbf{F}_m + \Gamma(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \eta(\mathbf{q}), \quad (26.4)$$

where \mathbf{F}_c represents the contact forces acting at the end-effector [26.4]. We can replace $\dot{\mathbf{x}}$ with \mathbf{F}_m because $\dot{\mathbf{x}}$ is acting on a dynamically decoupled system, i. e., a system that acts like a unit point mass. We can now control forces and motion in the operational frame by selecting the following control structure:

$$\mathbf{F}_x = \mathbf{F}_m + \mathbf{F}_c, \quad (26.5)$$

where

$$\mathbf{F}_m = \Lambda(\mathbf{q})\Omega \mathbf{F}'_m + \Gamma(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \eta(\mathbf{q}), \quad (26.6)$$

$$\mathbf{F}_c = \Lambda(\mathbf{q})\bar{\Omega} \mathbf{F}'_c, \quad (26.7)$$

where Ω and $\bar{\Omega}$ represent complementary task specification matrices [26.4] that determine along which directions the end-effector is position controlled and along which it is force controlled. By selecting Ω appropriately, the combination of position and force control can be tailored to the task. In its simplest form, Ω and $\bar{\Omega} = I - \Omega$ are diagonal matrices. The i -th diagonal entry of Ω is 1 if the i -th operational coordinate of the end-effector is position controlled and 0 if it is force controlled. In this simplest case, positions and forces are controlled along axes of the same coordinate frame. The concept of task specification matrix can be extended to include differently oriented coordinate frames for position and force control [26.4].

Once the force \mathbf{F}_x has been computed as given by (26.5), the corresponding joint torques used to control the robot are computed based on (26.1).

26.2.3 Operational Space Control of Redundant Mechanisms

The full expressiveness of task-level control comes to bear in the context of redundant manipulators. A manipulator is considered redundant with respect to the task it is performing if it has more degrees of freedom than required by the task. For example, the task of holding a cup of water only specifies two degrees of freedom, namely the two rotations about the axes spanning the horizontal plane – this task has two degrees of freedom. The mobile manipulator shown in Fig. 26.2 has ten degrees of freedom, leaving eight redundant degrees of freedom with respect to the task.

The operational space framework for task-level control of redundant manipulators decomposes the overall motion behavior into two components. The first component is given by the task, specified in terms of forces and moments, \mathbf{F}_{task} , acting at an operational point. This vector \mathbf{F} is translated into a joint torque based on (26.2): $\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{F}_{\text{task}}$. For a redundant manipulator, however, the torque vector $\boldsymbol{\tau}$ is not uniquely specified and we can select from a set of task-consistent torque vectors. The operational space framework performs this selection by considering a secondary task, the so-called posture behavior, making up the second component of the overall motion behavior. Posture behavior can be specified by an arbitrary torque vector $\boldsymbol{\tau}_{\text{posture}}$. To ensure that this additional torque does not affect the task behavior (\mathbf{F}_{task}), the torque $\boldsymbol{\tau}_{\text{posture}}$ is projected into the null space \mathbf{N} [26.6] of the task Jacobian \mathbf{J} . The null space of the Jacobian is the space orthogonal to the one spanned by \mathbf{J} and will be of rank $N_J - k$, where N_J is the number of degrees of freedom of the manipulator and $k = \text{rank}(\mathbf{J})$. The torque $\mathbf{N}^\top \boldsymbol{\tau}_{\text{posture}}$ resulting from the null space projection is task consistent, i.e., it is guaranteed not to affect on the behavior of the operational point. Since the vector $\mathbf{N}^\top \boldsymbol{\tau}_{\text{posture}}$ may not lie entirely within the null space of \mathbf{J} , however, the execution of the posture behavior cannot be guaranteed.

The operational space task ($\mathbf{J}^\top \mathbf{F}_{\text{task}}$) and the posture behavior ($\mathbf{N}^\top \boldsymbol{\tau}_{\text{posture}}$) are combined to obtain the general expression for the torque-level decomposition of the overall motion behavior:

$$\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{F}_{\text{task}} + \mathbf{N}^\top \boldsymbol{\tau}_{\text{posture}} . \quad (26.8)$$

The null-space projection \mathbf{N} associated with the task Jacobian \mathbf{J} can be obtained by

$$\mathbf{N} = \mathbf{I} - \bar{\mathbf{J}}\mathbf{J}, \quad (26.9)$$

where \mathbf{I} is the identity matrix, and $\bar{\mathbf{J}}$ is the dynamically consistent generalized inverse of \mathbf{J} , given by

$$\bar{\mathbf{J}} = \mathbf{H}^{-1} \mathbf{J}^\top \mathbf{A}, \quad (26.10)$$

where \mathbf{H} is the joint space inertia matrix and \mathbf{A} is the operational space inertia matrix for the operational point for which \mathbf{J} is defined. The use of this specific inverse to compute the null-space projection results in the selection of the task-consistent torque vector that minimizes kinetic energy.

26.2.4 Combining Mobility and Manipulation

The operational space framework does not distinguish between degrees of freedom used for mobility and those

used for manipulation. The end-effector-centric perspective of this approach considers all degrees of freedom to be in service to position and move the end-effector. An explicit coordination of manipulation and mobility for task-level control is not necessary.

A computationally efficient approach for coordinating manipulation and mobility was introduced in [26.7]. A similar, schema-based coordination of manipulation and mobility in the presence of dynamic obstacles was demonstrated in [26.8]. This approach is based on (26.2) and projects the forces that are derived from various schemas into the configuration space of the robot to determine its motion. Another coordination approach for manipulation and mobility considers a given end-effector path and generates a path of the base that maintains manipulability criteria [26.9]. This underlying representation of mobile manipulators can also be used to generate obstacle avoidance behavior of the base for a given end-effector path [26.10].

The coordination of a nonholonomic mobility platform and a cart-pushing task is addressed in [26.11]. In [26.12], an analysis of the task space for a mobile base with two manipulators is presented. Such a system with two manipulator arms can be viewed as a branching kinematic chain. Section 26.6 discusses extensions to the operational space framework to such branching mechanisms.

26.2.5 Combining Multiple Task Behaviors

The concept of decomposing a redundant robot's overall motion into task and posture behavior can be generalized to an arbitrary number of behaviors [26.13, 14]. Assume a set of n tasks T_i , where T_i has higher priority than T_j if $i < j$. Every task T_i is associated with a force vector \mathbf{F}_i and the corresponding joint torque $\boldsymbol{\tau}_i$. These tasks can be performed simultaneously by projecting the joint torque associated with each task into the combined null space of all tasks with higher priority, just as task and posture behavior were combined in the previous section. The null-space projection ensures that the execution of task i does not affect the execution of tasks with higher priority, given by the set $\text{prec}(i)$.

Given a task i , the joint torque consistent with the set of higher priority tasks $\text{prec}(i)$ can be obtained by projecting $\boldsymbol{\tau}_i$ into the combined null space of $\text{prec}(i)$,

$$\boldsymbol{\tau}_{i|\text{prec}(i)} = \mathbf{N}_{\text{prec}(i)}^\top \boldsymbol{\tau}_i , \quad (26.11)$$

where the combined null space $\mathbf{N}_{\text{prec}(i)}^\top$ is computed as

$$\mathbf{N}_{\text{prec}(n)} = \mathbf{N}_{n-1} \mathbf{N}_{n-2} \cdots \mathbf{N}_1 . \quad (26.12)$$

We say that $\tau_{i|\text{prec}(i)}$ is the torque for task i given the preceding tasks $\text{prec}(i)$. Applying this torque to the robot will not affect the execution of higher-priority tasks. The original torque vector τ_i can be computed based on (26.2).

Given the ability to compute a task torque that is consistent with preceding tasks we are able to combine an arbitrary number of tasks into a single motion behavior:

$$\tau = \tau_1 + \tau_{2|\text{prec}(2)} + \tau_{3|\text{prec}(3)} + \cdots + \tau_{n|\text{prec}(n)}, \quad (26.13)$$

where τ is the torque used to control the robot.

Note that τ_1 is not projected into any null space, since it is the task with the highest priority. Task 1 is therefore performed in the full space defined by the robot's kinematics. If the robot has N degrees of freedom, this space has N dimensions. As the number of tasks performed on the robot increases, the null-space projections $N_{\text{prec}(i)}$ will project the N -dimensional torque vectors associated with lower-priority tasks into a subspace of decreasing dimension. Eventually, the null space will be reduced to the trivial case, when all torque vectors are projected onto the null vector. This prevents lower-priority tasks from being executed. The dimensionality of the null space of tasks $\text{prec}(i)$ can be computed by counting the nonzero singular values [26.6] of $N_{\text{prec}(i)}$, permitting a programmatic assessment of task feasibility.

If the execution of a particular task has to be guaranteed, it should be associated with task 1 in (26.13). Therefore, the highest-priority task is generally used for hard constraints that under no circumstances should be violated. These constraints may include contact constraints, joint limits, and balancing in the case of humanoid robots, for example (Chap. 56).

The projection of (26.11) maps the torque τ_i of task i into the null space of all preceding tasks. This projection also scales the vector, which may significantly impair the execution of task i . This effect can be reduced by scaling the desired accelerations \ddot{x} at the operational point with the task-consistent inertia matrix $\Lambda_{i|\text{prec}(i)}$, given by

$$\Lambda_{i|\text{prec}(i)} = \left(\mathbf{J}_{i|\text{prec}(i)} \mathbf{H}^{-1} \mathbf{J}_{i|\text{prec}(i)}^\top \right)^{-1}, \quad (26.14)$$

where \mathbf{H} is the joint space inertia matrix and

$$\mathbf{J}_{i|\text{prec}(i)} = \mathbf{J}_i N_{\text{prec}(i)} \quad (26.15)$$

is the task Jacobian consistent with all preceding tasks. This Jacobian projects operational space forces into joint torques that do not cause any acceleration at the operational points of tasks in $\text{prec}(i)$. The task-consistent

inertia matrix $\Lambda_{i|\text{prec}(i)}$ then captures the inertia perceived at the operational point when its motion is limited to the subspace consistent with all preceding tasks.

Using the task-consistent inertia matrix, we can obtain the task-consistent operational space dynamics by projecting the joint space dynamics into the space defined by the dynamically consistent inverse of $\mathbf{J}_{i|\text{prec}(i)}$. Inverting (26.2) and replacing τ based on (6.1) we obtain

$$\mathbf{J}_{i|\text{prec}(i)}^\top (\mathbf{H}(\mathbf{q}) + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\tau}_g(\mathbf{q}) = \boldsymbol{\tau}_{k|\text{prec}(i)}) , \quad (26.16)$$

which yields the task-consistent equivalent to (26.3):

$$\mathbf{F}_{i|\text{prec}(i)} = \Lambda_{i|\text{prec}(i)} \ddot{\mathbf{x}} + \boldsymbol{\Gamma}_{i|\text{prec}(i)} \dot{\mathbf{x}} + \boldsymbol{\eta}_{i|\text{prec}(i)}, \quad (26.17)$$

where $\Lambda_{i|\text{prec}(i)}$ is the task-consistent operational space inertial matrix, $\boldsymbol{\Gamma}_{i|\text{prec}(i)}$ captures centrifugal and Coriolis forces in operational space, and $\boldsymbol{\eta}_{i|\text{prec}(i)}$ compensates for gravity forces. Equation (26.17) can be used to control a task at a particular operational point in a task-consistent manner, i. e., without causing acceleration at the operational points associated with the tasks in $\text{prec}(i)$. Note that in practice the terms $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ and $\boldsymbol{\tau}_g(\mathbf{q})$ can be computed in the joint space; they only need to be accounted for once in the case of multiple tasks.

Referring back to Fig. 26.3, we can analyze the effectiveness of the operational space framework. The control of operational points directly addresses force and position constraints on motion in manipulation tasks. Additional behaviors with lower priority than the task can be used to ensure the maintenance of kinematic and dynamic constraints, implement posture behavior, or perform reactive obstacle avoidance based on artificial potential fields [26.15]. The control of all of these aspects of manipulation tasks is computationally efficient. As a consequence, the operational space framework is able to maintain these motion constraints while satisfying feedback frequency requirements. However, the operational space framework does not include the consideration of global motion constraints, such as those imposed by the connectivity of the work space. Therefore, the operational space framework is susceptible to local minima, similarly to the artificial potential field method. Such local minima can occur for all of the aforementioned motion constraints and would prevent the robot from accomplishing its task. To overcome this problem, planning methods have to be applied (see Chap. 5 and Sect. 26.3).

The control basis approach [26.16] provides an alternative, compact formalism for combining multiple

behaviors. Each individual behavior is described by a controller, represented by a potential function $\phi \in \Phi$, sensors $\sigma \in \Sigma$, and effectors $\tau \in \Upsilon$. A particular controller ϕ can be parameterized with sensors and effectors. A particular instance of a behavior can be written as $\phi|_{\tau}^{\sigma}$. These controllers can be combined using null-space projections, similar to (26.13). In the control basis framework, (26.13) would be written more compactly as

$$\phi_n \triangleleft \dots \triangleleft \phi_3 \triangleleft \phi_2 \triangleleft \phi_1, \quad (26.18)$$

where we abbreviate $\phi_i|_{\tau_i}^{\sigma_i}$ with ϕ_i . The relation $\phi_i \triangleleft \phi_j$ means that ϕ_i is projected into the null space of ϕ_j . We say that ϕ_i is executed *subject to* ϕ_j . If more than

two behaviors are combined, as shown in (26.18), each controller ϕ_i is projected into the combined null space of all superior tasks.

The control basis represents a general framework for combining controllers and is not limited to the notion of task-level control. In addition to the aforementioned formalism for representing combinations of controllers, the control basis also encompasses discrete structures that define transitions between combinations of controllers. Such transitions can be specified by the user or learned with techniques from reinforcement learning [26.16]. The control basis can compose multiple task-level controllers to implement manipulation tasks that cannot be described in terms of a single task-level controller.

26.3 Manipulation Planning

In order to appreciate the computational challenges inherent to gross motion planning for manipulation, it is useful to adopt a mathematical formalism for analysis. The chapter on planning (Chap. 5) introduced the *configuration space* (*C-space*), which represents the space of allowable transformations of the robot. In general, the set of all allowable transformations forms an *n*-dimensional *manifold*, in which *n* is the total number of degrees of freedom (DOF) of the mechanical system. For a robotic manipulator, the configuration space is defined by its kinematic structure (see Chap. 1). One common class of manipulators is *serial-chain* manipulators, which consist of a series of revolute or prismatic joints connected to form a linear kinematic chain. The discussion of manipulation planning in this section focuses on configuration spaces arising from single serial-chain manipulators. However, the mathematical formulation generalizes to more complex robots such as humanoids (Fig. 26.4; Chap. 56), whose upper

body consists of two cooperating manipulator arms attached to a movable base (see Chap. 29). The model considered here greatly simplifies the problems of grasping, stability, friction, mechanics, and uncertainties and instead focuses on the geometric aspects. In this section, we will consider a simple example of a manipulation task that involves a classic pick-and-place operation. Section 26.4 further considers grasping and contact states in the context of assembly operations, and Sect. 26.5 gives an overview of techniques to unify feedback control and planning for more complex manipulation tasks.

26.3.1 Configuration Space Formalism

The basic motion planning problem is defined as finding a path in the configuration space connecting a start and a goal configuration while avoiding static obstacles in the environment (see Chap. 5). Manipulation planning involves additional complexity because manipulation tasks fundamentally require contact with objects in the environment. When objects are grasped, regrasped, and moved, the structure and topology of the free configuration space can change drastically. However, manipulation planning shares the same basic theoretical foundations and computational complexity as classical path planning, such as PSPACE-hardness (see Chap. 5).

To be more precise, we will utilize a formalization for manipulation planning that is primarily due to Alami et al. [26.17], and adapted in LaValle's book [26.18]. Our goal is to gain understanding and intuition regarding

Fig. 26.4 Simulation of the H6 humanoid robot manipulating an object

the search space for manipulation tasks and the different situations that can arise. Throughout this discussion, bear in mind that the geometry and relative positions of the manipulator, the manipulated objects, and the obstacles in the workspace determine both the geometry and topological structure of the free configuration space. Within this framework, manipulation planning can be intuitively placed in the context of planning for *hybrid systems* [26.19]. Hybrid systems involve a mixture of continuous variables and discrete *modes*, whose transitions are defined by switching functions (for a discussion of hybrid systems in a planning context, see Chap. 7 of *LaValle's book* [26.18]). In the case of manipulation planning, the effect of grasping, repositioning, and releasing objects in the environment corresponds to switching between different continuous configuration spaces.

Let us consider a simple example of a simple *pick-and-place manipulation task* that requires a robot manipulator \mathcal{A} to reposition a single movable rigid object (part) \mathcal{P} from its current location in the workspace to some desired goal location. Note that accomplishing the task only requires that the part \mathcal{P} reach the goal location, without regard to precisely *how* the manipulator does so. Because the part cannot move by itself, it must either be transported by the robot or be placed at rest in some stable intermediate configuration. There are some configurations in which the robot is able to grasp and move the part to other locations in the environment. There are also forbidden configurations in which the robot or the part collides with obstacles in the environment. The solution of a manipulation planning problem consists of a sequence of subpaths for the robot moving alone or moving while grasping the part. The primary constraints on the allowable motions are:

1. The robot manipulator must not collide with any obstacles in the environment while reaching for, grasping, or regrasping the part.
2. The robot must adequately grasp the part while transporting it (for details on grasping and metrics for stable grasps see Chap. 28).
3. The robot manipulator and movable part must not collide with any obstacles in the environment while the part is being transported.
4. If the part is not being transported by the robot, it must be placed at rest in some stable intermediate placement.
5. The part must end up at the desired goal location in the workspace.

The two modes of operation give rise to the hybrid systems formulation: either the robot moves alone, or the robot moves while grasping the part. In the literature, motions of the robot holding the object at a fixed grasp are called *transfer paths*, and motions of the robot while the part stays at a stable placement are called *transit paths* [26.17, 20, 21]. Solving a manipulation planning problem involves searching for a connected sequence of *transit* and *transfer* paths for the manipulator that will accomplish the task. For an autonomous robot, the ideal is to utilize planning algorithms that will automatically produce correct sequences of transfer and transit paths separated by grasping and ungrasping operations.

Admissible Configurations

Building on the notation introduced in Chap. 5, we define a robot manipulator \mathcal{A} with n degrees of freedom operating in a Euclidean *world* or *workspace*, $\mathcal{W} = \mathbb{R}^N$, in which $N = 2$ or $N = 3$. Let $\mathcal{C}^{\mathcal{A}}$ represent the n -dimensional \mathcal{C} -space of \mathcal{A} , and $q^{\mathcal{A}}$ be a configuration. $\mathcal{C}^{\mathcal{A}}$ is called the *manipulator configuration space*. Let \mathcal{P} denote a movable part, which is a solid rigid body modeled with geometric primitives. We will assume that \mathcal{P} is allowed to undergo rigid-body transformations. This gives rise to a *part configuration space*, $\mathcal{C}^{\mathcal{P}} = SE(2)$ or $\mathcal{C}^{\mathcal{P}} = SE(3)$. Let $q^{\mathcal{P}} \in \mathcal{C}^{\mathcal{P}}$ denote a part configuration. The area or volume in the workspace occupied by the transformed part model is denoted by $\mathcal{P}(q^{\mathcal{P}})$.

We define the combined (robot and part) configuration space \mathcal{C} as the Cartesian product

$$\mathcal{C} = \mathcal{C}^{\mathcal{A}} \times \mathcal{C}^{\mathcal{P}},$$

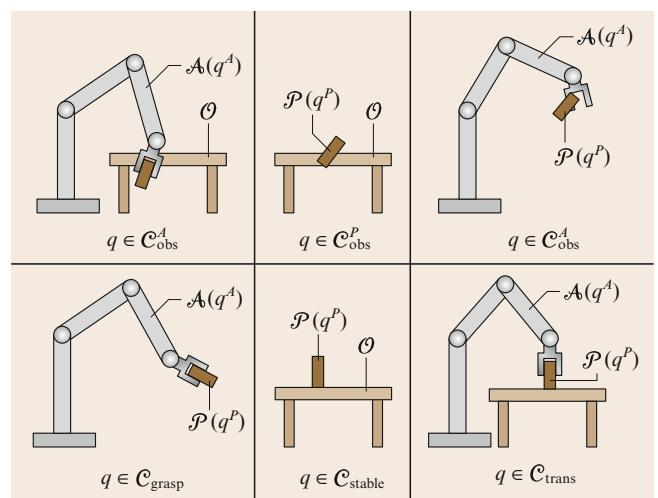

Fig. 26.5 Examples of the various configuration space subsets defined for manipulation planning

in which each configuration $q \in \mathcal{C}$ is of the form $q = (q^A, q^P)$. Note that the set of admissible configurations for manipulation planning purposes is more restrictive than simply $\mathcal{C}_{\text{free}}$, the space free of collisions with obstacle regions as defined in Chap. 5. We must incorporate the constraints on the allowable motions by removing inadmissible configurations. Figure 26.5 illustrates examples of some of the important subsets of \mathcal{C} for manipulation planning.

We start by removing all configurations that involve collisions with obstacles. Let the subset of configurations in which the manipulator collides with obstacles be given by

$$\mathcal{C}_{\text{obs}}^A = \{(q^A, q^P) \in \mathcal{C} \mid \mathcal{A}(q^A) \cap \mathcal{O} \neq \emptyset\}.$$

We also want to remove configurations for which the part collides with obstacles. However, we will allow the surface of the part to make contact with obstacle surfaces. This happens for example, when the part is resting on a shelf or table, or when a peg-shaped part is being inserted into a hole. Therefore, let

$$\mathcal{C}_{\text{obs}}^P = \{(q^A, q^P) \in \mathcal{C} \mid \text{int}(\mathcal{P}(q^P)) \cap \mathcal{O} \neq \emptyset\}$$

denote the open set for which \mathcal{O} intersects the interior volume $\text{int}(\mathcal{P}(q^P))$ of the part for any configuration q^P . If the interior of the part penetrates \mathcal{O} , then clearly these configurations should be avoided.

We can now define $\mathcal{C} \setminus (\mathcal{C}_{\text{obs}}^A \cup \mathcal{C}_{\text{obs}}^P)$, which is the set of all configurations in which both the robot and the part do not inappropriately collide with \mathcal{O} . Next consider the interaction between \mathcal{A} and \mathcal{P} . The manipulator must be allowed to make contact with the surface of the part, but penetration is once again not allowed. Therefore, let all configurations in which the interior of the part overlaps with the robot geometry be defined as

$$\mathcal{C}_{\text{obs}}^{PA} = \{(q^A, q^P) \in \mathcal{C} \mid \mathcal{A}(q^A) \cap \text{int}(\mathcal{P}(q^P)) \neq \emptyset\}.$$

Finally, we are able to define

$$\mathcal{C}_{\text{adm}} = \mathcal{C} \setminus (\mathcal{C}_{\text{obs}}^A \cup \mathcal{C}_{\text{obs}}^P \cup \mathcal{C}_{\text{obs}}^{PA}),$$

which represents the set of configurations remaining after subtracting away all unwanted configurations. We call this the set of *admissible configurations*.

Stable and Grasped Configurations

By definition, all configurations in the set \mathcal{C}_{adm} are free of penetrative collisions between the robot, the part, and obstacles in the environment. However, many of these configurations define the part as floating in space or on

the verge of falling. We now consider two important subsets of \mathcal{C}_{adm} that are used in manipulation planning (see Fig. 26.5). Let $\mathcal{C}_{\text{stable}}^P \subseteq \mathcal{C}^P$ denote the subset of *stable part configurations*, which are configurations at which the part can safely rest without any forces being applied by the manipulator. Examples of stable configurations include the part resting on a table or inserted into a larger assembly of other parts. The criteria for inclusion into the set of stable configurations depends on properties such as the part geometry, friction, mass distribution, and contacts with the environment. Our formalism does not consider these issues directly, but assumes that some method for evaluating the stability of a part configuration is available. Given $\mathcal{C}_{\text{stable}}^P$, we define $\mathcal{C}_{\text{stable}} \subseteq \mathcal{C}_{\text{adm}}$ to be the corresponding stable configurations of the part–robot system:

$$\mathcal{C}_{\text{stable}} = \{(q^A, q^P) \in \mathcal{C}_{\text{adm}} \mid q^P \in \mathcal{C}_{\text{stable}}^P\}.$$

The other important subset of \mathcal{C}_{adm} is the set of all configurations in which the robot is grasping the part and is capable of manipulating it according to some defined criteria. Let $\mathcal{C}_{\text{grasp}} \subseteq \mathcal{C}_{\text{adm}}$ denote the set of *grasp configurations*. For every configuration, $(q^A, q^P) \in \mathcal{C}_{\text{grasp}}$, the manipulator touches the part, which implies that $\mathcal{A}(q^A) \cap \mathcal{P}(q^P) \neq \emptyset$. Just as before, penetration between the robot and part geometry is not allowed because $\mathcal{C}_{\text{grasp}} \subseteq \mathcal{C}_{\text{adm}}$. In general, many configurations at which $\mathcal{A}(q^A)$ contacts $\mathcal{P}(q^P)$ will not necessarily be in $\mathcal{C}_{\text{grasp}}$. The criteria for a configuration to lie in $\mathcal{C}_{\text{grasp}}$ depends on the particular characteristics of the manipulator, the part, and the contact surfaces between them. For example, a typical manipulator would not be able to pick up a part by making contact at only a single point. (For additional information, see Sect. 26.4 for contact state identification, Chap. 27, and grasping criteria, such as *force closure* models in Chaps. 28 and 15).

For any robot and part configuration $q = (q^A, q^P) \in \mathcal{C}$ that we consider for manipulation planning we must always ensure that either $q \in \mathcal{C}_{\text{stable}}$ or $q \in \mathcal{C}_{\text{grasp}}$. We therefore define $\mathcal{C}_{\text{free}} = \mathcal{C}_{\text{stable}} \cup \mathcal{C}_{\text{grasp}}$, to reflect the subset of \mathcal{C}_{adm} that is permissible for manipulation planning. In the context of hybrid systems, this gives rise to the two distinct *modes* for manipulation planning: the *transit mode* and the *transfer mode*. Recall that in the transit mode, the manipulator is not carrying the part (i.e., only the robot moves), which requires that $q \in \mathcal{C}_{\text{stable}}$. In the transfer mode, the manipulator carries the part (i.e., both the robot and the part move), which requires that $q \in \mathcal{C}_{\text{grasp}}$. Based on these conditions, the only way the mode can change is if $q \in \mathcal{C}_{\text{stable}} \cap \mathcal{C}_{\text{grasp}}$. When the manipulator is in these

configurations, it has two available actions: (1) continue to grasp and move the part, or (2) release the part in its currently stable configuration. In all other configurations the mode remains unchanged. For convenience, we define $\mathcal{C}_{\text{trans}} = \mathcal{C}_{\text{stable}} \cap \mathcal{C}_{\text{grasp}}$ to denote the set of *transition configurations*, which are the places in which the mode may change and the robot may grasp or release the part.

Manipulation Planning Task Definition

Finally, the basic pick-and-place manipulation planning task can now be defined. An *initial part configuration*, $q_{\text{init}}^P \in \mathcal{C}_{\text{stable}}^P$, and a *goal part configuration*, $q_{\text{goal}}^P \in \mathcal{C}_{\text{stable}}^P$ are specified. Recall that this high-level task specification is only defined in terms of repositioning the part, without regard to how the manipulator actually accomplishes the task. Let $\mathcal{C}_{\text{init}} \subseteq \mathcal{C}_{\text{free}}$ be the set of all configurations in which the part configuration is q_{init}^P :

$$\mathcal{C}_{\text{init}} = \{(q^A, q^P) \in \mathcal{C}_{\text{free}} \mid q^P = q_{\text{init}}^P\}.$$

We define $\mathcal{C}_{\text{goal}} \subseteq \mathcal{C}_{\text{free}}$ similarly as the set of all configurations in which the part configuration is q_{goal}^P :

$$\mathcal{C}_{\text{goal}} = \{(q^A, q^P) \in \mathcal{C}_{\text{free}} \mid q^P = q_{\text{goal}}^P\}.$$

If the initial and final configurations of the manipulator are specified, then let $q_{\text{init}} = (q_{\text{init}}^A, q_{\text{init}}^P) \in \mathcal{C}_{\text{init}}$ and $q_{\text{goal}} = (q_{\text{goal}}^A, q_{\text{goal}}^P) \in \mathcal{C}_{\text{goal}}$. The objective of the planner is to compute a path τ such that

$$\tau : [0, 1] \mapsto \mathcal{C}_{\text{free}},$$

$$\tau(0) = q_{\text{init}}; \tau(1) = q_{\text{goal}}.$$

If the initial and final positions of the manipulator are unspecified, we implicitly define the objective of the

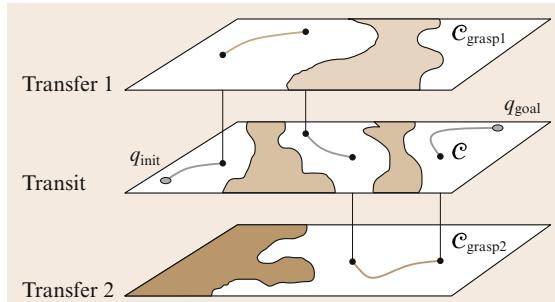

Fig. 26.6 Manipulation planning involves searching for a sequence of transfer and transit paths in a set of hybrid continuous configuration spaces. In this example, transfer paths in different \mathcal{C} -spaces arise from different ways of rigidly grasping a part

planner as computing a path $\tau : [0, 1] \mapsto \mathcal{C}_{\text{free}}$ such that $\tau(0) \in \mathcal{C}_{\text{init}}$ and $\tau(1) \in \mathcal{C}_{\text{goal}}$. In either case, a solution is an alternating sequence of transit paths and transfer paths, whose names follow from the mode. In between each transfer path, the part is placed in a stable intermediate configuration while the manipulator moves alone (transit path) in order to regrasp the part. This sequence continues until the part is ultimately placed to rest in its final goal configuration. This is depicted in Fig. 26.6.

26.3.2 Example of a Three-DOF Planar Manipulator

For manipulators with three or fewer degrees of freedom (DOF), we can construct visualizations of the \mathcal{C} -space in order to gain an intuition of the structure. Throughout this section, we will use the example of a three-DOF serial-chain manipulator whose end-effector operates a planar workspace (\mathbb{R}^2).

Figure 26.7 shows a simple redundant robot arm originally illustrated in [26.22]. The robot has three revolute joints with parallel axes and joint limits of $-\pi, \pi$ radians, providing three degrees of freedom. Since the end-effector of the robot can only reach positions in a plane, the arm is redundant in this plane and since it has only three DOF and limits imposed on the joint angles, \mathcal{C} can be visualized as a cube with an edge length of 2π . Generally, the \mathcal{C} -space manifold of a manipulator with n revolute joints is homeomorphic to an n -dimensional hypertorus if no joint limits are present, and homeomorphic to an n -dimensional hypercube if joint limits are present.

Recall that obstacles in the workspace are mapped to regions in the \mathcal{C} -space called \mathcal{C} -obstacles (Chap. 5), which represent the set of all joint configurations of the robot that cause an intersection of the geometry of the robot and the obstacle

$$\mathcal{C}_{\text{obs}}^A = \{(q^A, q^P) \in \mathcal{C} \mid A(q^A) \cap \mathcal{O} \neq \emptyset\}.$$

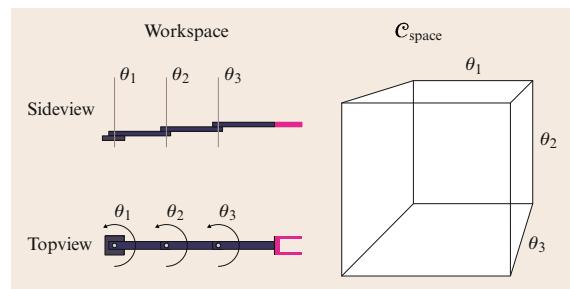

Fig. 26.7 Planar 3 DOF manipulator

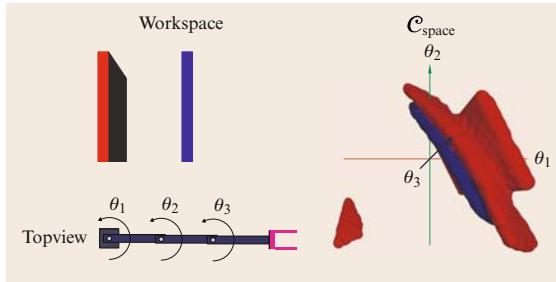

Fig. 26.8 Planar 3 DOF manipulator in a workspace with box-shaped obstacles and associated configuration space obstacles

In general, the structure of $\mathcal{C}_{\text{obs}}^A$ can be highly complex and involve multiple connected components of \mathcal{C} . An example visualization of a configuration space for the planar three-DOF manipulator corresponding to a workspace with two differently colored box-shaped obstacles is given in Fig. 26.8. The \mathcal{C} -obstacles are illustrated using the same color as the corresponding box-shaped obstacle in the workspace. The red, green, and blue coordinate axes correspond to the three joint angles $\theta_{\{1,2,3\}}$ of the manipulator, respectively.

Self-collisions induce special \mathcal{C} -obstacle regions that do not involve environment geometry, but only the geometric interference of the links of the robot itself. The robot shown in Fig. 26.7 is, by design, self-collision-free. Figure 26.9 shows a modified version of the manipulator, where self-collision is actually possible, and a visualization of the corresponding \mathcal{C} -obstacles.

\mathcal{C} -obstacles can cover large parts of the configuration space and even cause a complete disconnection between different components of $\mathcal{C}_{\text{free}}$. Figure 26.10 shows how the addition of only a small post as an obstacle can cause a wide range of configurations to produce collisions and disconnect regions of $\mathcal{C}_{\text{free}}$: the \mathcal{C} -obstacle corresponding to the post forms a *wall* of

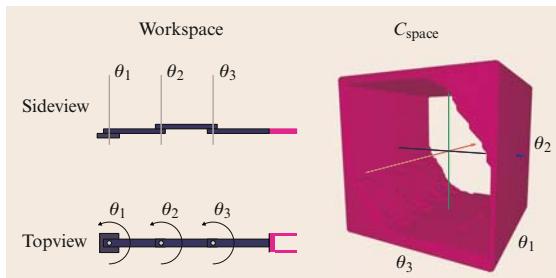

Fig. 26.9 Non-planar 3 DOF manipulator and corresponding self-collision \mathcal{C} -obstacle

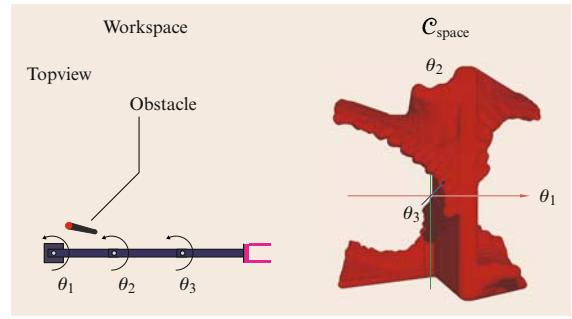

Fig. 26.10 Workspace mapping to a configuration space with topologically disconnected components

configurations parallel to the θ_2 – θ_3 -plane. This wall represents the range of values for θ_1 for which the first link of the manipulator intersects with the post, splitting $\mathcal{C}_{\text{free}}$ into two disconnected components. Having disconnected components $\mathcal{C}_1, \mathcal{C}_2 \in \mathcal{C}_{\text{free}}$ means that there is no collision-free path that starts in \mathcal{C}_1 and ends in \mathcal{C}_2 .

26.3.3 Inverse Kinematics Considerations

The typical formulation of a path planning problem requires a goal configuration q_{goal} as input (see Chap. 5). For the case of manipulation planning, this configuration is usually computed from the desired workspace pose of the end-effector by an inverse kinematics (IK) solver (see Sect. 1.7). Apart from special cases, there currently exist no known analytical methods for solving the inverse kinematics of a general redundant mechanism (greater than six degrees of freedom). Iterative, numerical techniques (such as Jacobian-based methods or gradient-based optimization) are typically used to calculate solutions in this case. Note that the numerical computation of inverse kinematics solutions can suffer from poor performance or even nonconvergence, depending on the quality of the initial guess, the distribution of singularities in the \mathcal{C} -space or a combination of these effects (see Sect. 1.7).

Most IK solvers are only able to compute one configuration for a given end-effector pose. For a redundant manipulator, however, an infinite, continuous range of configurations that cause the end-effector to assume the desired pose usually exists. In the context of path planning, this means that the IK solver will select one out of an infinite number of configurations as q_{goal} . Note that in some cases, the selected q_{goal} might not be collision-free, i.e., it is not part of $\mathcal{C}_{\text{free}}$. Such a configuration cannot be used as a goal for computing a global reaching strategy

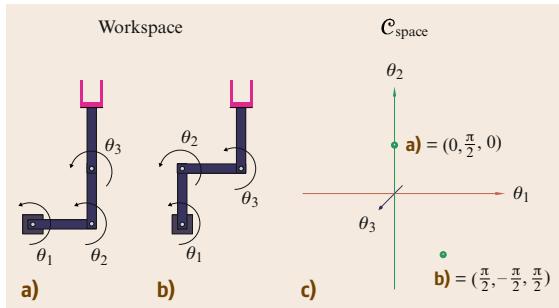

Fig. 26.11 Two inverse kinematics solutions for the same end-effector pose of a planar 3 DOF arm

because no solution exists for the corresponding path planning query in the classical sense (Chap. 5).

Another possibility is that the selected q_{goal} might be disconnected from q_{init} . In this case, q_{goal} is unsuitable for planning despite the fact that it is a member of $\mathcal{C}_{\text{free}}$, because it is in a component of $\mathcal{C}_{\text{free}}$ that is disconnected from the component in which q_{init} lies. Consider the planar manipulator shown in Fig. 26.7. Figure 26.11 shows two possible solutions for a certain end-effector pose. The corresponding configurations $q_a = (0, \frac{\pi}{2}, 0)$ and $q_b = (\frac{\pi}{2}, -\frac{\pi}{2}, \frac{\pi}{2})$ are marked by green spheres in the \mathcal{C} -space visualization. In this case, the IK solver might select one of the two solutions as q_{goal} . If the same obstacle as in Fig. 26.10 is added to the workspace, the two solutions will lie in disconnected components of $\mathcal{C}_{\text{free}}$, as shown in Fig. 26.12.

Let $q_{\text{init}} = (0, 0, 0)$ be the zero configuration, marked by the point of intersection of the \mathcal{C} -space axes in Fig. 26.12. Let the component of $\mathcal{C}_{\text{free}}$ in which it lies be denoted by \mathcal{C}_1 and the other component by \mathcal{C}_2 . Since $q_b \in \mathcal{C}_2$ and $\mathcal{C}_1 \cap \mathcal{C}_2 = \emptyset$, no solution for the planning problem can exist if the IK solver selects q_b as q_{goal} .

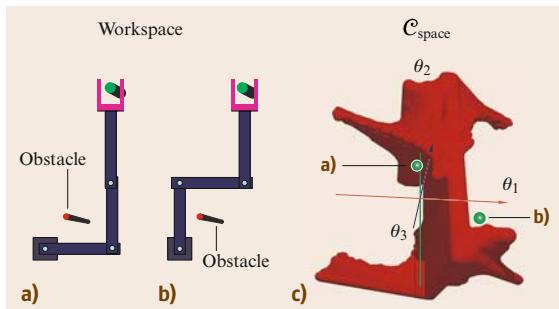

Fig. 26.12 Two inverse kinematics solutions lying in disconnected components of $\mathcal{C}_{\text{free}}$ due to a small obstacle in the workspace

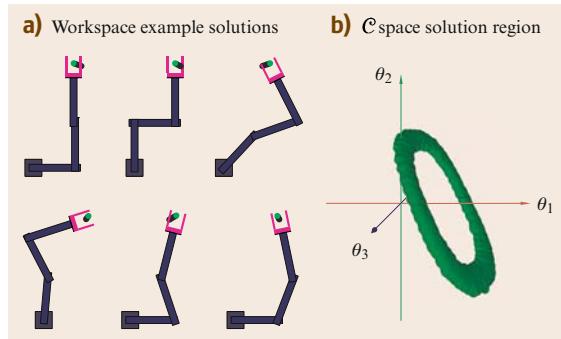

Fig. 26.13 (a) Multiple arm configurations that allow the manipulator to grasp the cylinder and **(b)** \mathcal{C} -space visualization of the set of solution configurations

This means that every planning attempt with this q_{goal} will invariably fail.

Since computing a complete representation of the connectivity of \mathcal{C} is a problem of similar complexity to path planning itself, it is virtually impossible to detect a disconnection between q_{goal} and q_{init} before the planning attempt has failed.

Recall that the workspace goal for a classical manipulation planning problem is defined by a desired end-effector pose computed using inverse kinematics. Note however, that the purpose of a manipulation task may not require moving the end-effector to that particular location, but rather moving it to *any* feasible location which enables the desired manipulation task to be solved. Thus, it becomes important to devise computational methods and control schemes that are focused around the task, and allow some flexibility and freedom with regards to the end-effector pose and manipulator configuration. This is one of the motivations and advantages of

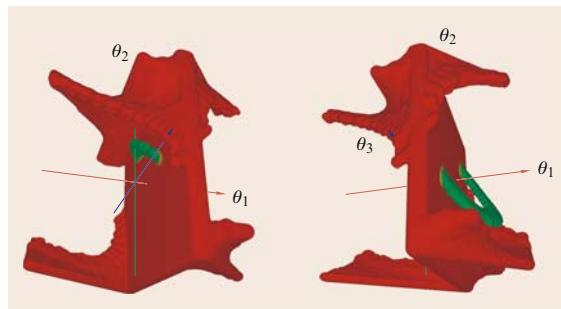

Fig. 26.14 Two views of the set of goal configurations (green) for grasping a cylindrical part in a disconnected \mathcal{C} -space

task space or operational space control techniques (Sect. 6.2).

As an example, consider the task of grasping a cylindrical part with the planar three-DOF manipulator. Figure 26.11 shows two possible solution configurations yielding the same end-effector pose. The addition of obstacles to this workspace may cause one of the configurations to become disconnected from the zero configuration. These two configurations, however, may not be the only valid configurations that allow the manipulator to grasp the cylindrical part. Figure 26.13a shows several other configurations that allow the manipulator to grasp the part. By interpolating between these, an infinite number of different workspace poses that provide solutions to the grasping problem is generated. The inverse kinematics solutions associated with these workspace poses are contained in the continuous subset $\mathcal{C}_{\text{goal}} \subseteq \mathcal{C}$, as shown in Fig. 26.13b, which represents the actual so-

lution space to the planning problem for this reaching task.

Adding the obstacle from Fig. 26.10 to the workspace of this manipulation task produces the configuration space depicted in Fig. 26.14. Note that the \mathcal{C} -obstacle corresponding to collisions between the manipulator and the cylinder itself has been disregarded in this visualization for clarity. Approximately half of the possible solutions are disconnected from the zero configuration and a quarter are in collision, which leaves only one quarter as reachable and therefore suitable candidates for q_{goal} in a classical planning query.

In this section, we have covered the basics of manipulation planning, developed a mathematical formulation for the kinds of search spaces that arise, and discussed some of the important geometric and topological considerations. Section 26.6 gives an overview of additional topics and extensions with pointers to further reading.

26.4 Assembly Motion

Assembly or an *assembly task* defines the process of putting together manufactured parts to make a complete product, such as a machine. It is a major operation in the manufacturing process of any product. Assembly automation with robots aims to reduce cost and increase

the quality and efficiency of the operation. In environments hazardous to humans, such as in space, having robots perform assembly tasks could save human lives. Assembly has long been not only an important but also one of the most challenging applications for robotics. There are many significant research issues related to the broad scope of assembly automation, from design for assembly to tolerance analysis, assembly sequence planning, fixture design, etc. This section is only focused on the issue of robotic motion for assembly.

The concerned *assembly motion* is that of a robot manipulator holding a part and moving it to reach a certain *assembled state*, i.e., a required spatial arrangement or contact against another part. The main difficulty of assembly motion is due to the requirement for high precision or low tolerance between the parts in an assembled state. As a result, the assembly motion has to overcome uncertainty to be successful. *Compliant motion* is defined as motion constrained by the contact between the held part and another part in the environment. As it reduces uncertainty through reducing the degrees of freedom of the held part, compliant motion is desirable in assembly.

Consider the peg-in-hole insertion example introduced earlier (see Fig. 26.2). If the clearance between the peg and the hole is very small, the effect of uncertainty will most likely cause a downward insertion

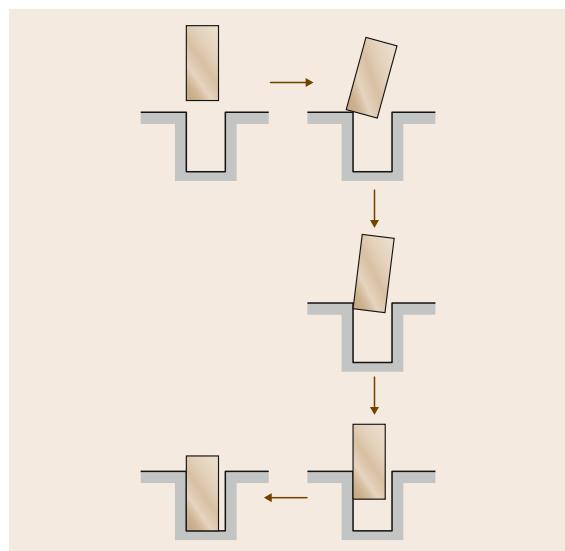

Fig. 26.15 A sequence of contact transitions for the peg-in-hole insertion task

motion of the peg to fail, i. e., the peg ends up colliding with the entrance of the hole in some way without reaching the desired assembled state. Therefore, a successful assembly motion has to move the peg out of such an unintended contact situation and lead it to reach the desired assembled state eventually. To make this transition, compliant motion is preferred. Often a sequence of contact transitions via compliant motion is necessary before the desired assembled state can be reached. Figure 26.15 shows a typical sequence of contact transitions for the peg-in-hole task.

Assembly motion strategies that incorporate compliant motion can be broadly classified into two groups: *passive compliance* and *active compliant motion*, and both groups of strategies require certain information characterizing *topological contact states* between parts.

26.4.1 Topological Contact States

When a part A contacts a part B, the configuration of A (or B) is a *contact configuration*. Often a set of contact configurations share the same high-level contact characteristics. For example, “a cup is on the table” is a high-level description shared by all the contact configurations of the cup when its bottom are on the table. Such a description is often what really matters in assembly motion as it characterizes a spatial arrangement that could be either an assembled state or just a *contact state* between a part and another part.

For contacting polyhedral objects, it is common to describe a *contact state* topologically as a set of *primitive contacts*, each of which is defined by a pair of contacting surface elements in terms of faces, edges, and vertices.

Different contact state representations essentially differ only in how primitive contacts are defined. One common representation [26.23] defines primitive contacts as point contacts in terms of vertex–edge contacts for two-dimensional (2-D) polygons, and vertex–face and edge–edge contacts for three-dimensional (3-D) polyhedra. Another representation [26.24] defines a primitive contact as between a pair of *topological surface elements* (i. e., faces, edges, and vertices). Here a contact primitive can characterize a contact region that is either a point, a line segment, or a planar face, unlike the point-contact notion. From the viewpoint of contact identification via sensing, however, both representations can result in states that are different by definition but indistinguishable in identification due to uncertainties. Figure 26.16 shows such an example.

The notion of a *principal contact* [26.25, 26] presents a high-level primitive contact that is more robust to recognition. A *principal contact (PC)* denotes a contact between a pair of topological surface elements that are not boundary elements of other contacting topological surface elements. The boundary elements of a face are the edges and vertices bounding it, and the boundary elements of an edge are the vertices bounding it. Different PCs between two objects correspond to different degrees of freedom of the objects, which often also correspond to significant differences in the contact forces and moments. As shown in Fig. 26.16, the indistinguishable states in terms of the other contact primitives are grouped as a single contact state in terms of PCs. Thus, there are also fewer contact states in terms of PCs, leading to a more concise characterization of contact states. In fact, every contact state between two convex polyhedral objects is described by a single PC.

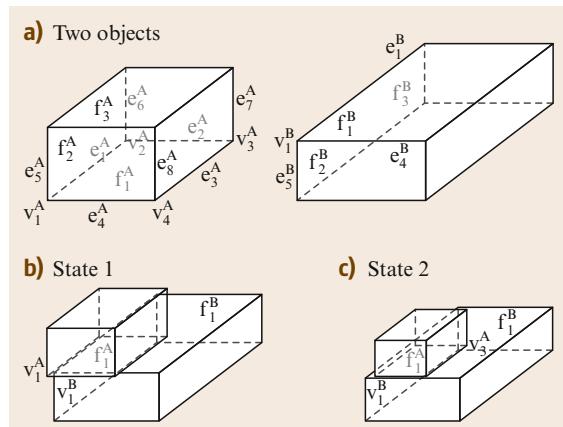

Fig. 26.16 Indistinguishable contact states due to positional uncertainty of the top part

26.4.2 Passive Compliance

Passive compliance refers to strategies that incorporate compliant motion for error correction during the assembly motion without requiring active and explicit recognition and reasoning of contact states between parts.

Remote Center Compliance

In the 1970s, a *remote center compliance (RCC)* device was developed to assist high-precision peg-in-hole insertion [26.27–29]. The RCC is a mechanical spring structure used as a tool attached to the end-effector of a robot manipulator to hold a round peg when it is inserted into a round hole. The RCC is designed to have high stiffness along the direction of insertion but high lat-

eral and angular compliances K_x and K_θ , and it projects the center of compliance near the tip of the peg (hence the name remote center compliance) to overcome small lateral and angular errors in the peg's position and orientation in response to the contact forces applied to the peg by the hole during insertion (Fig. 26.17). The large lateral and angular compliance of the RCC also helps to avoid *wedging* and *jamming*, conditions that cause the peg to stick in two-point contacts due to contact forces in direct opposition (wedging) or ill-proportioned contact forces/momenta (jamming). Because the RCC is low cost and reliable for fast insertions, it has long seen successful industrial applications.

However, the RCC has limitations. It only applies to round peg-in-hole insertions, and a particular RCC works better for a peg and hole of a particular size. Attempts have been made to expand the applicability of the RCC. Some attempts try to make certain parameters of an RCC adjustable to achieve variable compliance or projection (i.e., the position of the remote center) [26.30–32]. A spatial RCC (SRCC) [26.33] was proposed to achieve square-peg-in-hole insertions. A notable difference with this extension is the combinatorial explosion of the number of possible contact states, given the range of the position and orientation uncertainty of the held part that have to be considered in the design of the device. Unlike the case of the round peg and hole, which is essentially a 2-D problem with a handful of different contact states, there are hundreds of possible different contact states between a square peg and a square hole. From each of these possible contact states, a motion leading the held part to the goal assembled state has to be realized by the device. This makes it difficult to design an RCC device that works for parts

of more general and complex shapes with more possible contact states between them. This is a major limiting factor that prevent more extensions of the RCC to assembly of different parts.

Admittance Matrix

As an alternative method to the RCC, a particular form of manipulator force control, damping control, was proposed to achieve compliant motion of the held part by the manipulator and to correct small location errors of the held part during assembly. This approach eliminates the need to build a mechanical device like an RCC to achieve error correction. Among the force control laws [26.34], damping control is a common strategy, where a commanded velocity of the held part is modified based on the sensed force caused by contact between the held part and the environment. The resulted actual velocity leads to reduction and hopefully eventual correction of small position or orientation errors of the held part. Let v be a six-dimensional vector representing the actual translational and angular velocity of the held part, v_0 be the six-dimensional commanded velocity, and f be a six-dimensional vector representing the sensed force and moment. A linear damping control law is described as:

$$v = v_0 + Af,$$

where A is a 6×6 matrix, called an *admittance matrix* or accommodation matrix.

The effectiveness of such a damping control law depends on the existence and finding of a proper admittance matrix A . There is considerable research on the design of a single A that can make an assembly operation successful regardless of what contact states the held peg may encounter in the process [26.35–39]. This is aimed at cases where a single commanded velocity would be sufficient to achieve an assembly operation when there were no uncertainty or error, such as certain peg-in-hole insertion operations. One main approach to design A is based on explicit kinematic and static analysis of contact conditions under all possible contact states and mating requirements, which result in a set of linear inequalities as constraints on A . Learning is also used [26.38] to obtain an A that minimizes the force f without causing instability. Another approach [26.39] applies perturbations to the end-effector during insertion in order to obtain richer force information.

Learning Control for Assembly

Another category of approaches is to learn proper control for a particular assembly operation through stochastic or neural-network-based methods [26.40–44]. The essence

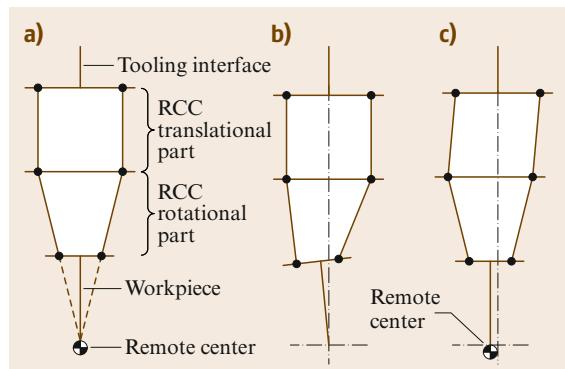

Fig. 26.17 (a) Planar representation of RCC. (b) Rotational part of RCC allowing workpiece to rotate. (c) Translational part of RCC allowing workpiece to translate

of most of these approaches is to learn to map a reaction force upon the held object caused by contact to the next commanded velocity in order to reduce errors and to achieve an assembly operation successfully. A more recent approach [26.44] maps fused sensory data of pose and vision obtained during human demonstration of assembly tasks to compliant motion signals for successful assembly.

A different approach observes assembly tasks performed by human operators through vision [26.45] or in a virtual environment [26.46, 47] and generates a motion strategy necessary for the success of the task that consists of a sequence of recognized contact state transitions and associated motion parameters.

As a sequence of commanded velocities can be generated, unlike RCC or strategies based on a single admittance matrix described above, can be applied to cases with large uncertainties. However, the learned controllers are task dependent.

All of the above assembly motion strategies do not require explicit recognition of contact states during their execution.

26.4.3 Active Compliant Motion

Active compliant motion is characterized by error correction based on online identification or recognition of contact states in addition to feedback of contact forces. The capability for active compliant motion allows a robot the flexibility to deal with a much broader range of assembly tasks with large uncertainties and tasks beyond assembly where compliance is required. An active compliant motion system generally requires the following components: a planner to plan compliant motion commands, an identifier to recognize contact states, state transitions, and other state information during task operation, and a controller to execute compliant motion plans based on both low-level feedback provided by sensors and high-level feedback provided by the identifier. Research on each component is described below.

Fine Motion Planning

Fine motion planning refers to planning fine-scale motions to make an assembly task successful in spite of significant uncertainties. A general approach was proposed [26.48] based on the concept of preimages in configuration space (\mathcal{C} -space) [26.23] to devise motion strategies that would not fail in the presence of uncertainties. Given a goal state of the held part defined by a region of goal configurations, a *preimage* of the goal state en-

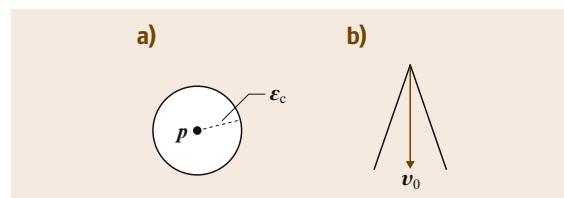

Fig. 26.18a,b Location and velocity uncertainties (in the \mathcal{C} -space). (a) The actual configuration of a part could be inside an uncertainty ball centered at an observed configuration. (b) The actual velocity of a part could be inside an uncertainty cone of a commanded velocity

codes those configurations from which a commanded velocity will guarantee that the held part reaches the goal state recognizably in spite of location and velocity uncertainties (Fig. 26.18).

Given the initial location of the held part and the goal state, the preimage approach generates a motion plan in backward chaining by finding the preimage of the goal state associated with a commanded velocity and then the preimage of the preimage, and so on, until a preimage that includes the initial configuration of the held part is found. Figure 26.19 shows an example.

The sequence of commanded velocities associated with the sequence of preimages (starting from the initial preimage that includes the initial location) forms the motion plan that guarantees the success of the task. Starting from the initial preimage, each subsequent preimage in the sequence can be viewed as a subgoal state. In this approach, compliant motions are preferred wherever possible because they typically produce larger preimages [26.48] than pure positioning motions, and subgoal states are often contact states. The approach was further extended [26.49] to include modeling uncertainties of objects.

However, the computability of the approach is a major problem. The requirement of both goal reachability

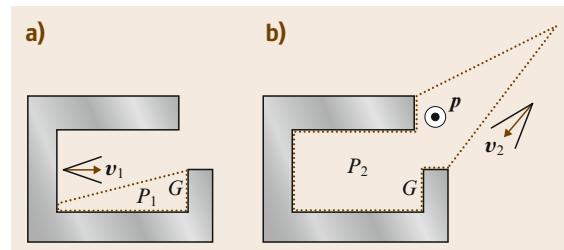

Fig. 26.19 Backward chaining of preimages: P_1 is the preimage of the goal region G , and P_2 is the preimage of P_1

and recognizability under sensing uncertainties, which are intertwined issues, complicates the computation of preimages. It has been shown [26.50] that the time complexity of generating a plan can be double exponential in nmr , where n is the number of plan steps, m is the environment complexity (of the physical space), and r is the dimension of the configuration space. By separating reachability and recognizability and restricting the recognizability power of the original preimage model, computability was improved [26.51, 52].

As an alternative, a two-phase approach is to simplify the fine motion planning into (1) global and offline nominal path planning assuming no uncertainty and (2) local and online replanning to deal with unintended contacts due to uncertainties. Different variations of the two-phase approach have been proposed [26.53–59]. The success of such an approach depends on successful online identification of contact states (see Sect. 26.4.3).

Several researchers also studied the representation and propagation of uncertainties and constraints that have to be satisfied for the success of a task [26.60–64].

Compliant Motion Planning

Compliant motion planning focuses on planning motions of objects always in contact. Hopcroft and Wilfong [26.65] proved that, if two arbitrary objects in contact can be moved to another configuration where they are also in contact, then there is always a path of contact configurations (on the boundary of configuration space obstacles, or \mathcal{C} -obstacles) connecting the first and second contact configurations. Therefore, not only is compliant motion desirable in many cases, but it is always possible given initial and goal contact configurations.

Because compliant motion occurs on the boundary of \mathcal{C} -obstacles, planning compliant motion poses special challenges not present in collision-free motion planning: it requires the exact information of contact configurations on the boundary of \mathcal{C} -obstacles. Unfortunately computing \mathcal{C} -obstacles exactly remains a formidable task to date. While there are exact descriptions of \mathcal{C} -obstacles for polygons [26.66, 67], which are three dimensional, there are only approximations of \mathcal{C} -obstacles for polyhedra [26.68, 69], which are six dimensional. If m and n indicate the complexity of two polyhedral objects in contact, the complexity of the corresponding \mathcal{C} -obstacle is $\Theta(m^6n^6)$ [26.70].

Researchers have focused on either reducing the dimensionality and scope of the problem or getting around the problem of computing \mathcal{C} -obstacles altogether. Some researchers have studied compliant motion planning on \mathcal{C} -obstacles of reduced dimensions [26.59, 71, 72]. It is more popular to plan compliant motions based on a predetermined graph of topological contact states to avoid the problem of computing \mathcal{C} -obstacles [26.73–76]. In particular, one approach [26.74, 75] models an assembly task of polygonal parts as a discrete event system using Petri nets. However, contact states and transitions are often generated manually, which is awfully tedious for even assembly tasks of simple geometry [26.33] and is practically infeasible for complex tasks due to the huge number of different contact states.

Therefore, automatic generation of a contact state graph is desirable and even necessary. A method was first developed to enumerate all possible contact states and their connections between two convex polyhedral objects [26.77]. Recall that a contact state between two convex polyhedra can be described by a single principal contact (Sect. 26.4.1), and any principal contact between two topological surface elements of two convex polyhedra describes a geometrically valid contact state. These are nice properties and greatly simplify the problem of contact state graph generation. In general, however, to construct a contact state graph between two objects automatically requires the handling of two rather difficult issues:

1. how to generate *valid* contact states, i. e., how to tell if a set of principal contacts corresponds to a geometrically valid contact state, given the geometries of objects, and
2. how to link one valid contact state to another in the graph, i. e., how to find the neighboring (or adjacency) relations among the regions of contact

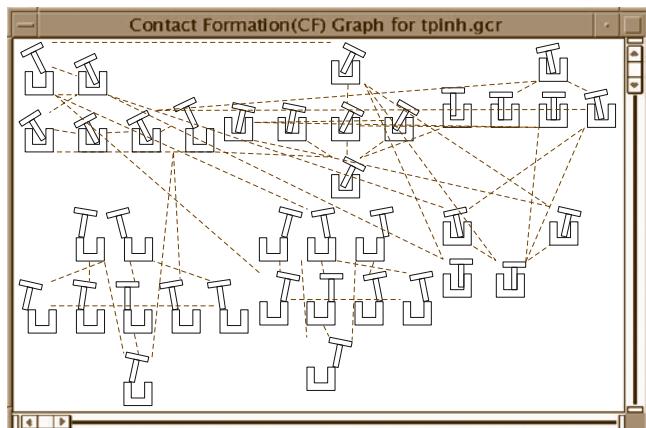

Fig. 26.20 A contact state graph between two planar parts

configurations belonging to different contact states in the contact configuration space.

A general and efficient divide-and-merge approach was introduced [26.26] for automatically generating a contact state graph between two arbitrary polyhedra. Each node in the graph denotes a contact state, described by a topological *contact formation* (**CF**) [26.25] as a set of principal contacts and a configuration satisfying the **CF**. Each edge connects the nodes of two neighboring contact states. Figure 26.20 shows an example contact state graph between two planar parts.

The approach handled the above two issues simultaneously by directly exploiting both topological and geometrical knowledge of contacts in the *physical space* of objects and by dividing the problem into simpler subproblems of generating and merging special subgraphs. Specifically, the approach takes advantage of the fact that a contact state graph can be divided into special subgraphs called the *goal-contact relaxation* (**GCR**) graphs, where each **GCR** graph is defined by a locally most constrained valid contact state, called the seed, and its less-constrained neighboring valid contact states, which is easier to generate because of several properties. The main properties include:

- given a valid contact state, CS_i , all of its less constrained neighboring contact states can be hypothesized topologically from the principal contacts in CS_i ,
- a hypothesized less constrained neighboring contact state, CS_j , is valid, if and only if there exists a compliant motion to relax certain constraints of CS_i to obtain CS_j which does not result in any other contact state, called neighboring relaxation,
- neighboring relaxation can often be achieved by instantaneous compliant motion.

With this approach, a contact state graph of several hundreds or thousands of nodes and links can be generated in a few seconds.

With a contact state graph, the problem of compliant motion planning can be decomposed into two simpler subproblems at two levels: (1) high level: graph search for state transitions from one node to another in a contact state graph, and (2) low level: contact motion planning within the set of contact configurations constrained by the *same* contact state (and the same contact formation), called ***CF**-compliant motion planning*. A general contact motion plan crossing several contact states can be considered as consisting of segments of

CF-compliant motions in different contact states. One approach plans [26.78] **CF**-compliant motions based on random sampling of **CF**-compliant configurations and extending the probabilistic roadmap motion planning technique [26.79].

Contact State Identification

Successful execution of a fine-motion or compliant motion plan depends on correct online identification of contact states during execution. Contact state identification uses both model information of contact states (including topological, geometrical and physical information) and sensory information of location and force/torque of the end-effector. The presence of sensing uncertainties make the identification problem nontrivial. Approaches for contact state identification are different in ways of dealing with uncertainties.

One class of approaches obtain the mapping between sensory data (in the presence of sensing uncertainties) and corresponding contact states through learning. Models for learning include hidden Markov models [26.80, 81], thresholds [26.82, 83], neural network structures, and fuzzy classifiers [26.84–88]. Training data are obtained either in an unsupervised way or by human task demonstration. Such approaches are task dependent: a new task or environment requires new training.

Another class of approaches are based on analytical models for contact states. A common strategy is to predetermine the set of configurations, constraints on configurations, or the set of forces/torques or force/torque constraints that are possible for each contact state and match such information against the sensed data to identify contact states online. Some approaches do not consider the effect of uncertainties [26.89, 90], while others consider uncertainties modeled either by uncertainty bounds or by probability distributions [26.24, 76, 91–95]. An alternative strategy is based on checking the distance between contacting elements in Cartesian space: either by growing the objects with pose uncertainty and intersecting the obtained regions [26.96], or by combining the distance between the objects with several other factors such as the instantaneous approach direction [26.97].

In terms of how sensory data are used, some identification schemes are rather static because they do not consider the prior motion and state identifications before the current contact state is reached, while others use prior history or even use new motion or *active sensing* to help current identification. The latter include approaches that perform simultaneous contact state identification and

parameter estimation. In such approaches, an analytical contact state model is expressed as a function of uncertain parameters, such as the pose or dimension of an object in contact. At each contact state, some of the uncertain parameters can be observed or estimated with reduced uncertainty. For example, if the held object is at a face–face contact with another object, parameters describing the normals of the contacting faces can be estimated with the help of force/torque sensing. During a task execution (i. e., the execution of a motion plan), the uncertain parameters are estimated along with the identification of contact states with increasing accuracy, which in turn makes the subsequent contact state identifications more accurate. This also improves force control and contact state transition monitoring. The increased performance, however, comes at a higher computational cost.

Simultaneous contact state identification and parameter estimation is most often done by ruling out contact state models that are inconsistent with sensed data or parameter estimation results [26.98–104]. One notable exception [26.105] performs a truly simultaneous estimation by describing the system as a hybrid joint probability distribution of contact states and parameters.

Active sensing is about deliberate use of applied force/torque or motion to better aid contact state identification and parameter estimation. Earlier research focused on simple force strategy [26.106] or movability tests [26.24, 97]. More recently, methods were introduced [26.107] to design sequences of contact state transitions and compliant motion strategies that were optimized for active sensing to determine all uncertain geometric parameters while achieving certain goal contact state.

From a different perspective, an approach was introduced to analyze contact state distinguishability and unknown/uncertain parameter identifiability [26.108]

during the design phase of a contact state identifier or parameter estimator.

Execution of Compliant Motion Plans

While compliant or force control is a much researched subject (see Chap. 8), how to execute a compliant motion plan automatically has received much less attention until recently.

A general compliant motion plan (as the output of a compliant motion or fine motion planner) usually consists of a sequence of contact states, and within each contact state, a path of contact configurations compliant to the contact state and leads to the next contact state in the sequence. Such topological and geometrical information alone is not sufficient for a compliant controller to execute the plan, especially when there are many different and complex contact states.

A hybrid position/force controller requires a specification that separates dimensions of force control from those of position/velocity control. Such specifications not only have to vary for different contact states but may have to vary from one contact configuration to another within the same contact state, i. e., a control specification is a function of time or configuration along a compliant trajectory in general. Moreover, it is far from trivial to make control specifications for complex contact states involving multiple principal contacts [26.109].

Recently an approach was introduced [26.110] to convert automatically a compliant path of contact configurations across a sequence of contact states into wrench, twist, and position control signals $w(t)$, $t(t)$, and $p(t)$ for a hybrid controller to execute the plan. The approach was experimentally verified successfully.

However, there is not yet a full integration of planning, online contact state identification, online re-planning (to deal with contact states that are off the preplanned path due to uncertainty), and compliant motion control.

26.5 Unifying Feedback Control and Planning

In previous sections we discussed task-level control methods and planning algorithms. Both task-level control and planning methods are able to address specific constraints imposed on robot motion in the context of manipulation tasks. However, as illustrated in Fig. 26.3, neither of these categories of methods is able to address all constraints completely. Control remains susceptible to local minima and thus cannot guarantee that a particular motion will lead to the desired result. Planning

methods, on the other hand, overcome the problem of local minima by projecting possible motions into the future to predict if a sequence of motion will lead to success. Given certain assumptions, the resulting plan can be guaranteed to succeed. However, the computations associated with this process are generally too computationally complex to satisfy the feedback requirements of manipulation tasks. Unfortunately, this means that control and motion planning by themselves are unable

to address the problem of moving robots for general manipulations tasks.

In this final section of this chapter, we will review efforts to combine the advantages of control methods and planning methods into a single approach to determine the motion of a robot. These efforts aim to create methods that avoid the susceptibility to local minima while satisfying the feedback requirements. Early attempts of integrating planning and control occurred in the early 1990s. Not all of these efforts are specifically directed at manipulation but many contain insights relevant to the topic. In this section, we will review these efforts and also discuss some of the more recent research efforts aimed at unifying motion planning and feedback control.

Motion planning (Chap. 5) and motion control (Chap. 6) have traditionally been regarded as two distinct areas of research. However, these areas have many features in common. Both areas are concerned with the motion of robotic mechanisms, and more importantly planning and control methods both determine a representation that maps robot state to robot motion. In the case of feedback control, this representation is a potential function defined for a given region of the state space. The gradient of the potential function at a specific state encodes the motion command. In contrast, motion planning determines motion plans. These motion plans also encode motions for a set of states.

Motion planning and feedback control also differ in certain aspects. A motion planner generally makes stronger assumptions than a controller about the environment, the ability to assess its state, and the changes that can occur in the environment. Motion planning also requires the ability to project the robot's state into the future, given its current state and a particular action. By using this ability together with global information about the environment, motion planners can determine motions that are not susceptible to local minima. This positive characteristic of motion planners, however, results in significantly increased computational cost (see Chap. 5). The large discrepancy in computational requirements for planning and control and the resulting divergence of computational techniques may explain the current separation of the two fields. Researchers are beginning to attempt to reverse this separation by devising a unified theory of planning and control.

26.5.1 Feedback Motion Planning

Feedback motion planning combines planning and feedback into a single motion strategy. A planner considers

global information to compute a feedback motion plan free of local minima. Such a feedback motion plan can be interpreted as a potential function or vector field whose gradient will lead the robot to the goal state from any reachable part of the state space [26.18]. Local minima-free potential functions are also called navigation functions [26.111, 112]. Given the current state of the robot and the global navigation function, feedback control is used to determine the robot's motion. The consideration of feedback about the robot's state in the context of a global navigation function reduces the susceptibility to sensing and actuation uncertainty.

Feedback motion planning, in principle, can address the entire spectrum of motion constraints and their feedback requirements (see Fig. 26.3). Given a global navigation function that considers all motion constraints, the feedback requirements can easily be satisfied, since the feedback motion plan already specifies the desired motion command for the entire state space. Obviously, the major challenge in feedback motion planning is the computation of such a navigation function or feedback motion plan. The problem becomes particularly difficult in the context of a manipulation task, since the state space (or configuration space) changes each time the robot grasps or releases an object in the environment (Sect. 26.3). This change makes it necessary to recompute the feedback motion plan. Frequent recomputation is also necessary in dynamic environments, where the motion of obstacles can repeatedly invalidate a previously computed feedback motion plan.

In the remainder of this section, we will review a variety of methods for computing navigation functions. In general, the problem of efficiently computing feedback motion plans for manipulation tasks remains unsolved. We therefore also present methods that do not explicitly consider manipulation. These methods can be divided into three categories: (1) exact methods, (2) approximate methods based on dynamic programming, and (3) approximate methods based on composing and sequencing simpler potential functions.

The earliest exact methods for the computation of navigation functions are applicable to simple environments with obstacles of specific shapes [26.111–113]. Approximate methods based on discretized spaces (grids) overcome this limitation but possess an exponential computational complexity in the number of dimensions of the state space. These approximate navigation functions are called numerical navigation functions [26.114]. These navigation functions are often used for applications in mobile robotics. Due to the low-dimensional configuration space associated with

mobile robots, they can generally solve motion planning problems robustly and efficiently.

Some physical processes, such as heat transfer or fluid flow, can be described by a specific type of differential equation, called harmonic functions. These functions possess properties that make them suitable as navigation functions [26.115–119]. Navigation functions based on harmonic functions are most commonly computed in an approximate, iterative fashion. The requirement for iterative computation increases the computational cost relative to the simpler numerical navigation functions [26.114].

More recent methods for the computation of numerical navigation functions consider differential motion constraints at a significantly reduced computational cost [26.120]. These methods rely on classical numerical dynamic programming techniques and numerical optimal control. However, in spite of their reduced computational complexity, these methods remain too computationally costly to be applied to manipulation tasks with many degrees of freedom in dynamic environments.

Navigation functions can also be computed by composing local potential functions based on global information. This is illustrated in Fig. 26.21. The goal is to compute a navigation function for the entire configuration space \mathcal{C} . This is accomplished by sequencing overlapping funnels. Each of the funnels represents a simple, local potential function. By following the gradient of this potential function, motion commands can be determined for a subset of the configuration space. If the funnels are sequenced correctly, the composition of local funnels can yield a global feedback plan. This feedback plan can be viewed as a hybrid system [26.121] in which the sequencing of funnels represents a discrete transition structure, whereas the individual controllers operate in a continuous domain. The composition of funnels is considered planning. The consideration of global information during the planning permits to determine a funnel composition that avoids local minima.

One of the earliest methods based on the global composition of local funnels was proposed by Choi et al. [26.122]. In this method, the state space of the robot is decomposed into convex regions. The connectivity of these regions is analyzed to determine global information about the state space. This information can be used to combine simple, local potential functions, one for each convex regions of state space, into a local minima-free potential function. More rigorous approaches based on this idea have been developed. These approaches can consider the dynamics of the robot and nonholonomic

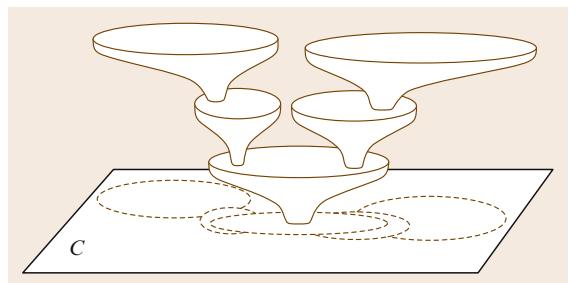

Fig. 26.21 Composing funnels into a navigation function

motion constraints [26.123–125]. These methods have only been applied to low-dimensional state spaces and cannot easily be applied to manipulation tasks.

The random neighborhood graph [26.126] is a sampling-based method of computing a decomposition of the overall state space. As before, a navigation function can be computed by analyzing the global connectivity of the decomposition and imposing adequate local potential functions for each subdivision. A specialized method following the same principle for planar robots in polygonal environments has also been proposed [26.127]. The idea of composing local potential functions has also been applied successfully to a complex robot control task [26.128]. Finally, in [26.129] a general and efficient method of computing a smooth feedback plan over a cylindrical algebraic decomposition of configuration space has been proposed.

The computation of a navigation function over the entire configuration space quickly becomes intractable as the dimensionality of the space increases. To overcome this challenge, in particular in the context of autonomous mobile manipulation, workspace heuristics have been employed to determine a navigation function efficiently. This navigation function does not cover the entire configuration space but only those regions heuristically determined to be relevant to the motion problem [26.130]. This method of generating feedback plans is able to satisfy the various motion constraints depicted in Fig. 26.3 and their respective feedback requirements.

26.5.2 Augmenting Global Plans with Feedback

The manipulation planning techniques described in Sect. 26.3 are not susceptible to local minima, as they consider global state space information. Due to the computational complexity associated with the consideration of global information, these planning techniques are

not able to satisfy the feedback requirements of manipulation tasks. However, the required frequency of feedback about global motion are relatively low: the global connectivity of the configuration space changes relatively infrequently (Fig. 26.3). It would therefore be possible to consider feedback for global motion at the slow rates the planner can accommodate, while considering feedback for other motion constraints at higher frequencies. To achieve this, global motion plans have to be augmented with reactive components that incrementally modify the global plan in response to feedback from the environment. As long as the global connectivity information captured by the plan remains valid, the incremental modifications can ensure that all other motion constraints, ranging from task requirements to reactive obstacles avoidance, are satisfied.

The elastic-band framework [26.131] augments global plans with reactive obstacle avoidance. A global configuration space path, determined by a planner, is covered with local potential functions, each of which is derived from the local distribution of obstacles around the path. These local potentials cause the path to deform so as to maintain a minimum distance from obstacles. Visually, the path behaves as an elastic band that is deformed by the motion of obstacles. The local potential functions, together with the global path, can be viewed as a navigation function for a local region of the configuration space. Integrated with a global planner and replanner, the elastic-band framework permits real-time obstacle avoidance that is not susceptible to local minima. However, the feedback frequency for global motion remains limited by the global motion planner. Specific task constraints have

not been integrated into the elastic-band framework; consequently, its application to manipulation tasks is limited.

In its original formulation, the elastic-band framework assumed that all degrees of freedom of the robot are holonomic. An extended formulation augments motion paths for nonholonomic platforms with reactive components [26.132].

The elastic-strip framework [26.133] also augments global motion plans with reactive obstacle avoidance. In addition to reactive obstacle avoidance, however, the elastic-strip framework can accommodate task constraints. Similarly to an elastic band, an elastic strip covers a global path with local potential functions. In contrast to the elastic-band framework, these potential functions are based on task-level controllers (Sect. 26.2) and therefore allow the task-consistent modification of the global path. The elastic-strip framework is therefore well suited for the execution of manipulation plans in dynamic environments. An elastic strip will be incrementally modified to represent a constraint-consistent trajectory, as long as the global information captured by the underlying plan remains valid. The elastic-strip framework has been applied to a variety of manipulation tasks on a mobile manipulation platform.

Extending the elastic-band and elastic-strips frameworks, the elastic-roadmap framework combines reactive task-level control with efficient global motion planning [26.130]. The elastic roadmap represents a hybrid system of task-level controllers that are composed into a navigation function, thereby satisfying the motion constraints depicted in Fig. 26.3 and their respective feedback requirements.

26.6 Conclusions and Further Reading

In this chapter, an overview of motion generation and control strategies in the context of robotic manipulation tasks has been provided. Issues related to modeling the interfaces between the robot and the environment at the different time scales of motion and incorporating sensing and feedback were considered. Manipulation planning was introduced as an extension to the basic motion planning problem, which can be modeled as a hybrid system of continuous configuration spaces arising from the act of grasping and moving parts in the environment. The important example of assembly motion has been discussed through the analysis of contact states and compliant motion control. The operational space framework, as described in Sect. 26.2, permits the position and

force control of operational points on a serial-chain manipulator. A number of extensions have been proposed in the literature, extending the framework to situations with multiple concurrent contact points, cooperative manipulation scenarios, and branching kinematic chains. For manipulation planning, extensions involving grasp and regrasp planning, multiple robots, multiple parts, and movable obstacles have been considered. In this section we will briefly discuss these extensions and refer to the appropriate literature.

General Contact Models

The hybrid force/motion control described by *Raiert* and *Craig* [26.134] has been shown to have shortcom-

ings [26.135]. A general contact model for dynamically decoupled force/motion control in the context of operational space control that overcomes these problems has been presented in [26.135]. This general contact model has been extended into a compliant motion control framework to enable force control for multiple contact points [26.136] in nonrigid environments, and to enable force control for multiple contact points on different links of a kinematic chain [26.137]. The operational space framework for task-level control has been applied for the real-time simulation of complex dynamic environments [26.138]. Contact points between objects in the environment are modeled as operation points, resulting in a mathematically elegant framework for resolving impulses and contact constraints for moving bodies.

Cooperative Manipulation Control

If multiple task-level controlled robots collaborate to manipulate an object, they form a closed kinematic chain that is connected through the object. The dynamics of the entire system can be described using the notion of an augmented object [26.139, 140], in which the dynamics of the manipulators and the object are combined to form a model of the overall system. The internal forces that occur at the grasp points during motion can be modeled using the virtual linkage framework [26.141]. A number of alternative strategies for the cooperative manipulation of multiple robots outside of the operational space framework have been proposed [26.142–148].

Control of Branching Mechanisms

So far, we have implicitly assumed that the task-controlled robot consists of a single kinematic chain. This assumption does not hold in the case of kinematically more complex mechanisms, such as humanoid robots (Chap. 56). These robots can consist of multiple branching kinematic chains. If we consider the torso of a humanoid robot to be the robot's base, for example, then the legs, arms, and the head represent five kinematic chains attached to this base. We call such a mechanism a branching mechanism if it does not contain any closed kinematic loops. Tasks performed by a branching mechanism may require the specification of operational points on any one of those branches; for example, while the legs perform locomotion the hands achieve a manipulation task and the head is oriented to maintain visibility of the manipulated object.

The operational space framework has been extended to task-level control of branching mechanisms [26.149]. This extension combined operational points and associated Jacobians and computes an operational space

inertia matrix that combines all operational points. This matrix can be computed efficiently with an algorithm that in practice is linear in the number of operational points [26.150, 151].

Nonholonomic Mobile Manipulation

All previously discussed work on task-level control assumes that the degrees of freedom are holonomic. For manipulator arms this is generally a valid assumption. The most common type of mobility platform, however, is based on either differential drives, synchro-drives, or Ackerman steerings (point to a section), all of which are subject to nonholonomic constraints. The operational space framework has been extended to mobile manipulation platforms that combine a nonholonomic mobility platform with a holonomic manipulator arm [26.152–154], enabling the task-level control of a large class of mobile manipulation platforms.

Learning Models with Uncertainty

The efficacy of operational space control depends on the accuracy of the dynamic model of the robot. In particular when multiple behaviors are executed using null-space projections, modeling errors can have significant effects. To overcome the reliance on accurate dynamic models, reinforcement learning can be used to learn operational space controllers [26.155].

Grasping and Regrasp Planning

Deciding the intermediate stable configurations for a part necessary to complete a manipulation task and selecting proper grasps are both difficult problems in themselves that operate over a continuum of possible solutions. Simeon et al. developed a manipulation planning framework that considers continuous grasps and placements [26.156]. However, selecting from among all possible grasp configurations and deciding when to regrasp is still an open research problem. For an overview of various grasp quality metrics, see Miller and Allen [26.157, 158] and Chap. 28.

Multiple Parts

The manipulation planning framework nicely generalizes to multiple parts, $\mathcal{P}_1, \dots, \mathcal{P}_k$. Each part has its own \mathcal{C} -space, and \mathcal{C} is formed by taking the Cartesian product of all the part \mathcal{C} -spaces with the manipulator \mathcal{C} -space. The set \mathcal{C}_{adm} is defined in a similar way, but now part–part collisions also have to be removed, in addition to part–manipulator, manipulator–obstacle, and part–obstacle collisions. The definition of $\mathcal{C}_{\text{stable}}$ re-

quires that all parts be in stable configurations; the parts may even be allowed to stack on top of each other. The definition of $\mathcal{C}_{\text{grasp}}$ requires that one part is grasped and all other parts are stable. There are still two modes, depending on whether the manipulator is grasping a part. Once again, transitions occur only when the robot is in $\mathcal{C}_{\text{trans}} = \mathcal{C}_{\text{stable}} \cap \mathcal{C}_{\text{grasp}}$.

Planning for Multiple Robots

Generalizing to k robots would lead to $2k$ modes, in which each mode indicates whether each robot is grasping a part. Multiple robots may even be allowed to grasp the same part, which leads to the interesting problem of planning for closed kinematic chains and cooperative motion (see Chap. 29). *Koga* addressed multi-arm manipulation planning where the same object must be grasped and moved by several manipulator arms [26.21]. Another generalization could allow a single robot to grasp more than one part simultaneously.

Planning for Closed Kinematic Chains

The subspace of \mathcal{C} that results from maintaining kinematic closure arises when multiple robots grasp the same part, or even when multiple fingers of the same hand grasp a single part (see Chap. 15). Planning in this context requires that paths remain on a lower-dimensional variety for which a parameterization is not available. Planning the motion of parallel mechanisms or other systems with loops typically requires maintaining multiple closure constraints simultaneously (Chap. 12).

Planning with Movable Obstacles

In some cases, the robot may be allowed to reposition obstacles in the environment rather than simply avoid them. *Wlfong* first addressed motion planning in the presence of movable obstacles [26.159]. Wil-

fong proved that the problem is PSPACE-hard even in two-dimensional environments where the final positions of all movable objects are specified. *Erdmann* and *Lozano-Perez* considered coordinated planning for multiple moving objects [26.160]. *Alami* presented a general algorithm for the case of one robot and one movable object and formulated the space of grasping configurations into a finite number of cells [26.17]. *Chen* and *Hwang* developed a planner for a circular robot that is allowed to push objects aside as it moves [26.161]. *Stilman* and *Kuffner* considered movable obstacles in the context of navigation planning [26.162], and manipulation planning [26.163]. *Nieuwenhuisen* et al. also developed a general framework for planning with movable obstacles [26.164].

Nonprehensile Manipulation

Lynch and *Mason* explored scenarios in which grasping operations are replaced by pushing operations [26.165]. The space of stable pushing directions imposes non-holonomic constraints on the motion of the robot, which opens up issues related to controllability. Related issues also arise in the context of part-feeders and manipulation for manufacturing and assembly (Chap. 42).

Assembly Motion Extensions

The work in assembly motion described in this chapter has focused on rigid-part assembly, and the parts considered are mostly polyhedral or of simple non-polyhedral shapes, such as round pegs and holes. More recent work on contact state analysis for curved objects can be found in [26.166]. An emerging field in assembly is micro/nanoassembly (Chap. 18). Flexible or deformable part assembly has also begun to attract attention [26.167–169]. Virtual assembly [26.170] for simulation and prototyping is another interesting area of study.

27. Contact Modeling and Manipulation

Imin Kao, Kevin Lynch, Joel W. Burdick

Part D | 27

Robotic manipulators use contact forces to grasp and manipulate objects in their environments. Fixtures rely on contacts to immobilize workpieces. Mobile robots and humanoids use wheels or feet to generate the contact forces that allow them to locomote. Modeling of the *contact interface*, therefore, is fundamental to analysis, design, planning, and control of many robotic tasks.

This chapter presents an overview of the modeling of contact interfaces, with a particular focus on their use in manipulation tasks, including grasping or *nonprehensile* manipulation modes such as pushing. Analysis and design of grasps and fixtures also depends on contact modeling, and these are discussed in more detail in Chap. 28. Sections 27.2–27.5 focus on rigid-body models of contact. Section 27.2 describes the kinematic constraints caused by contact, and Sect. 27.3 describes the contact forces that may arise with Coulomb friction. Section 27.4 provides examples of analysis of multicontact manipulation tasks with rigid bodies and Coulomb friction. Section 27.5 extends the analysis to manipulation by pushing. Section 27.6 introduces modeling of contact interfaces, kinematic duality, and pressure distribution. Section 27.7 describes the concept of the friction limit surface and illustrates it with an example demonstrating the construction of a limit surface for a soft contact. Finally, Sect. 27.8 discusses how these more accurate models can be used in fixture analysis and design.

27.1 Overview

A contact model characterizes both the forces that can be transmitted through the contact as well as the allowed relative motions of the contacting bodies. These char-

acteristics are determined by the geometry of the contacting surfaces and the material properties of the parts, which dictate friction and possible contact deformation.

27.1.1 Choosing a Contact Model

The choice of a contact model largely depends upon the application or analysis that must be carried out. When appropriate analytical models are used, one can determine if a manipulation plan or fixture design meets desired functional requirements within the model's limits.

Rigid-Body Models

Many approaches to manipulation, grasp, and fixture analysis are based on rigid-body models. In the rigid-body model, no deformations are allowed at the points or surfaces of contact between two bodies. Instead, contact forces arise from two sources: the constraint of incompressibility and impenetrability between the rigid bodies, and surface frictional forces. Rigid-body models are straightforward to use, lead to computationally efficient planning algorithms, and are compatible with solid-modeling software systems. Rigid-body models are often appropriate for answering qualitative questions such as *will this fixture be able to hold my workpiece?* and for problems involving stiff parts with low to moderate contact forces.

Rigid-body models are not capable of describing the full range of contact phenomena, however; for example, rigid-body models cannot predict the individual contact forces of a multiple-contact fixture (the static indeterminacy problem [27.1, 2]). Furthermore, workpieces held in fixtures experience non-negligible deformations in many high-force manufacturing operations [27.3–6]. These deformations, which crucially impact machining accuracy, cannot be determined from rigid-body models. Also, a rigid-body model augmented with a Coulomb friction model can lead to mechanics problems that have no solution or multiple solutions [27.7–15]. To overcome the limitations inherent in the rigid-body model, one must introduce compliance into the contact model.

Compliant Models

A *compliant* contact deforms under the influence of applied forces. The forces of interaction at the contact are derived from the *compliance* or *stiffness* model. While

compliant contact models are typically more complicated, they have several advantages: they overcome the static indeterminacy inherent to rigid-body models and they predict the deformations of grasped or fixtured parts during loading.

A detailed model of the deformations of real materials can be quite complex. Consequently, for analysis we often introduce *lumped-parameter* or *reduced-order* compliance models having a limited number of variables. In this chapter we summarize a reduced-order *quasi-rigid-body* approach to modeling that can model a variety of compliant materials in a way that is consistent with both the solid mechanics literature and conventional robot analysis and planning paradigms.

Finally, three-dimensional finite-element models [27.16–18] or similar ideas [27.19, 20] can be used to analyze workpiece deformations and stresses in fixtures. While accurate, these numerical approaches have some drawbacks, for example, the grasp stiffness matrix can only be found through difficult numerical procedures. Stiffness matrices are often needed to compute quality measures that are the basis for optimal grasping plans or fixturing designs [27.21, 22]. Thus, these numerical approaches are better suited for verifying final fixture designs.

27.1.2 Grasp/Manipulation Analysis

Once a contact model has been chosen, we can use it to analyze tasks involving multiple contacts. If a part is subject to multiple contacts, the kinematic constraints and force freedoms due to the individual contacts must be combined. This combined analysis facilitates manipulation planning – choosing the contact locations, and possibly the motions or forces applied by those contacts, to achieve the desired behavior of the part. A prime example is the grasping or fixturing problem: choosing contact locations, and possibly contact forces, to prevent motion of a part in the face of external disturbances. This well-studied topic is discussed in greater detail in Chap. 28. Other examples include problems of partial constraint, such as pushing a part or inserting a peg into a hole.

27.2 Kinematics of Rigid-Body Contact

Contact kinematics is the study of how two or more parts can move relative to each other while respecting the rigid-body impenetrability constraint. It also classifies motion in contact as either rolling or slipping.

Consider two rigid bodies whose position and orientation (configuration) is given by the local coordinate column vectors \mathbf{q}_1 and \mathbf{q}_2 , respectively. Writing the composite configuration as $\mathbf{q} = (\mathbf{q}_1^\top, \mathbf{q}_2^\top)^\top$, we define

a *distance* function $d(\mathbf{q})$ between the parts that is positive when they are separated, zero when they are touching, and negative when they are in penetration. When $d(\mathbf{q}) > 0$, there are no constraints on the motions of the parts. When the parts are in contact ($d(\mathbf{q}) = 0$), we look at the time derivatives \dot{d} , \ddot{d} , etc., to determine if the parts stay in contact or break apart as they follow a trajectory $\mathbf{q}(t)$. This can be determined by the following table of possibilities:

| d | \dot{d} | \ddot{d} | ... |
|---------------|-----------|------------|---------------------------|
| > 0 | | | no contact, |
| < 0 | | | infeasible (penetration), |
| $= 0 > 0$ | | | breaking contact, |
| $= 0 < 0$ | | | infeasible (penetration), |
| $= 0 = 0 > 0$ | | | breaking contact, |
| $= 0 = 0 < 0$ | | | infeasible (penetration), |
| etc. | | | |

The contact is maintained only if all time derivatives are zero.

The first two time derivatives are written

$$\dot{d} = \left(\frac{\partial d}{\partial \mathbf{q}} \right)^\top \dot{\mathbf{q}}, \quad (27.1)$$

$$\ddot{d} = \dot{\mathbf{q}}^\top \frac{\partial^2 d}{\partial \mathbf{q}^2} \dot{\mathbf{q}} + \left(\frac{\partial d}{\partial \mathbf{q}} \right)^\top \ddot{\mathbf{q}}. \quad (27.2)$$

The terms $\partial d / \partial \mathbf{q}$ and $\partial^2 d / \partial \mathbf{q}^2$ carry information about the local contact geometry. The former corresponds to the contact normal, while the latter corresponds to the relative curvature of the parts at the contact.

If contact is maintained, we can classify the contact as slipping or rolling. Analogous to the table above, the contact is rolling if and only if there is zero relative tangential velocity, acceleration, etc., between the contact points on the parts. If the relative tangential velocity is nonzero, the parts are slipping; if the relative velocity is zero but relative tangential acceleration or (higher-order derivatives) is not, slipping is incipient.

In this section we focus on a *first-order* analysis of contact kinematics. A first-order analysis concludes that contact is maintained if $d(\mathbf{q}) = 0$ and $\dot{d} = 0$. This local linearization of contact kinematics focuses on the velocity $\dot{\mathbf{q}}$ and the contact normal in $\partial d / \partial \mathbf{q}$; higher-order spatial derivatives of the contact geometry (curvature, etc.) are not considered. While this is a good starting point, it may occasionally lead to erroneous conclusions. For example, *Rimon* and *Burdick* [27.23–25] showed that a first-order analysis may incorrectly predict mobil-

ity of a part in a fixture when a second-order analysis shows that it is in fact completely constrained.

Analysis of the kinematics of rolling contact of parameterized surfaces can be found in [27.26]; see also [27.27–30].

27.2.1 Contact Constraints

As described in Chap. 1, a rigid body in space has six degrees of freedom, specified by the location of the origin of a coordinate frame P affixed to the part and the orientation of this coordinate frame relative to an inertial frame O fixed in the world. Let ${}^O\mathbf{p}_P \in \mathbb{R}^3$ be the position of the part center of mass and ${}^O\mathbf{R}_P \in SO(3)$ be the rotation matrix describing the orientation of the part relative to O . The spatial velocity of the part can be written as $\mathbf{t} \in \mathbb{R}^6$, sometimes called a *twist*,

$$\mathbf{t} = (\boldsymbol{\omega}^\top, \mathbf{v}^\top)^\top,$$

where $\boldsymbol{\omega} = (\omega_x, \omega_y, \omega_z)^\top$ and $\mathbf{v} = (v_x, v_y, v_z)^\top$ give the angular velocity and linear velocity of P in the world frame O , respectively, such that $\boldsymbol{\omega}$ satisfies

$${}^O\dot{\mathbf{R}}_P = \boldsymbol{\omega} \times {}^O\mathbf{R}_P$$

and \mathbf{v} satisfies

$$\mathbf{v} = {}^O\dot{\mathbf{p}}_P - \boldsymbol{\omega} \times {}^O\mathbf{p}_P.$$

It is worth taking a moment to really understand the spatial velocity of a body. It consists of the body's angular velocity expressed in the world frame O , along with the linear velocity of a point as if it were rigidly attached to the body but currently at the origin of the world frame. This point need not be physically on the body. In other words, \mathbf{v} is not simply ${}^O\dot{\mathbf{p}}_P$. This notation will simplify the following expressions, where all velocities and forces will be expressed in the common world frame O . (Be aware that twists are sometimes defined in a body frame instead.)

A point contact acting on the part provides a unilateral constraint which prevents the part from locally moving against the contact normal. Let \mathbf{x} be the location of the contact in O . The linear velocity of the point on the part in contact is

$$\mathbf{v}_C = \mathbf{v} + \boldsymbol{\omega} \times \mathbf{x}.$$

(We drop the pre-superscripts O for simplicity; for example, ${}^O\mathbf{x}$ is written simply as \mathbf{x} .) Let $\hat{\mathbf{u}}$ be the unit vector normal pointing into the part (Fig. 27.1). The first-order condition that the part not move into the unilateral

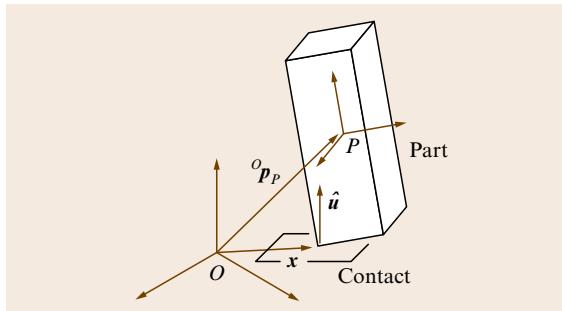

Fig. 27.1 Notation for a part in contact with a manipulator or the environment

constraint can be written

$$v_C^\top \hat{u} = (v + \omega \times x)^\top \hat{u} \geq 0. \quad (27.3)$$

In other words, the velocity of the part at C cannot have a component in the opposite direction of the contact normal. To write this another way, define a generalized force or *wrench* \mathbf{w} consisting of the torque \mathbf{m} and force \mathbf{f} acting on the part for a unit force along the contact normal:

$$\mathbf{w} = (\mathbf{m}^\top, \mathbf{f}^\top)^\top = [(\mathbf{x} \times \hat{\mathbf{u}})^\top, \hat{\mathbf{u}}^\top]^\top.$$

Then (27.3) can be rewritten as

$$\mathbf{t}^\top \mathbf{w} \geq 0. \quad (27.4)$$

If the external constraint point is moving with linear velocity v_{ext} , (27.4) changes to

$$\mathbf{t}^\top \mathbf{w} \geq v_{\text{ext}}^\top \hat{\mathbf{u}}, \quad (27.5)$$

which reduces to (27.4) if the constraint is stationary.

Each inequality of the form (27.5) constrains the velocity of the part to a half-space of its six-dimensional velocity space bounded by the hyperplane $\mathbf{t}^\top \mathbf{w} = v_{\text{ext}}^\top \hat{\mathbf{u}}$. Unioning the set of all constraints, we get a convex polyhedral set of feasible part velocities. A constraint is redundant if its half-space constraint does not change the feasible velocity polyhedron. For a given twist \mathbf{t} , a constraint is active if

$$\mathbf{t}^\top \mathbf{w} = v_{\text{ext}}^\top \hat{\mathbf{u}}; \quad (27.6)$$

otherwise the part is breaking contact at that point. In general, the feasible velocity polyhedron for a part can consist of a six-dimensional interior (where no contact constraint is active), five-dimensional hyperfaces, four-dimensional hyperfaces, and so on, down to one-dimensional edges and zero-dimensional points. A part

velocity on an n -dimensional facet of the velocity polyhedron indicates that $6 - n$ independent (nonredundant) constraints are active.

If all of the constraints are stationary ($v_{\text{ext}} = 0$), then each constraining half-plane defined by (27.5) passes through the origin of the velocity space, and the feasible velocity set becomes a cone rooted at the origin. Let \mathbf{w}_i be the constraint wrench of stationary contact i . Then the feasible velocity cone is

$$V = \{ \mathbf{t} \mid \mathbf{t}^\top \mathbf{w}_i \geq 0 \quad \forall i \}.$$

If the \mathbf{w}_i span the six-dimensional generalized force space, or, equivalently, the convex hull of the \mathbf{w}_i contains the origin in the interior, then the stationary contacts completely constrain the motion of the part, and we have form closure, as discussed in Chap. 28.

In the discussion above, each constraint (27.5) divides the part velocity space into three categories: a hyperplane of velocities that maintain contact, a half-space of velocities that separate the parts, and a half-space of velocities that cause the parts to penetrate. Velocities where the contact is maintained can be further broken down into two categories: velocities where the part slips over the contact constraint, and velocities where the part sticks or rolls on the constraint. In the latter case, the part velocity satisfies the three equations

$$\mathbf{v} + \boldsymbol{\omega} \times \mathbf{x} = \mathbf{v}_{\text{ext}}. \quad (27.7)$$

Now we can give each point contact i a label m_i corresponding to the type of contact, called the contact label: b if the contact is breaking, f if the contact is fixed (including rolling), and s if the contact is slipping, i.e., (27.6) is satisfied but (27.7) is not. The *contact mode* for the entire system can be written as the concatenation of the contact labels at the k contacts, $m_1 m_2 \dots m_k$.

27.2.2 Collections of Parts

The discussion above can be generalized to find the feasible velocities of multiple parts in contact. If parts i and j make contact at a point \mathbf{x} , where $\hat{\mathbf{u}}_i$ points into part i and $\mathbf{w}_i = [(\mathbf{x} \times \hat{\mathbf{u}}_i)^\top, \hat{\mathbf{u}}_i^\top]^\top$, then their spatial velocities \mathbf{t}_i and \mathbf{t}_j must satisfy the constraint

$$(\mathbf{t}_i - \mathbf{t}_j)^\top \mathbf{w}_i \geq 0 \quad (27.8)$$

to avoid penetration. This is a homogeneous half-space constraint in the composite $(\mathbf{t}_i, \mathbf{t}_j)$ velocity space. In an assembly of multiple parts, each pairwise contact contributes another constraint in the composite part velocity

space, and the result is a polyhedral convex cone of kinematically feasible velocities rooted at the origin of the composite velocity space. The contact mode for the entire assembly is the concatenation of the contact labels at each contact in the assembly.

If there are moving contacts whose motion is prescribed, e.g., robot fingers, the constraints on the motion of the remaining parts will no longer be homogeneous. As a result, the convex polyhedral feasible velocity space is no longer a cone rooted at the origin.

27.2.3 Graphical Planar Methods

When a part is confined to move in the x - y -plane, the twist \mathbf{t} reduces to $\mathbf{t} = (\omega_x, \omega_y, \omega_z, v_x, v_y, v_z)^\top = (0, 0, \omega_z, v_x, v_y, 0)^\top$. The point $(-v_y/\omega_z, v_x/\omega_z)$ is called the center of rotation (CoR) in the projective plane, and we can represent any planar twist by its CoR and rotational velocity ω_z . (Note that the case $\omega_z = 0$ must be treated with care, as it corresponds to a CoR at infinity.) This is sometimes useful for graphical purposes: for a single part constrained by stationary fixtures, at least, we can easily draw the feasible twist cone as CoRs [27.14, 31].

As an example, Fig. 27.2a shows a planar part standing on a table and being contacted by a robot finger. This finger is currently stationary, but we will later set it in motion. The finger defines one constraint on the part's motion and the table defines two more. (Note that contact points in the interior of the edge between the part and the table provide redundant kinematic constraints.) The constraint wrenches can be written

$$\mathbf{w}_1 = (0, 0, -1, 0, 1, 0)^\top,$$

$$\mathbf{w}_2 = (0, 0, 1, 0, 1, 0)^\top,$$

$$\mathbf{w}_3 = (0, 0, 1, -1, 0, 0)^\top.$$

For a stationary finger, the kinematic constraints yield the feasible twist cone shown in Fig. 27.2b. This region can also be easily visualized in the plane by using the following method: at each contact, draw the contact normal line. Label all points on the normal \pm , points to the left of the inward normal $+$, and points to the right $-$. For each contact constraint, all the points labeled $+$ can serve as CoRs with positive angular velocity, and all the points labeled $-$ can serve as CoRs with negative angular velocity, without violating the contact constraint. After doing this for all the contact normals, keep only the CoRs that are consistently labeled. These CoRs are a planar representation of the feasible twist cone (Fig. 27.2c).

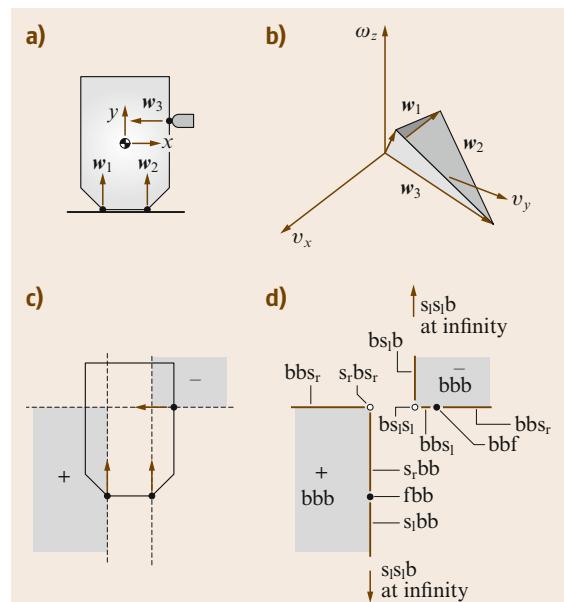

Fig. 27.2 (a) A part resting on a table and the three contact constraints. (b) The twist cone satisfying the contact constraints. The contact normals are shown with their associated constraint planes. (c) The equivalent representation as CoRs, shown in grey. Note that the lines that extend off to the *left* and to the *bottom wrap around* at infinity and come back in from the *right* and the *top*, respectively, so this *COR* region should be interpreted as a single connected convex region, equivalent to the twist cone representation in (b). (d) The contact modes assigned to each feasible motion. The zero velocity contact mode is *fff*

We can refine this method by assigning contact modes to each feasible CoR. For each contact normal, label the CoR at the contact point f for fixed, other CoRs on the normal line s for slipping, and all other CoRs b for breaking contact. The concatenation of these labels gives the part's contact mode for a particular part motion. In the planar case, the label s on the contact normal line can be further refined into s_r or s_l , indicating whether the part is slipping right or left relative to the constraint. An s CoR labeled $+$ above the contact (in the direction of the contact normal) or $-$ below the contact should be relabeled s_r , and an s CoR labeled $-$ above the contact or $+$ below should be relabeled s_l (Fig. 27.2d).

This method can be used readily to determine if the part is in form closure. If there is no CoR labeled consistently, then the feasible velocity cone consists of only

the zero velocity point, and the part is immobilized by the stationary contacts. This method also makes it clear that at least four contacts are necessary to immobilize the part by the first-order analysis (see also Chap. 28). This is a weakness of the first-order analysis – curvature effects can be used to immobilize a part with three

or even two contacts [27.24]. This weakness can also be seen in Fig. 27.2d. A pure rotation about the CoR labeled $\{+, s_r; b_s r\}$ is actually not feasible, but it would be if the part had a small radius of curvature at the contact with the finger. The first-order analysis ignores this curvature.

27.3 Forces and Friction

A commonly used model of friction in robotic manipulation is Coulombs law [27.32]. This experimental law states that the friction force magnitude f_t in the tangent plane at the contact interface is related to the normal force magnitude f_n by $f_t \leq \mu f_n$, where μ is called the friction coefficient. If the contact is sliding, then $f_t = \mu f_n$, and the friction force opposes the direction of motion. The friction force is independent of the speed of sliding.

Often two friction coefficients are defined, a static friction coefficient μ_s and a kinetic (or sliding) friction coefficient μ_k , where $\mu_s \geq \mu_k$. This implies that a larger friction force is available to resist initial motion, but once motion has begun, the resisting force decreases. Many other friction models have been developed with

different functional dependencies on factors such as the speed of sliding and the duration of static contact before sliding. All of these are aggregate models of complex microscopic behavior. For simplicity, we will assume the simplest Coulomb friction model with a single friction coefficient μ . This model is reasonable for hard, dry materials. The friction coefficient depends on the two materials in contact, and typically ranges from 0.1 to 1.

Figure 27.3a shows that this friction law can be interpreted in terms of a *friction cone*. The set of all forces that can be applied to the disk by the supporting line is constrained to be inside this cone. Correspondingly, any force the disk applies to the support is inside the negative of the cone. The half-angle of the cone is $\beta = \tan^{-1} \mu$, as shown in Fig. 27.4. If the disk slips to the left on the support, the force the support applies to it acts on the right edge of the friction cone, with a magnitude determined by the normal force.

If we choose a coordinate frame, the force f applied to the disk by the support can be expressed as a wrench

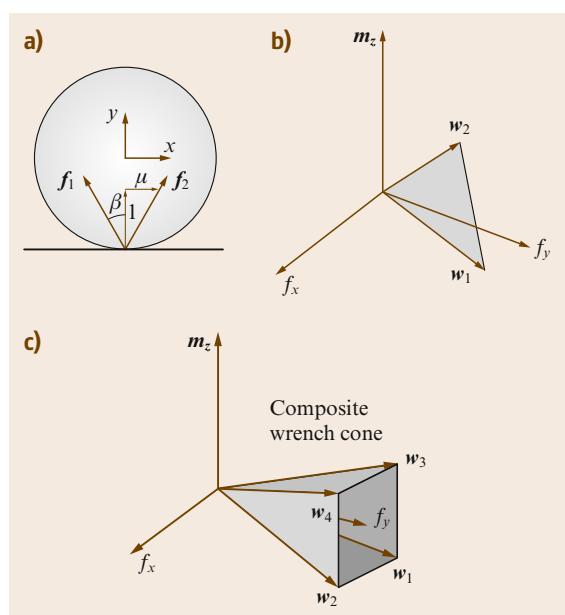

Fig. 27.3 (a) A planar friction cone. (b) The corresponding wrench cone. (c) An example composite wrench cone resulting from two frictional contacts

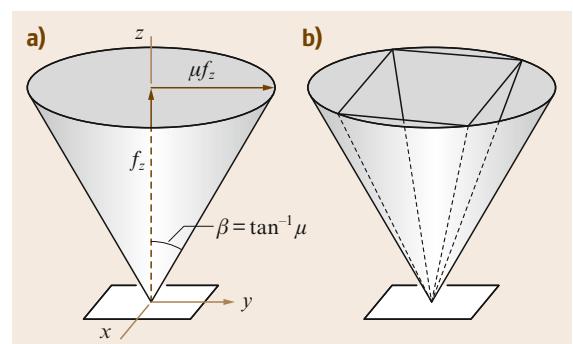

Fig. 27.4 (a) A spatial friction cone. The half-angle of the cone is $\beta = \tan^{-1} \mu$. (b) An inscribed pyramidal approximation to the friction cone. A more accurate inscribed pyramidal approximation can be used by increasing the number of faces of the pyramid. Depending on the application, a circumscribed pyramid could be used instead of an inscribed pyramid

$\mathbf{w} = [(\mathbf{x} \times \mathbf{f})^\top, \mathbf{f}^\top]^\top$, where \mathbf{x} is the contact location. Thus the friction cone turns into a wrench cone, as shown in Fig. 27.3b. The two edges of the planar friction cone give two half-lines in the wrench space, and the wrenches that can be transmitted to the part through the contact are all nonnegative linear combinations of basis vectors along these edges. If \mathbf{w}_1 and \mathbf{w}_2 are basis vectors for these wrench cone edges, we write the wrench cone as

$$\mathcal{WC} = \{k_1 \mathbf{w}_1 + k_2 \mathbf{w}_2 \mid k_1, k_2 \geq 0\}.$$

If there are multiple contacts acting on a part, then the total set of wrenches that can be transmitted to the part through the contacts is the nonnegative linear combination of all the individual wrench cones \mathcal{WC}_i ,

$$\begin{aligned}\mathcal{WC} &= \text{pos}(\{\mathcal{WC}_i\}) \\ &= \left\{ \sum_i k_i \mathbf{w}_i \mid \mathbf{w}_i \in \mathcal{WC}_i, k_i \geq 0 \right\}.\end{aligned}$$

This composite wrench cone is a convex polyhedral cone rooted at the origin. An example composite wrench cone arising from two planar frictional contacts is shown in Fig. 27.3c. If the composite wrench cone is the entire wrench space, then the contacts can provide a force closure grasp (Chap. 28).

In the spatial case, the friction cone is a circular cone, defined by

$$\sqrt{f_x^2 + f_y^2} \leq \mu f_z, f_z \geq 0 \quad (27.9)$$

when the contact normal is in the $+z$ -direction (Fig. 27.4). The resulting wrench cone, and composite wrench cone $\text{pos}(\{\mathcal{WC}_i\})$ for multiple contacts, is a convex cone rooted at the origin, but it is not polyhedral. For computational purposes, it is common to approximate circular friction cones as pyramidal cones, as shown in Fig. 27.4. Then individual and composite wrench cones become polyhedral convex cones in the six-dimensional wrench space.

If a contact or set of contacts acting on a part is ideally force controlled, the wrench \mathbf{w}_{ext} specified by the controller must lie within the composite wrench cone corresponding to those contacts. Because these force-controlled contacts choose a subset of wrenches (possibly a single wrench) from this wrench cone, the total composite wrench cone that can act on the part (including other non-force-controlled contacts) may no longer be a homogeneous cone rooted at the origin. This is roughly analogous to the case of velocity-controlled contacts in Sect. 27.2.1, which results in a feasible twist set for the part that is not a cone rooted at the origin. Ideal robot manipulators may be controlled by position

control, force control, hybrid position–force control, or some other scheme. The control method must be compatible with the parts’ contacts with each other and the environment to prevent excessive forces [27.33].

27.3.1 Graphical Planar Methods

Just as homogeneous twist cones for planar problems can be represented as convex signed (+ or –) CoR regions in the plane, homogeneous wrench cones for planar problems can be represented as convex signed regions in the plane. This is called *moment labeling* [27.14, 34]. Given a collection of lines of force in the plane (e.g., the edges of friction cones from a set of point contacts), the set of all nonnegative linear combinations of these can be represented by labeling all the points in the plane with either a ‘+’ if all resultants make nonnegative moment about that point, a ‘–’ if all make nonpositive moment about that point, a ‘±’ if all make zero moment about that point, and a blank label if there exist resultants making positive moment and resultants making negative moment about that point.

The idea is best illustrated by an example. In Fig. 27.5a, a single line of force is represented by labeling the points to the left of the line with a + and points to the right of the line with a –. Points on the line are labeled ±. In Fig. 27.5b, another line of force is added. Only the points in the plane that are consistently labeled for both lines of force retain their labels; inconsistently labeled points lose their labels. Finally, a third line of force is added in Fig. 27.5c. The result is a single region labeled +. A nonnegative combination of the three lines of force can create any line of force in the plane that passes around this region in a counterclockwise sense. This representation is equivalent to a homogeneous convex wrench cone representation.

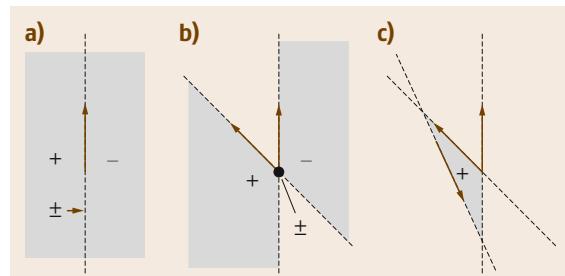

Fig. 27.5 (a) Representing a line of force by moment labels. (b) Representing the nonnegative linear combinations of two lines of force by moment labels. (c) Nonnegative linear combinations of three lines of force

27.3.2 Duality of Contact Wrenches and Twist Freedoms

Our discussion of kinematic constraints and friction should make it apparent that, for any point contact and contact label, the number of equality constraints on the part's motion caused by that contact is equal to the number of wrench freedoms it provides. For example, a breaking contact b provides zero equality constraints on the part motion and also allows no contact force. A fixed contact f provides three motion constraints (the motion of a point on the part is specified) and three freedoms on the contact force: any wrench in the interior of the contact wrench cone is consistent with the contact mode. Finally, a slipping contact s provides one equality motion constraint (one equation on the part's motion must be satisfied to maintain the contact), and for a given motion satisfying the constraint, the contact wrench has only one freedom, the magnitude of the contact wrench on the edge of the friction cone and opposite the slipping direction. In the planar case, the motion constraints and wrench freedoms for b , s , and f contacts are zero, one, and two, respectively.

At each contact, the force and velocity constraints can be represented by an $n \times 6$ *constraint* or *selection* matrix, \mathbf{H} [27.3], at the contact interface. This constraint matrix works like a filter to transmit or deny certain components of motion across the contact interface. By the same token, forces/momenta applied across the contact interface are also filtered by the same constraint matrix, \mathbf{H}^\top , in a dual relationship. Three typical contact models are illustrated below. Contact forces and wrenches are measured in a frame at the contact, with the contact normal in the $+z$ -direction.

- The *point contact without friction* model. Only a normal force f_z can be exerted between the contacting bodies:
- $$f_z \geq 0, \quad \mathbf{w} = \mathbf{H}^\top f_z = (0 \ 0 \ 1 \ 0 \ 0 \ 0)^\top f_z. \quad (27.10)$$
- The *point contact with friction* model includes tangential friction forces, f_x and f_y , in addition to normal force f_z ,

$$f_z \geq 0; \quad |f_t| = \sqrt{f_x^2 + f_y^2} \leq \mu f_z, \\ \mathbf{w} = \mathbf{H}^\top \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix}, \quad (27.11)$$

where f_x and f_y are the x - and y -components of the tangential contact force, and f_z is the normal force.

- The *soft finger* contact model with a finite contact patch allows, in addition to the friction and normal forces, a torsional moment with respect to the contact normal [27.35–39]. We have

$$f_z \geq 0; \\ \mathbf{w} = \mathbf{H}^\top \begin{pmatrix} f_x \\ f_y \\ f_z \\ m_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} f_x \\ f_y \\ f_z \\ m_z \end{pmatrix}, \quad (27.12)$$

where m_z is the moment with respect to the normal of contact. The finite contact area assumed by the soft contact interface results in the application of a friction moment in addition to the traction forces. If the resultant force on the tangential plane of contact is denoted as $f_t = \sqrt{f_x^2 + f_y^2}$ and the moment with respect to the contact normal is m_z , the following elliptical equation represents the relationship between the force and moment at the onset of sliding:

$$\frac{f_t^2}{a^2} + \frac{m_z^2}{b^2} = 1, \quad (27.13)$$

where $a = \mu f_z$ is the maximum friction force, and $b = (m_z)_{\max}$ is the maximum moment defined in equation (27.32). Further readings on this subject can be found in [27.35–42].

As can be appreciated from the three cases above, the rows of \mathbf{H} are the directions along which contact forces are supported. Conversely, relative motions of the two objects are constrained along these same directions: $\mathbf{H}\dot{\mathbf{q}} = 0$. Thus, the constraint matrix works like a kinematic filter which dictates the components of motions that can be transmitted through the contact interface. The introduction of this matrix makes it easy to model the contact mechanics in analysis using the dual kinematic relationship between force/moment and motion, as described in Table 27.1. For example, the constraint filter matrix in (27.12) describes that all three components of forces and one component of the moment with respect to the normal of contact can be transmitted through the contact interface of a soft finger.

In Chap. 28, when multiple contacts are considered, such \mathbf{H} matrices associated with each finger can be con-

Table 27.1 Duality of the kinematics of contact interface. The force/motion relationships for finger and grasped object are dual to each other in the joint space, contact interface, and the Cartesian space of the object. In this table, the notation of θ , x_f , x_p , and x_b are the displacement in the joint space, the Cartesian space at the contact point on the finger, the Cartesian space at the contact point on the object, and the reference frame on the object, respectively, with x_{tr} denoting the transmitted components. The δ prefix denotes infinitesimal changes in the named coordinates. The forces with corresponding subscripts are referenced to the corresponding coordinates as those of the displacement described above

catenated in an augmented matrix to work in conjunction with the grasp and Jacobian matrices for the analysis of grasping and manipulation.

Table 27.1 summarizes the dual relationship between the force/moment and displacement – a result that is derived from the principle of virtual work. In Table 27.1, J_θ

is the joint Jacobian matrix relating joint velocities to fingertip velocities, and J_c is the Cartesian coordinate transformation matrix relating the contact point with the centroidal coordinates of the grasped object. In addition, the number of degrees of freedom (DOFs) in the task space is n and the number of DOFs in the joint spaces is m .

27.4 Rigid-Body Mechanics with Friction

The manipulation planning problem is to choose the motions or forces applied by manipulator contacts so that the part (or parts) moves as desired. This requires solving the subproblem of determining the motion of parts given a particular manipulator action.

Let $q \in \mathbb{R}^n$ be local coordinates describing the combined configuration of the system consisting of one or more parts and robot manipulators, and let $w_i \in \mathbb{R}^6$ represent a wrench at an active contact i , measured in the common coordinate frame O . Let $w_{all} \in \mathbb{R}^{6k}$ be the vector obtained by stacking the w_i , $w_{all} = (w_1^\top w_2^\top \dots w_k^\top)^\top$ (where there are k contacts), and let $A(q) \in \mathbb{R}^{n \times 6k}$ be a matrix indicating how (or if) each contact wrench acts on each part. (Note that a contact wrench w_i acting on one part means that there is a contact wrench $-w_i$ acting on the other part in contact.) The problem is to find the contact forces w_{all} and the system acceleration \ddot{q} , given the state of the system (q, \dot{q}) , the system mass matrix $M(q)$ and resulting Coriolis matrix $C(q, \dot{q})$, the gravitational forces $g(q)$, the control forces τ , and the matrix $T(q)$ indicating how the control forces τ act on the system. (Alternatively, if we view the manipulators as position controlled, the manipulator components of \dot{q} can be directly specified and the corresponding components of the control forces τ solved for.) One way to solve this problem is to (a) enumerate the set of all possible

contact modes for the current active contacts, and (b) for each contact mode, determine if there are wrenches w_{all} and accelerations \ddot{q} that satisfy the dynamics

$$A(q)w_{all} + T(q)\tau - g(q) = M(q)\ddot{q} + C(q, \dot{q})\dot{q} \quad (27.14)$$

and that are consistent with the contact mode's kinematic constraints (constraints on \ddot{q}) and friction cone force constraints (constraints on w_{all}). This formulation is quite general and applies to multiple parts in contact. Equation (27.14) may be simplified by appropriate representations of the configurations and velocities of rigid-body parts (for example, using angular velocities of the rigid bodies instead of derivatives of local angular coordinates).

This formulation leads to some surprising conclusions: there may be multiple solutions to a particular problem (ambiguity) or there may be no solutions (inconsistency) [27.7–14]. This strange behavior arises from the status of Coulomb's law as an approximate law, and it disappears for zero friction, or friction that is small enough. Despite this weakness of the Coulomb friction law, it is a useful approximation. Nonetheless, if we would like to prove (under the Coulomb model) that a particular desired part motion occurs, we generally must also show that no other motion can occur. Other-

wise we have only shown that the desired motion is one of the possible outcomes.

27.4.1 Complementarity

The conditions that each contact provides an equal number of motion constraints and wrench freedoms (Sect. 27.3.2) can be written as *complementarity* conditions. Thus the problem of solving (27.14), subject to contact constraints, can be formulated as a complementarity problem (**CP**) [27.12, 13, 43–46]. For planar problems, or spatial problems with approximate pyramidal friction cones, the problem is a linear complementarity problem [27.47]. For circular spatial friction cones, the problem is a nonlinear complementarity problem, due to the quadratic constraints describing the cones. In either case, standard algorithms can be used to solve for possible contact modes and part motions.

Alternatively, assuming linearized friction cones, we can formulate a linear constraint satisfaction program (**LCSP**) for each contact mode (e.g., a linear program with no objective function). The contact mode places linear constraints on the part accelerations, and the solver solves for the part accelerations and the nonnegative coefficients multiplying each of the edges of the friction cones, subject to the dynamics (27.14). Each **LCSP** with a feasible solution represents a feasible contact mode.

27.4.2 Quasistatic Assumption

A common assumption in robot manipulation planning is the *quasistatic* assumption. This assumption says that parts move slowly enough that inertial effects are negligible. This means that the right- and left-hand sides of (27.14) are zero. With this assumption, we often solve for part *velocities* rather than accelerations. These velocities must be consistent with the kinematic constraints and force constraints, and forces acting on the parts must always sum to zero.

27.4.3 Examples

While rigid-body mechanics problems with friction are usually solved using computational tools for **CPs** and **LCSPs**, equivalent graphical methods can be used for some planar problems to assist the intuition. As a simple example, consider the pipe clamp in Fig. 27.6 [27.14]. Under the external wrench \mathbf{w}_{ext} , does the clamp slide down the pipe, or does it remain fixed in place? The figure uses moment labeling to represent the composite wrench cone of contact forces that can act on the

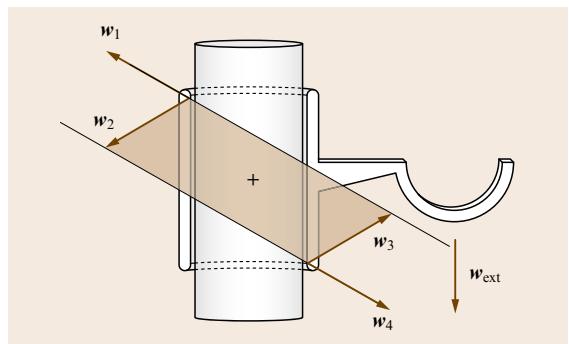

Fig. 27.6 The moment-labeling representation of the composite wrench cone of contact forces the pipe can apply to the pipe clamp. In this figure, the wrench \mathbf{w}_{ext} applied to the pipe clamp can be resisted by forces within the composite wrench cone

clamp from the pipe. The wrench \mathbf{w}_{ext} acting on the clamp can be exactly balanced by a wrench in the composite wrench cone. This is evident from the fact that the wrench opposing \mathbf{w}_{ext} passes around the '+' labeled region in a counterclockwise sense, meaning that it is contained in the contact wrench cone. As a result, static equilibrium (the **ff** contact mode) is a feasible solution for the pipe clamp. To arrive at the same result using an **LCSP**, label the unit wrenches at the edges of the friction cones $\mathbf{w}_1, \dots, \mathbf{w}_4$. Then the clamp can remain at rest if there exist coefficients a_1, \dots, a_4 such that

$$\begin{aligned} a_1, a_2, a_3, a_4 &\geq 0, \\ a_1 \mathbf{w}_1 + a_2 \mathbf{w}_2 + a_3 \mathbf{w}_3 + a_4 \mathbf{w}_4 + \mathbf{w}_{\text{ext}} &= 0. \end{aligned}$$

To show that static equilibrium is the only solution, all other contact modes must be ruled out. Note that, if the friction coefficient at the contacts is too small, the clamp will fall under \mathbf{w}_{ext} .

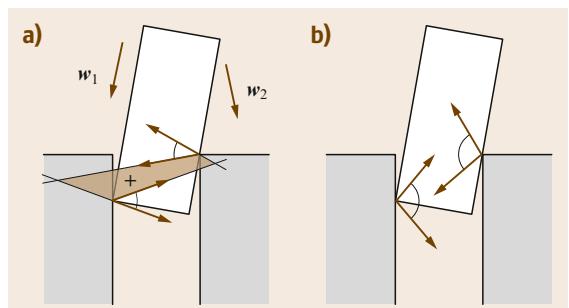

Fig. 27.7 (a) The peg will proceed into the hole under the external wrench \mathbf{w}_1 but will get stuck under the wrench \mathbf{w}_2 . (b) The peg is wedged

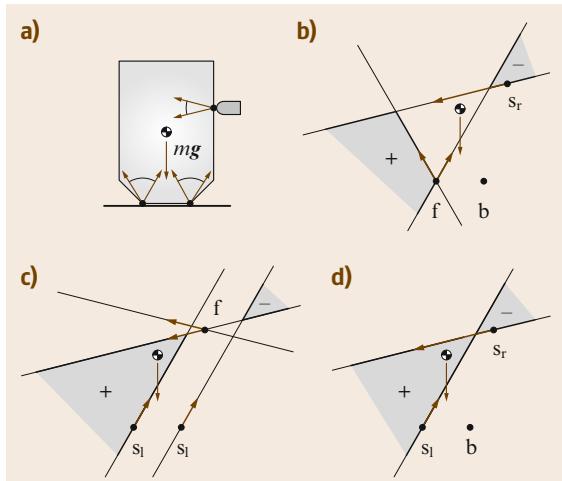

Fig. 27.8 (a) A finger moves *left* into a planar block resting on a table in gravity. The contact friction cones are shown. (b) Possible contact forces for the contact label f at the leftmost bottom contact, b at the rightmost bottom contact, and r at the pushing contact. This contact mode f_{blr} corresponds to the block tipping over the leftmost contact. Note that the contact wrench cone (represented by moment labels) can provide a force that exactly balances the gravitational force. Thus this contact mode is quasistatically possible. (c) The contact wrench cone for the $11f$ contact mode (block slides *left* on the table) cannot balance the gravitational force. This contact mode is not quasistatically possible. (d) The contact wrench cone for the $1br$ contact mode (block slides and tips) is not quasistatically possible

Analysis of the classic peg-in-hole problem is similar to that of the pipe clamp. Figure 27.7a shows an angled peg making two-point contact with the hole. If we apply the wrench w_1 , the forces from the two-point contact cannot resist, so the ff mode contact mode is not a possibility, and the peg will continue to move into the hole. If we apply the wrench w_2 , however, the contacts can resist, and the peg will get stuck. This is called *jamming* [27.48]. If there is higher friction at the contacts, as in Fig. 27.7b, then each friction cone may be able to see the base of the other, and the feasible contact wrenches span the entire wrench space [27.49]. In this case, any wrench we apply may be resisted by the contacts. The peg is said to be *wedged* [27.48]. Whether or not the peg will actually resist our applied wrench depends on how much internal force acts between the contacts. This cannot be answered by our rigid-body model; it requires a compliant contact model, as discussed in Sect. 27.6.

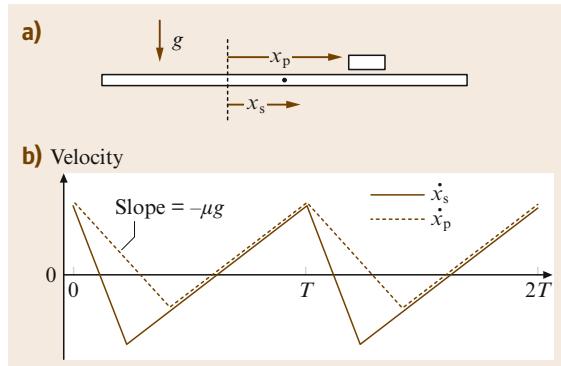

Fig. 27.9 (a) A part supported by a horizontally vibrating surface. (b) Friction between the part and the surface causes the part to always try to catch up to the surface, but its acceleration is bounded by $\pm\mu g$. The asymmetric motion of the surface gives the part an average positive velocity over a cycle

As a slightly more complex quasistatic example, consider a block on a table being pushed by a finger that moves horizontally to the left (Fig. 27.8) [27.50, 51]. Does the part begin to tip over, slide, or both tip and slide? The corresponding contact modes are f_{bsr} , $s_l s_l f$, and $s_1 b s_r$, as shown in Fig. 27.8. The figure also shows the composite contact wrench cones using moment labels. It is clear that quasistatic balance between the gravitational force and the contact wrench cone can only occur for the tipping without slipping contact mode f_{bsr} . Therefore, the only quasistatic solution is that the block begins to tip without sliding, and the speed of this motion is determined by the speed of the finger's motion. The graphical construction can be used to confirm our intuition that tipping of the block occurs if we push high on the block or if the friction coefficient at the block's support is high. Try it by pushing a can or glass. Quasistatically, the height of the center of mass is immaterial.

A final example is given in Fig. 27.9. A part of mass m and friction coefficient μ is supported by a horizontal surface that moves periodically in the horizontal direction. The periodic motion consists of a large negative acceleration for a short duration and a smaller positive acceleration for a longer duration. The horizontal friction force that can be applied to the part is bounded by $\pm\mu mg$, so the part's horizontal acceleration is bounded by $\pm\mu g$. As a result, the part cannot keep up with the surface as it accelerates backward. Instead, the part slips forward with respect to the surface, which means that the maximal friction force acts in the negative direction, and the part attempts to slow down to the surface's ve-

lacity. Eventually the part catches up with the surface as it executes its slow forward acceleration, which is less than μg . Once the part catches up to the surface, it sticks to it, until the next backward acceleration phase. As is evident in Fig. 27.9, the average part velocity over a cycle is positive, so the part moves forward on the surface [27.52, 53]. This idea can be extended to cre-

ate a wide variety of frictional force fields on a rigid plate vibrated with three degrees of freedom in a horizontal plane [27.54, 55] or with a full six degrees of freedom [27.56].

For further examples of manipulation planning using the rigid-body model with Coulomb friction, see [27.14] and the references therein.

27.5 Pushing Manipulation

The friction limit surface (Sect. 27.7) is useful for analyzing pushing manipulation, as it describes the friction forces that can occur as a part slides over a support surface. When the part is pushed with a wrench contained within the limit surface, friction between the part and the support resists the pushing wrench and the part remains motionless. When the part slides quasistatically, the pushing wrench w lies on the limit surface, and the part's twist t is normal to the limit surface at w (Fig. 27.10). When the part translates without rotating, the friction force magnitude is μmg , where m is the part's mass and g is gravitational acceleration. The force applied by the part to the surface is directed through the part's center of mass in the direction of translation.

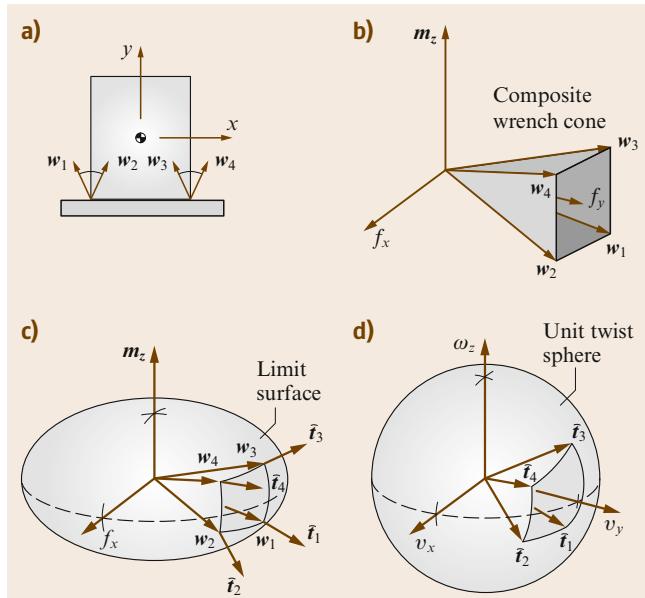

Fig. 27.10 (a) Contact between a pusher and a sliding object. (b) The composite contact wrench cone. (c) Mapping the wrench cone through the limit surface to twists of the object. (d) The unit twists that can result from forces in the composite wrench cone

If the pushing wrench makes positive moment about the part's center of mass, the part will rotate counter-clockwise (CCW), and if it makes negative moment

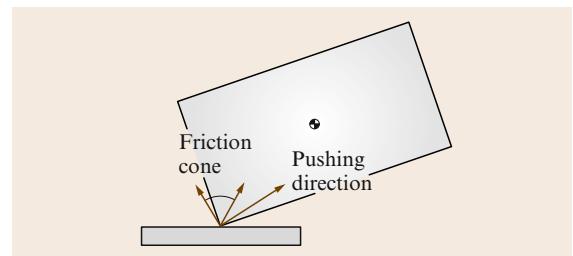

Fig. 27.11 The pusher's motion direction votes for counter-clockwise rotation of the part, but it is outvoted by the two edges of the friction cone, which both indicate clockwise rotation

Fig. 27.12 Stable pushes can be used to maneuver a part among obstacles

about the part's center of mass, it will rotate clockwise (**CW**). Similarly, if the contact point on the part moves along a line that passes around the part's center of mass in a **CW** (respectively, **CCW**) sense, then the part will rotate **CW** (**CCW**). From these two observations and considering all possible contact modes, we can conclude that a part pushed at a point contact will rotate **CW** (**CCW**) if either (1) both edges of the contact friction cone pass **CW** (**CCW**) about the center of mass, or (2) one edge of the friction cone and the pushing direction at the contact both pass around the center of mass in a **CW** (**CCW**) sense [27.14, 57], (Fig. 27.11).

This observation allows pushing to be used to reduce uncertainty in part orientation. A series of pushes with a flat fence can be used to completely eliminate the uncertainty in the orientation of a polygonal

part [27.57–59]. Bounds on the rate of rotation of parts [27.14, 60, 61] allow the use of a sequence of stationary fences suspended above a conveyor belt to orient parts by pushing them as they are carried along by the conveyor [27.62, 63]. *Stable* pushing plans (Fig. 27.12) use pushing motions that are guaranteed to keep the part fixed to the pusher as it moves, even in the face of uncertainty in the part's pressure distribution [27.14, 64, 65]. Extensions of this work find pushing motions for planar assemblies of parts so that they remain fixed in their relative configurations during motion [27.66–68].

The examples above assume that pushing forces and support friction forces act in the same plane. Other work on pushing has considered three-dimensional effects, where pushing forces are applied above the support plane [27.69].

27.6 Contact Interfaces and Modeling

Contact interface is a general expression to describe the kinematics and kinetics of contacts. Contact applies in various contexts in robotics research; thus, it is more meaningful to refer to generic contact as an *interface*, which is not limited to fingers in grasping and manipulation. The concept of *contact interface* extends the traditional context of physical *contact*. It refers to an interface which imparts kinematic filtering as well as the duality of force/motion transmitted across the contact interface.

Consequently, a contact interface, whether it is rigid or deformable, can be considered as a *kinematic filter* which includes two characteristics: (a) motion and force transmission, and (b) kinematic duality between force/moment and motion. Different contact interfaces will be described in the following sections.

Previous sections of this chapter have assumed rigid bodies in contact. In reality, however, all contacts are accompanied by some deformation of the objects. Often this is by design, as in the case of compliant robot fingertips. When deformation is non-negligible, elastic contact models can be used.

27.6.1 Modeling of Contact Interface

Contact modeling depends on the nature of bodies in contact, including their material properties, applied force, contact deformation, and elastic properties. This section discusses different contact models.

Rigid-Body and Point-Contact Models

With the rigid-body assumption, as discussed in the previous sections of this chapter, two models are often used: (a) *point contact without friction* and (b) *point contact with friction*. In the former case, the contact can only apply force in the direction normal to the contact. In the latter case, a tangential friction force is applied in addition to the normal force. The simplest analytical model for point contact with friction is the Coulomb friction model as presented in (27.9).

Hertzian Contact Model

Elastic contact modeling was first studied and formulated more than a century ago by Hertz in 1882 [27.70] based on contact between two linear elastic materials with a normal force which results in very small contact deformation. This is commonly called the *Hertzian* contact and can be found in most mechanics textbooks, such as [27.71, 72]. Hertz made two important explicit assumptions in order for his contact model to be applicable:

1. objects of linear elastic materials in contact
2. small contact deformation compared to the dimension of object

Hertz also conducted experiments using a spherical glass lens against a planar glass plate to validate the contact theory.

Two relevant results of the Hertzian contact theory applied to robotic contact interfaces are summarized as follows. The first pertains to the radius of the contact area. Hertz [27.70] studied the growth of the contact area as a function of the applied normal force N based on the linear elastic model. Based on ten experimental trials, he concluded that the radius of contact is proportional to the normal force raised to the power of $1/3$, which is consistent with the analytical results he derived based on the linear elastic model. That is, the radius of contact, a , is related to the normal force, N , by

$$a \propto N^{1/3}. \quad (27.15)$$

The second result pertains to the pressure distribution over the assumed symmetric contact area – a second-order pressure distribution of the nature of an ellipse or circle. For a symmetric and circular contact area, the pressure distribution is

$$p(r) = \frac{N}{\pi a^2} \sqrt{1 - \left(\frac{r}{a}\right)^2}, \quad (27.16)$$

where N is the normal force, a is the radius of contact, and r is the distance from the center of contact with $0 \leq r \leq a$.

Soft Contact Model

A typical contact interface between a soft finger and contact surface is illustrated in Fig. 27.13. In typical robotic contact interfaces, the materials of the fingertips are not linear elastic. A model that extends linear to nonlinear elastic contact was presented in [27.38] with a power-law equation which subsumes the Hertzian contact theory,

$$a = c N^\gamma, \quad (27.17)$$

where $\gamma = n/(2n + 1)$ is the exponent of the normal force, n is the strain-hardening exponent, and c is a constant depending on the size and curvature of the fingertip

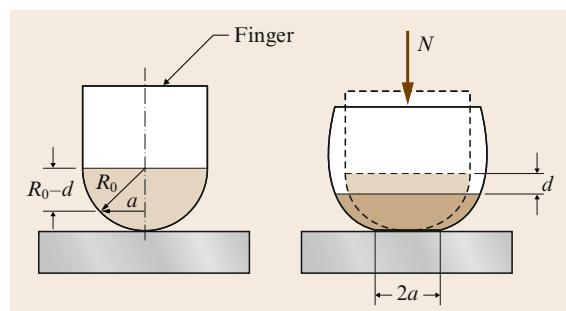

Fig. 27.13 An elastic soft fingertip with a hemispherical tip making contact with a rigid surface

as well as the material properties. Equation (27.17) is the new power law that relates the growth of the circular contact radius to the applied normal force for soft fingers. Note that the equation is derived assuming circular contact area. For linear elastic materials, the constant n is equal to 1 with $\gamma = 1/3$, resulting in the Hertzian contact model in (27.15). Therefore, the soft contact model in (27.17) subsumes the Hertzian contact model.

Other Models

Other models include anthropomorphic contacts and viscoelastic contacts. In modeling viscoelastic contacts, the creep or relaxation phenomenon is incorporated with a time-dependent function, in addition to the elastic deformation described in the general (27.17).

27.6.2 Pressure Distribution at Contacts

In Sect. 27.6.1, when the Hertzian contact theory is considered, the assumed pressure distribution for small elastic deformation is given in (27.16). As the radius of curvature of the two asperities increases and the material properties change to hyperelastic, the pressure distribution becomes more uniform [27.38, 73, 74]. Generalizing equation (27.16), the pressure distribution function for circular contact area with radius a is

$$p(r) = C_k \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a}\right)^k \right]^{\frac{1}{k}}, \quad (27.18)$$

where N is the normal force, a is the radius of contact, r is the radius with $0 \leq r \leq a$, k determines the shape of the pressure profile, and C_k is a coefficient that adjusts for the profile of pressure distribution over the contact area to satisfy the equilibrium condition. In (27.18), $p(r)$ is defined for $0 \leq r \leq a$. By symmetry, $p(r) = p(-r)$ when $-a \leq r \leq 0$, as shown in Fig. 27.14. When k becomes larger, the pressure distribution approaches uniform distribution, as shown in Fig. 27.14. It is also required that the integral of the pressure over the contact area be equal

Table 27.2 Values of the coefficient C_k in the pressure distribution (27.18),

| k | Coefficient C_k |
|----------------------------------|-------------------|
| $k = 2$ (circular) | $C_2 = 1.5$ |
| $k = 3$ (cubic) | $C_3 = 1.24$ |
| $k = 4$ (quadruple) | $C_4 = 1.1441$ |
| $k \rightarrow \infty$ (uniform) | $C_\infty = 1.0$ |

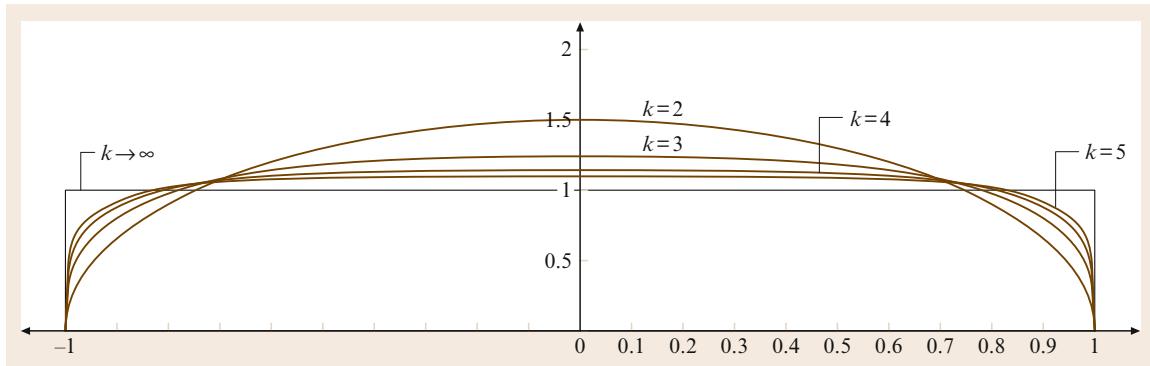

Fig. 27.14 Illustration of pressure distribution with respect to the normalized radius, r/a . The plot shows an axisymmetric pressure distribution with $k = 2, 3, 4, 5$, and ∞ . As k increases, the pressure profile becomes more uniform

to the normal force; that is,

$$\int_R p(r) dA = \int_{\theta=0}^{2\pi} \int_{r=0}^a p(r) r dr d\theta = N. \quad (27.19)$$

The coefficient C_k can be obtained by substituting (27.18) into (27.19). It is interesting to note that when (27.19) is integrated, both the normal force and radius of contact vanish, leaving only the constant C_k as follows

$$C_k = \frac{3}{2} \frac{k \Gamma(\frac{3}{k})}{\Gamma(\frac{1}{k}) \Gamma(\frac{2}{k})}, \quad (27.20)$$

where $k = 1, 2, 3, \dots$ are typically integer values (although noninteger k values are also possible) and $\Gamma()$ is the gamma function [27.75]. The numerical values of C_k for a few values of k are listed in Table 27.2 for reference. A normalized pressure distribution with respect to the normalized radius, r/a , is plotted in Fig. 27.14. As can be seen from the figure, when k approaches infinity, the pressure profile will become that of a uniformly distributed load with magnitude of $N/(\pi a^2)$, in which case $C_k = 1.0$.

For linear elastic materials, $k = 2$ can be used, although it is found that $k \approx 1.8$ is also appropriate in some cases [27.76]. For nonlinear elastic and viscoelastic materials, the value of k tends to be higher, depending on the properties of the material.

27.7 Friction Limit Surface

Section 27.3 introduced the notion of a wrench cone, describing the set of wrenches that can be applied through a point contact with friction. Any contact wrench is limited to lie within the surface of the cone. This gives rise to the general notion of a *friction limit surface* – the surface bounding the set of wrenches that can be applied through a given contact or set of contacts.

In this section we study the particular case of limit surfaces arising from planar contact patches [27.77, 78]. A planar contact patch occurs when a flat object slides on the floor, a soft robot finger presses against a face of a polyhedron, or a foot of a humanoid robot pushes on the ground. We would like to know what wrenches can be transmitted through such a contact. In the rest of this section, we focus on the properties of the limit sur-

face of a planar contact patch with a specified pressure distribution over the patch.

For ease of discussion, we will call one of the objects in contact the *part* (e.g., the flat object on the floor or the robot finger) and the other object a stationary *support*. We define a coordinate frame so that the planar contact patch is in the $z = 0$ plane, and let $p(\mathbf{r}) \geq 0$ be the contact pressure distribution between the part and support as a function of the location $\mathbf{r} = (x, y)^\top$. The friction coefficient at the contact patch is μ . If the planar velocity of the part is $\mathbf{t} = (\omega_z, v_x, v_y)^\top$, then the linear velocity at \mathbf{r} is

$$\mathbf{v}(\mathbf{r}) = (v_x - \omega_z y, v_y + \omega_z x)^\top,$$

and the unit velocity is $\hat{\mathbf{v}}(\mathbf{r}) = \mathbf{v}(\mathbf{r}) / \|\mathbf{v}(\mathbf{r})\|$. The infinitesimal force applied by the part to the support at \mathbf{r} , in the

plane of sliding, is

$$d\mathbf{f}(\mathbf{r}) = [d\mathbf{f}_x(\mathbf{r}), d\mathbf{f}_y(\mathbf{r})]^\top = \mu p(\mathbf{r}) \hat{\mathbf{v}}(\mathbf{r}). \quad (27.21)$$

The total wrench the part applies to the support is

$$\begin{aligned} \mathbf{w} &= \begin{pmatrix} m_z \\ f_x \\ f_y \end{pmatrix} \\ &= \int_A \begin{pmatrix} x d\mathbf{f}_y(\mathbf{r}) - y d\mathbf{f}_x(\mathbf{r}) \\ d\mathbf{f}_x(\mathbf{r}) \\ d\mathbf{f}_y(\mathbf{r}) \end{pmatrix} dA, \end{aligned} \quad (27.22)$$

where A is the support area.

As expected, the wrench is independent of the speed of motion: for a given t_0 and all $\alpha > 0$, the wrench resulting from velocities αt_0 is identical. Viewing (27.22) as a mapping from twists to wrenches, we can map the surface of the unit twist sphere ($\|\hat{\mathbf{t}}\| = 1$) to a surface in the wrench space. This surface is the limit surface, and it is closed, convex, and encloses the origin of the wrench space (Fig. 27.15c). The portion of the wrench space enclosed by this surface is exactly the set of wrenches the part can transmit to the support. When the part slips on the support ($t \neq 0$), the contact wrench \mathbf{w} lies on the limit surface, and by the maximum-work inequality, the twist \mathbf{t} is normal to the limit surface at \mathbf{w} . If the pressure distribution $p(\mathbf{r})$ is finite everywhere, the limit surface is smooth and strictly convex, and the mapping from unit twists to unit wrenches, and vice versa, is continuous and one-to-one. The limit surface also satisfies the property $\mathbf{w}(-\hat{\mathbf{t}}) = -\mathbf{w}(\hat{\mathbf{t}})$.

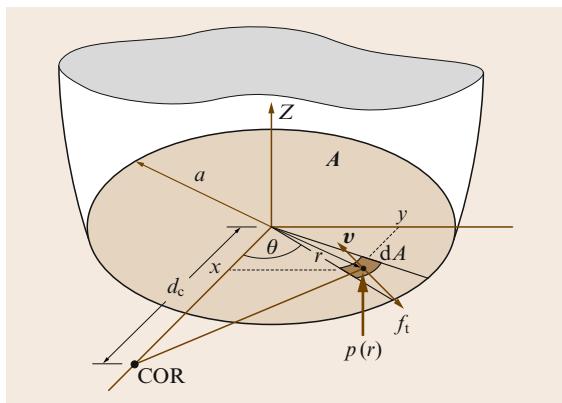

Fig. 27.15 Contact and coordinates for CoR and local infinitesimal area dA for numerical integration to construct the limit surface of soft fingers

27.7.1 The Friction Limit Surface at a Soft Contact Interface

Given a pressure distribution in (27.18) we can numerically construct the corresponding friction limit surface by using (27.21) and (27.22). For an infinitesimal contact area, the contact resembles a point contact. Hence, the Coulomb's law of friction can be employed.

In the following, we will exploit the kinematic property of center of rotation (CoR) with modeling symmetry to formulate equations for the magnitudes of friction force and moment on a circular contact patch. Figure 27.15 shows a circular contact patch with an instantaneous CoR. By moving (or scanning) the CoR along the x -axis, different possible combinations of friction force and moment can be obtained to construct the limit surface. More details can be found in [27.35–38, 42, 77–80].

The following derivation is for the total friction force (f_t) and moment (m_z) on the contact interface for the CoR at a distance d_c along the x -axis, as shown in Fig. 27.15. By varying the CoR distance d_c from $-\infty$ to ∞ , all possible combinations of (f_t, m_z) can be found in order to construct the entire friction limit surface.

The tangential force over the entire contact area can be obtained by integrating shear force on each infinitesimal areas, dA , on which the Coulomb's law of friction is observed, over the entire contact area, A . When Hertzian contact pressure distribution [27.70] is considered, use $k = 2$ in (27.18). Setting $\mathbf{r} = (x, y)^\top$ and $r = \|\mathbf{r}\|$, the total tangential force can be integrated using (27.21) to obtain

$$\mathbf{f}_t = \begin{pmatrix} f_x \\ f_y \end{pmatrix} = - \int_A \mu \hat{\mathbf{v}}(\mathbf{r}) p(r) dA, \quad (27.23)$$

where A denotes the circular contact region in Fig. 27.15, \mathbf{f}_t is the tangential force vector with the direction shown in Fig. 27.15, μ is the coefficient of friction, $\hat{\mathbf{v}}(\mathbf{r})$ is the unit vector in the direction of the velocity vector $\mathbf{v}(\mathbf{r})$ with respect to the CoR on the infinitesimal area dA at the location \mathbf{r} , and $p(r)$ is the pressure distribution at distance r from the center of contact. Since the pressure along the annular ring with distance r from the center is the same, we denote it by $p(r)$ instead of $p(\mathbf{r})$. The minus sign denotes the opposite directions of $\hat{\mathbf{v}}(\mathbf{r})$ and \mathbf{f}_t . Since we are primarily interested in the magnitude of the friction force and moment, we shall omit this sign in the later derivation when magnitudes are concerned.

Similarly, the moment about the z -axis, or the normal to the contact area, is

$$m_z = \int_A \mu \|\mathbf{r} \times \hat{\mathbf{v}}(\mathbf{r})\| p(r) dA, \quad (27.24)$$

where $\|\mathbf{r} \times \hat{\mathbf{v}}(\mathbf{r})\|$ is the magnitude of the cross product of the vectors \mathbf{r} and $\hat{\mathbf{v}}(\mathbf{r})$, whose direction is normal to the contact surface.

The unit vector $\hat{\mathbf{v}}(\mathbf{r})$ is related to the distance d_c from the origin to the CoR chosen on the x -axis from Fig. 27.15, and can be written as follows

$$\begin{aligned} \hat{\mathbf{v}}(\mathbf{r}) &= \frac{1}{\sqrt{(x-d_c)^2+y^2}} \begin{bmatrix} -y \\ x-d_c \end{bmatrix} \\ &= \frac{1}{\sqrt{(r \cos \theta - d_c)^2 + (r \sin \theta)^2}} \\ &\times \begin{bmatrix} -r \sin \theta \\ r \cos \theta - d_c \end{bmatrix}. \end{aligned} \quad (27.25)$$

Due to symmetry, $f_x = 0$ for all CoRs along the x -axis; therefore, the magnitude of the tangential force in the contact tangent plane is $f_t = f_y$. Substituting equations (27.18) and (27.25) into (27.23) and (27.24), we obtain

$$\begin{aligned} f_t &= \int_A \mu \frac{(r \cos \theta - d_c)}{\sqrt{r^2 + d_c^2 - 2rd_c \cos \theta}} C_k \\ &\times \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}} dA. \end{aligned} \quad (27.26)$$

Similarly, the moment about the axis normal to the plane is

$$\begin{aligned} m_z &= \int_A \mu \frac{r^2 - r d_c \cos \theta}{\sqrt{r^2 + d_c^2 - 2rd_c \cos \theta}} C_k \\ &\times \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}} dA. \end{aligned} \quad (27.27)$$

In (27.26) and (27.27), polar coordinates are defined such that $x = r \cos \theta$, $y = r \sin \theta$, and $dA = r dr d\theta$. We also introduce a normalized coordinate

$$\tilde{r} = \frac{r}{a}. \quad (27.28)$$

From (27.28), we can write $dr = a d\tilde{r}$. We also denote $\tilde{d}_c = d_c/a$, and assume that μ is constant throughout the contact area. Substituting the normalized coordinate into equation (27.26) and dividing both sides by μN , we

can derive

$$\begin{aligned} \frac{f_t}{\mu N} &= \frac{C_k}{\pi} \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^2 \cos \theta - \tilde{r} \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \\ &\times (1 - \tilde{r}^k)^{\frac{1}{k}} d\tilde{r} d\theta. \end{aligned} \quad (27.29)$$

Substituting again $\tilde{r} = r/a$ and $dr = a d\tilde{r}$ into (27.27) and normalizing with $a\mu N$, we obtain

$$\begin{aligned} \frac{m_z}{a\mu N} &= \frac{C_k}{\pi} \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^3 \cos \theta - \tilde{r}^2 \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \\ &\times (1 - \tilde{r}^k)^{\frac{1}{k}} d\tilde{r} d\theta. \end{aligned} \quad (27.30)$$

Equations (27.29) and (27.30) can be numerically integrated for a distance d_c or \tilde{d}_c to yield a point on the limit surface for a prescribed pressure distribution $p(r)$ given by (27.18). Both equations involve elliptic integrals whose closed-form solutions may not exist but can be evaluated numerically. When the CoR distance d_c varies from $-\infty$ to ∞ , all possible combinations of (f_t, m_z) can be obtained for plotting the friction limit surface.

27.7.2 Example of Constructing a Friction Limit Surface

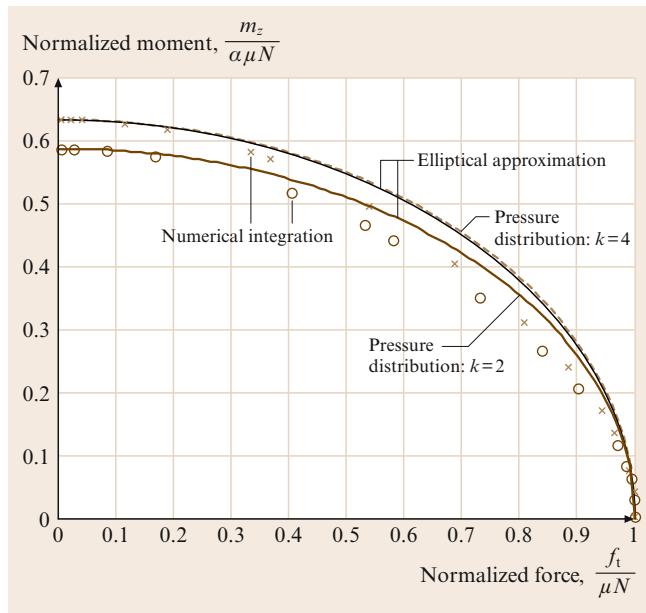

When the pressure distribution is fourth order with $k = 4$, the coefficient from Table 27.2 is $C_4 = (6/\sqrt{\pi})(\Gamma(3/4)/\Gamma(1/4)) = 1.1441$. Equations (27.29) and (27.30) can be written as

$$\begin{aligned} \frac{f_t}{\mu N} &= 0.3642 \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^2 \cos \theta - \tilde{r} \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \\ &\times (1 - \tilde{r}^4)^{\frac{1}{4}} d\tilde{r} d\theta. \\ \frac{m_z}{a\mu N} &= 0.3642 \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^3 \cos \theta - \tilde{r}^2 \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \\ &\times (1 - \tilde{r}^4)^{\frac{1}{4}} d\tilde{r} d\theta. \end{aligned}$$

Numerical integration for different values of \tilde{d}_c yields pairs of $(f_t/(\mu N), m_z/(a\mu N))$. Plots of these pairs are shown in Fig. 27.16.

A reasonable approximation to these numerical results is given by the following equation of an ellipse

$$\left(\frac{f_t}{\mu N} \right)^2 + \left(\frac{m_z}{(m_z)_{\max}} \right)^2 = 1, \quad (27.31)$$

where the maximum moment $(m_z)_{\max}$ is

$$(m_z)_{\max} = \int_A \mu |r| C_k \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}} dA. \quad (27.32)$$

obtained by (27.27) with the CoR at $d_c = 0$. This defines the quarter-elliptical curves in Fig. 27.16. This approximation is the basis for constructing a three-

Fig. 27.16 Example limit surface obtained by numerical integration and elliptical approximation. The numerical integration is based on the pressure distribution, $p(r)$, and the coefficient, C_k . In this figure, the pressure distributions in (27.18) of both $k = 2$ and $k = 4$ are used

◀

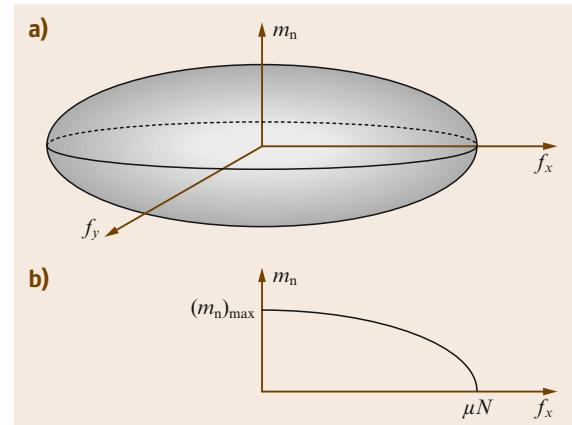

Fig. 27.17a,b Friction limit surface for soft fingers: (a) a 3-D ellipsoid representing the limit surface, and (b) a section of the ellipsoidal limit surface showing the coupled relationship between the force and moment

dimensional (3-D) ellipsoidal limit surface, as illustrated in Fig. 27.17, and is a good model for the soft contact described in Sect. 27.6.1. More details can be found in [27.35–37, 39, 40, 42, 78].

27.8 Contacts in Grasping and Fixture Designs

It is often important to relate the force and contact displacement (or deformation of contact interface) in grasping and fixture design in which deformable contacts are concerned. Furthermore, such a force-displacement relationship is typically nonlinear due to the nature of contact. A linear expression such as Hooke's law cannot capture the instantaneous and overall characteristics of force and displacement for these contacts. In this section, we formulate and discuss such a relationship using the elastic contact model.

From Fig. 27.13 and the geometry of contact, (27.17), relating the contact radius with normal force, can be rewritten. Assuming $d \ll R_0$, the following equation can be derived [27.39]

$$N = c_d d^\zeta, \quad (27.33)$$

where c_d is a proportional constant, and ζ is

$$\zeta = \frac{1}{2\gamma}. \quad (27.34)$$

Both c_d and ζ can be obtained experimentally. The exponent ζ can also be obtained from γ through (27.34) if γ is already known for the fingertip. The range of the exponent in (27.33) is $\frac{3}{2} \leq \zeta < \infty$. In (27.33), the approach or the vertical depression of the fingertip, d , is proportional to the normal force raised to the power of 2γ (cf. (27.34)) which ranges from 0 to $2/3$.

A plot of normal force versus displacement of contact is shown in Fig. 27.18 using (27.33) with a nonlinear power-law equation. Experimental data of contact between a soft finger and flat surface show consistent results when compared with Fig. 27.18 [27.39].

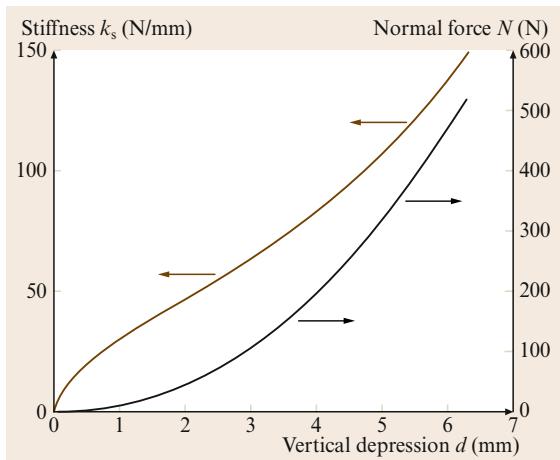

Fig. 27.18 The typical load-depression curve in (27.33) shown with a scale to the right, and the contact stiffness, k_s , as given by (27.35) with a scale to the left

27.8.1 Contact Stiffness of Soft Fingers

The nonlinear contact stiffness of a soft finger is defined as the ratio of the change in normal force with respect to the change in vertical depression at the contact. The contact stiffness of soft fingers can be obtained by differentiating (27.33) as follows

$$k_s = \frac{\partial N}{\partial d} = c_d \zeta d^{\zeta-1} = \zeta \left(\frac{N}{d} \right). \quad (27.35)$$

Substitute (27.33) with $d = \left(\frac{N}{c_d} \right)^{1/\zeta}$ into (27.35) to derive

$$k_s = c_d^{\frac{1}{\zeta}} \zeta N^{\frac{\zeta-1}{\zeta}} = c_d^{2\gamma} \zeta N^{1-2\gamma}. \quad (27.36)$$

Thus, the nonlinear contact stiffness of soft fingers, derived in a succinct form in (27.35), is the product of the exponent ζ and the ratio of the normal force versus the approach, N/d . A typical contact stiffness as a function of vertical depression is plotted in Fig. 27.18. The stiffness shown in the figure increases with the force. The expressions for the stiffness, k_s , as a function of various parameter(s) are summarized in the following Table 27.3.

Table 27.3 Summary of equations of contact stiffness

| | $f(d)$ | $f(N)$ | $f(N, d)$ |
|-------|-------------------------|---------------------------------------------------------|------------------------------------|
| k_s | $c_d \zeta d^{\zeta-1}$ | $c_d^{\frac{1}{\zeta}} \zeta N^{\frac{\zeta-1}{\zeta}}$ | $\zeta \left(\frac{N}{d} \right)$ |

The change in stiffness can be obtained by differentiating (27.35) to derive the following equations:

$$\frac{\partial k_s}{\partial d} = c_d \zeta (\zeta - 1) d^{\zeta-2}, \quad (27.37)$$

$$\frac{\partial k_s}{\partial N} = \frac{\zeta - 1}{d}. \quad (27.38)$$

Equation (27.35) suggests that the stiffness of soft contacts always increases because the ratio N/d always increases, with constant ζ for prescribed fingertip material and range of normal force. This is consistent with the observation that the contact stiffness becomes larger (i.e., stiffer) with larger depression and force. Additionally, (27.38) suggests that the contact stiffness k_s always increases with the normal force because $\partial k_s / \partial N > 0$ owing to $\zeta \geq 1.5$. Moreover, the change in stiffness with respect to the normal load is inversely proportional to the vertical depression, d , as derived in (27.38). This result asserts that the rate of increase in the contact stiffness will gradually become less and less as the normal load and vertical depression increase.

A summary of the equations for soft fingers is presented in Table 27.4. The range of the exponent of the general power-law equation in (27.17) is $0 \leq \gamma \leq 1/3$. The Hertzian contact has an exponent of $\gamma = 1/3$; therefore, the Hertzian contact theory for linear elastic materials is a special case of (27.17). Linear elastic materials, such as steel or other metallic fingertips, under small deformation, generally follow the Hertzian contact theory fairly well. The power-law equation in (27.17) should be employed for fingertips made of softer materials, such as soft rubber or silicone or even viscoelastic fingertips.

27.8.2 Application of Soft Contact Theory to Fixture Design

The preceding analysis and results can be applied in fixture design and other applications that involve contact with finite areas [27.6]. In fixture design with soft contacts (e.g., copper surfaces) under relatively large deformation and load, the power-law equations in Table 27.4 should be considered in place of the Hertzian contact equation. In these cases, the Hertzian contact model is no longer accurate and should be replaced. On the other hand, if linear elastic materials are used in fixture design with relatively small deformation ($d/R_0 \leq 5\%$), the exponent should be taken as $\gamma = 1/3$ when applying the contact theory. Furthermore, the exponent γ was found to be material dependent and not geometry dependent in general [27.38]. Once the value of γ is determined

Table 27.4 Summary of the contact mechanics equations for linear elastic (when $\gamma = 1/3$ or $\zeta = 3/2$) and nonlinear elastic soft fingers

| Description | Equation for soft fingers | Parameters |
|-----------------------|-----------------------------------------------------------------------------|--------------------------------------|
| Power law | $a = c N^\gamma$ | $0 \leq \gamma \leq \frac{1}{3}$ |
| Pressure distribution | $p(r) = p(0) \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}}$ | Typically $k \geq 1.8$ |
| Contact approach | $N = c_d d^\zeta$ | $\frac{3}{2} \leq \zeta \leq \infty$ |
| Contact stiffness | $k_s = \zeta \frac{N}{d}$ | Nonlinear |

for the material (for example, using a tensile testing machine with the experimental procedure in [27.38]), it can

be employed for the analysis of fixturing design using the relevant equations presented herewith.

27.9 Conclusions and Further Reading

In this chapter, both rigid-body and elastic models of contact interfaces are discussed, including kinematic constraints and the duality between the contact wrenches and twists. Contact forces that may arise with Coulomb friction are described. Multiple-contact manipulation tasks with rigid-body and Coulomb friction are presented. The friction limit surface is introduced and utilized to analyze pushing problems. An example of constructing a friction limit surface for soft contact is presented based on the formulation of force/moment of soft contact interface. Applications of these contact models in fixture analysis and design are presented with the modeling of contact interface. Many references in the bibliography section of this chapter provide further reading on this subject.

Manipulation modes include grasping, pushing, rolling, batting, throwing, catching, casting, and other kinds of quasistatic and dynamic manipulation [27.81].

This chapter presents an overview of contact modeling interfaces, with a particular focus on their use in manipulation tasks, including graspless or *nonprehensile* manipulation modes such as pushing. Analyses of grasps and fixtures are also presented. *Mason's* textbook [27.14] expands on a number of themes in this chapter, including the theory of polyhedral convex cones, graphical methods for planar problems, and applications to manipulation planning. Fundamental material on polyhedral cones can be found in [27.82] and their application to representations of twists and wrenches in [27.10, 83–85]. Twists and wrenches are elements of classical *screw theory*, which is covered in the texts [27.86, 87] and from the point of view of robotics in the texts [27.30, 88, 89].

In addition, several relevant chapters in this handbook provide further reading for theory and applications, for example, Chaps. 1 and 28.

Grasping

28. Grasping

Domenico Prattichizzo, Jeffrey C. Trinkle

This chapter introduces fundamental models of grasp analysis. The overall model is a coupling of models that define contact behavior with widely used models of rigid-body kinematics and dynamics. The contact model essentially boils down to the selection of components of contact force and moment that are transmitted through each contact. Mathematical properties of the complete model naturally give rise to five primary grasp types whose physical interpretations provide insight for grasp and manipulation planning.

After introducing the basic model and types of grasps, this chapter focuses on the most important grasp characteristic: complete restraint. A grasp with complete restraint prevents loss of contact and thus is very secure. Two primary restraint properties are *form closure* and *force closure*. A form closure grasp guarantees maintenance of contact as long as the links of the hand and the object are well approximated as rigid and as long as the joint actuators are sufficiently strong. As will be seen, the primary difference between form closure and force closure grasps is the latter's reliance on contact friction. This translates into

requiring fewer contacts to achieve force closure than form closure.

28.1 Background

Mechanical hands were developed to give robots the ability to grasp objects of varying geometric and physical properties. The first robotic hand designed for dexterous manipulation was the Salisbury hand [28.1]. It has three three-jointed fingers; enough to control all six degrees of freedom of an object and the grip pressure. The fundamental grasp modeling and analysis done by Salisbury provides a basis for grasp synthesis and dexterous manipulation research which continues today. Some of the most mature analysis techniques are embedded in the software *GraspIt!* [28.2]. *GraspIt!*

contains models for several robot hands and provides tools for grasp selection, dynamic grasp simulation, and visualization.

The goal of this chapter is to give a thorough understanding of the all-important grasp properties of form and force closure. This will be done through detailed derivations of grasp models and discussions of illustrative examples. For an in-depth historical perspective and a treasure-trove bibliography of papers addressing a wide range of topics in grasping, the reader is referred to [28.3].

28.2 Models and Definitions

A mathematical model of grasping must be capable of predicting the behavior of the hand and object under the various loading conditions that may arise during grasping. Generally, the most desirable behavior is grasp maintenance in the face of unknown disturbing forces and moments applied to the object. Typically these disturbances arise from inertia forces which become appreciable during high-speed manipulation or applied forces such as those due to gravity. Grasp maintenance means that the contact forces applied by the hand are such that they prevent contact separation and unwanted contact sliding. The special class of grasps that can be maintained for every possible disturbing load is known as closure grasps. Figure 28.1 shows the Salisbury hand [28.1, 4] executing a closure grasp of an object by wrapping its fingers around it and pressing the object against its palm. Formal definitions, analysis, and computational tests for closure will be presented in Sect. 28.5.

Figure 28.2 illustrates some of the main quantities that will be used to model grasping systems. Assume that the links of the hand and the object are rigid and that there is a unique, well-defined tangent plane at each contact point. Let $\{N\}$ represent a conveniently chosen inertial frame fixed in the workspace. The frame $\{B\}$ is fixed to the object with its origin defined relative to $\{N\}$ by the vector $p \in \mathbb{R}^3$, where \mathbb{R}^3 denotes three-dimensional Euclidean space. A convenient choice for p is the center of mass of the object. The position of contact point i in $\{N\}$ is defined by the vector $c_i \in \mathbb{R}^3$. At contact point i , we define a frame $\{C_i\}$, with axes $\{\hat{n}_i, \hat{t}_i, \hat{o}_i\}$ ($\{C_i\}$ is shown in *exploded view*). The unit vector \hat{n}_i contains c_i is normal to the contact tangent

Fig. 28.1 The Salisbury hand grasping an object

plane, and is directed toward the object. The other two unit vectors are orthogonal and lie in the tangent plane of the contact.

Let the joints be numbered from 1 to n_q . Denote by $\mathbf{q} = [q_1 \cdots q_{n_q}]^\top \in \mathbb{R}^{n_q}$ the vector of joint displacements, where the superscript \top indicates matrix transposition. Also, let $\boldsymbol{\tau} = [\tau_1 \cdots \tau_{n_q}]^\top \in \mathbb{R}^{n_q}$ represent joint loads (forces in prismatic joints and torques in revolute joints). These loads can result from actuator actions, other applied forces, and inertia forces. They could also arise from contacts between the object and hand. However, it will be convenient to separate joint loads into two components: those arising from contacts and those arising from all other sources. Throughout this chapter, noncontact loads will be denoted by $\boldsymbol{\tau}$.

Let $\mathbf{u} \in \mathbb{R}^{n_u}$ denote the vector describing the position and orientation of $\{B\}$ relative to $\{N\}$. For planar systems $n_u = 3$. For spatial systems, n_u is three plus the number of parameters used to represent orientation, typically three (for Euler angles) or four (for unit quaternions). Denote by $\mathbf{v} = [v^\top \omega^\top]^\top \in \mathbb{R}^{n_v}$ the twist of the object described in $\{N\}$. It is composed of the translational velocity $v \in \mathbb{R}^3$ of the point p and the angular velocity $\omega \in \mathbb{R}^3$ of the object, both expressed in $\{N\}$. A twist of a rigid body can be referred to any convenient frame fixed to the body. The components of the referred twist represent the velocity of the origin of the new frame and the angular velocity of the body, both expressed in the new frame. For a rigorous treatment of twists and

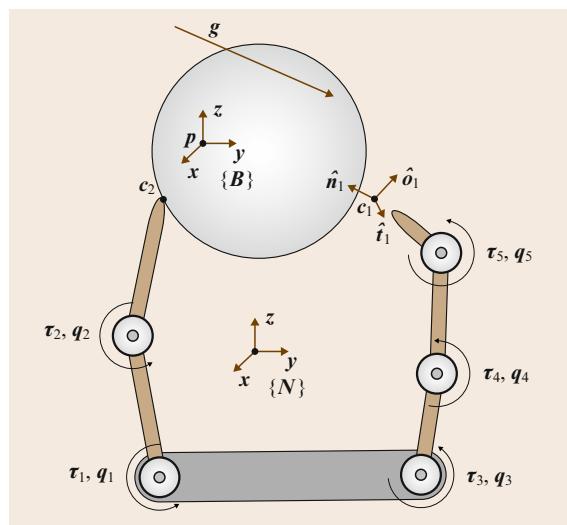

Fig. 28.2 Main quantities for grasp analysis

wrenches see [28.5, 6]. Note that for planar systems, $\mathbf{v} \in \mathbb{R}^2$ and $\omega \in \mathbb{R}$, and so $n_v = 3$.

Another important point is $\dot{\mathbf{u}} \neq \mathbf{v}$. Instead, these variables are related by the matrix \mathbf{V} as:

$$\dot{\mathbf{u}} = \mathbf{V}\mathbf{v}, \quad (28.1)$$

where the matrix $\mathbf{V} \in \mathbb{R}^{n_u \times n_v}$ is not generally square but nonetheless satisfies $\mathbf{V}^\top \mathbf{V} = \mathbf{I}$ [28.7], \mathbf{I} is the identity matrix, and the dot over the \mathbf{u} implies differentiation with respect to time. Note that, for planar systems, $\mathbf{V} = \mathbf{I} \in \mathbb{R}^{3 \times 3}$.

Let $\mathbf{f} \in \mathbb{R}^3$ be the force applied to the object at the point \mathbf{p} and let $\mathbf{m} \in \mathbb{R}^3$ be the applied moment. These are combined into the object load, or wrench, vector denoted by $\mathbf{g} = [\mathbf{f}^\top \mathbf{m}^\top]^\top \in \mathbb{R}^{n_v}$, where \mathbf{f} and \mathbf{m} are expressed in $\{N\}$. Like twists, wrenches can be referred to any convenient frame fixed to the body. One can think of this as translating the line of application of the force until it contains the origin of the new frame, then adjusting the moment component of the wrench to offset the moment induced by moving the line of the force. Last, the force and adjusted moment are expressed in the new frame. As done with the joint loads, the object wrench will be partitioned into two main parts: contact and noncontact wrenches. Throughout this chapter, \mathbf{g} will denote the noncontact wrench on the object.

28.2.1 Velocity Kinematics

The material in this chapter is valid for a wide range of robot hands and other grasping mechanisms. The hand is assumed to be composed of a palm that serves as the common base for any number of fingers, each with any number of joints. The formulations given in this chapter are expressed explicitly in terms of only revolute and prismatic joints. However, most other common joints can be modeled by combinations of revolute and prismatic joints (e.g., cylindrical, spherical, and planar). Any number of contacts may occur between any link and the object.

Grasp Matrix and Hand Jacobian

Two matrices are of the utmost importance in grasp analysis: the *grasp matrix* \mathbf{G} and the *hand Jacobian* \mathbf{J} . These matrices define the relevant velocity kinematics and force transmission properties of the contacts. The following derivations of \mathbf{G} and \mathbf{J} will be done under the assumption that the system is three-dimensional. Changes for planar systems will be noted later.

Each contact should be considered as two coincident points: one on the hand and one on the object. The hand

Jacobian maps the joint velocities to the twists of the hand expressed in the contact frames, while the transpose of the grasp matrix refers the object twist to the contact frames. Finger joint motions induce a rigid-body motion in each link of the hand. It is implicit in the terminology, *twists of the hand*, that the twist referred to contact i is the twist of the link involved in contact i . Thus these matrices can be derived from the transforms that change the reference frame of a twist.

To derive the grasp matrix, let $\boldsymbol{\omega}_{\text{obj}}^N$ denote the angular velocity of the object expressed in $\{N\}$ and let $\mathbf{v}_{i,\text{obj}}^N$, also expressed in $\{N\}$, denote the velocity of the point on the object coincident with the origin of $\{C\}_i$. These velocities can be obtained from the object twist referred to $\{N\}$ as:

$$\begin{pmatrix} \mathbf{v}_{i,\text{obj}}^N \\ \boldsymbol{\omega}_{\text{obj}}^N \end{pmatrix} = \mathbf{P}_i^\top \mathbf{v}, \quad (28.2)$$

where

$$\mathbf{P}_i = \begin{pmatrix} \mathbf{I}_{3 \times 3} & \mathbf{0} \\ \mathbf{S}(\mathbf{c}_i - \mathbf{p}) & \mathbf{I}_{3 \times 3} \end{pmatrix}, \quad (28.3)$$

$\mathbf{I}_{3 \times 3} \in \mathbb{R}^{3 \times 3}$ is the identity matrix, and $\mathbf{S}(\mathbf{c}_i - \mathbf{p})$ is the cross-product matrix, that is, given a three-vector $\mathbf{r} = [r_x \ r_y \ r_z]^\top$, $\mathbf{S}(\mathbf{r})$ is defined as:

$$\mathbf{S}(\mathbf{r}) = \begin{pmatrix} 0 & -r_z & r_y \\ r_z & 0 & -r_x \\ -r_y & r_x & 0 \end{pmatrix}.$$

The object twist referred to $\{C\}_i$ is simply the vector on the left-hand side of (28.2) expressed in $\{C\}_i$. Let $\mathbf{R}_i = [\hat{\mathbf{n}}_i \ \hat{\mathbf{t}}_i \ \hat{\mathbf{o}}_i] \in \mathbb{R}^{3 \times 3}$ represent the orientation of the i -th contact frame $\{C\}_i$ with respect to the inertial frame (the unit vectors $\hat{\mathbf{n}}_i$, $\hat{\mathbf{t}}_i$, and $\hat{\mathbf{o}}_i$ are expressed in $\{N\}$). Then the object twist referred to $\{C\}_i$ is given as:

$$\mathbf{v}_{i,\text{obj}} = \overline{\mathbf{R}}_i^\top \begin{pmatrix} \mathbf{v}_{i,\text{obj}}^N \\ \boldsymbol{\omega}_{\text{obj}}^N \end{pmatrix}, \quad (28.4)$$

where $\overline{\mathbf{R}}_i = \text{Blockdiag}(\mathbf{R}_i, \mathbf{R}_i) = \begin{pmatrix} \mathbf{R}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_i \end{pmatrix} \in \mathbb{R}^{6 \times 6}$.

Substituting $\mathbf{P}_i^\top \mathbf{v}$ from (28.2) into (28.4) yields the partial grasp matrix $\tilde{\mathbf{G}}_i^\top \in \mathbb{R}^{6 \times 6}$, which maps the object twist from $\{N\}$ to $\{C\}_i$:

$$\mathbf{v}_{i,\text{obj}} = \tilde{\mathbf{G}}_i^\top \mathbf{v}, \quad (28.5)$$

where

$$\tilde{\mathbf{G}}_i^\top = \overline{\mathbf{R}}_i^\top \mathbf{P}_i^\top. \quad (28.6)$$

The hand Jacobian can be derived similarly. Let $\omega_{i,\text{hnd}}^N$ be the angular velocity of the link of the hand touching the object at contact i , expressed in $\{N\}$, and define $v_{i,\text{hnd}}^N$ as the translational velocity of contact i on the hand, expressed in $\{N\}$. These velocities are related to the joint velocities through the matrix Z_i whose columns are the Plücker coordinates of the axes of the joints [28.5, 6]. We have:

$$\begin{pmatrix} v_{i,\text{hnd}}^N \\ \omega_{i,\text{hnd}}^N \end{pmatrix} = Z_i \dot{q}, \quad (28.7)$$

where $Z_i \in \mathbb{R}^{6 \times n_q}$ is defined as:

$$Z_i = \begin{pmatrix} d_{i,1} & \dots & d_{i,n_q} \\ l_{i,1} & \dots & l_{i,n_q} \end{pmatrix}, \quad (28.8)$$

with the vectors $d_{i,j}, l_{i,j} \in \mathbb{R}^3$ defined as:

$$d_{i,j} = \begin{cases} \mathbf{0}_{3 \times 1} & \text{if contact } i \text{ does} \\ & \text{not affect joint } j, \\ \hat{z}_j & \text{if joint } j \text{ is prismatic,} \\ S(c_i - \zeta_j)^\top \hat{z}_j & \text{if joint } j \text{ is revolute,} \end{cases}$$

$$l_{i,j} = \begin{cases} \mathbf{0}_{3 \times 1} & \text{if contact } i \text{ does} \\ & \text{not affect joint } j, \\ \mathbf{0}_{3 \times 1} & \text{if joint } j \text{ is prismatic,} \\ \hat{z}_j & \text{if joint } j \text{ is revolute,} \end{cases}$$

where ζ_j is the origin of the coordinate frame associated with the j -th joint and \hat{z}_j is the unit vector in the direction of the z -axis in the same frame, as shown in Fig. 28.11. Both vectors are expressed in $\{N\}$. These frames may be assigned by any convenient method, for example, the Denavit–Hartenberg method [28.8]. The \hat{z}_j -axis is the rotational axis for revolute joints and the direction of translation for prismatic joints.

The final step in referring the hand twists to the contact frames is to change the frame of expression of $v_{i,\text{hnd}}^N$ and $\omega_{i,\text{hnd}}^N$ to $\{C\}_i$:

$$v_{i,\text{hnd}} = \bar{R}_i^\top \begin{pmatrix} v_{i,\text{hnd}}^N \\ \omega_{i,\text{hnd}}^N \end{pmatrix}. \quad (28.9)$$

Combining (28.9) and (28.7) yields the partial hand Jacobian $\tilde{J}_i \in \mathbb{R}^{6 \times n_q}$, which relates the joint velocities to the contact twists on the hand:

$$v_{i,\text{hnd}} = \tilde{J}_i \dot{q}, \quad (28.10)$$

where

$$\tilde{J}_i = \bar{R}_i^\top Z_i. \quad (28.11)$$

To compact notation, stack all the twists of the hand and object into the vectors $v_{c,\text{hnd}} \in \mathbb{R}^{6n_c}$ and $v_{c,\text{obj}} \in \mathbb{R}^{6n_c}$ as follows:

$$v_{c,\xi} = \left(v_{1,\xi}^\top \cdots v_{n_c,\xi}^\top \right)^\top, \quad \xi = \{\text{obj, hnd}\}.$$

Now the *complete grasp matrix* $\tilde{G} \in \mathbb{R}^{6 \times 6n_c}$ and the *complete hand Jacobian* $\tilde{J} \in \mathbb{R}^{6n_c \times n_q}$ relate the various velocity quantities as

$$v_{c,\text{obj}} = \tilde{G}^\top v, \quad (28.12)$$

$$v_{c,\text{hnd}} = \tilde{J} \dot{q}, \quad (28.13)$$

where

$$\tilde{G}^\top = \begin{pmatrix} \tilde{G}_1^\top \\ \vdots \\ \tilde{G}_{n_c}^\top \end{pmatrix}, \quad \tilde{J} = \begin{pmatrix} \tilde{J}_1 \\ \vdots \\ \tilde{J}_{n_c} \end{pmatrix}. \quad (28.14)$$

The term *complete* is used to emphasize that all $6n_c$ twist components at the contacts are included in the mapping. See Example 1, Part 1 and Example 3, Part 1 at the end of this chapter for clarification.

Contact Modeling

Three contact models useful for grasp analysis are reviewed here. For a complete discussion of contact modeling in robotics, readers are referred to Chap. 27.

The three models of greatest interest in grasp analysis are known as *point contact without friction*, *hard finger*, and *soft finger* [28.9]. These models select components of the contact twists to transmit between the hand and the object. This is done by equating a subset of the components of the hand and object twist at each contact. The corresponding components of the contact force and moment are also equated, but without regard for the constraints imposed by contact unilaterality and friction models (Sect. 28.5.2).

The point-contact-without-friction (**PwoF**) model is used when the contact patch is very small and the surfaces of the hand and object are slippery. With this model, only the normal component of the translational velocity of the contact point on the hand (i.e., the first component of $v_{i,\text{hnd}}$) is transmitted to the object. The two components of tangential velocity and the three components of angular velocity are not transmitted. Analogously, the normal component of the contact force is transmitted, but the frictional forces and moments are assumed to be negligible.

Table 28.1 Primary notation for grasp analysis

| Notation | Definition |
|------------------------------------------|----------------------------------------|
| n_c | number of contacts |
| n_q | number of joints of hand |
| n_v | number of degrees of freedom of object |
| $\mathbf{q} \in \mathbb{R}^{n_q}$ | joint displacements |
| $\dot{\mathbf{q}} \in \mathbb{R}^{n_q}$ | joint velocities |
| $\boldsymbol{\tau} \in \mathbb{R}^{n_q}$ | noncontact joint loads |
| $\mathbf{u} \in \mathbb{R}^{n_u}$ | position and orientation of object |
| $\mathbf{v} \in \mathbb{R}^{n_v}$ | twist of object |
| $\mathbf{g} \in \mathbb{R}^{n_v}$ | noncontact object wrench |
| $\{\mathbf{B}\}$ | frame fixed in object |
| $\{\mathbf{C}_i\}$ | frame at contact i |
| $\{\mathbf{N}\}$ | inertial frame |

A hard-finger (**HF**) model is used when there is significant contact friction, but the contact patch is small, so that no appreciable friction moment exists. When this model is applied to a contact, all three translational velocity components of the contact point on the hand (i.e., the first three components of $\mathbf{v}_{i,\text{hnd}}$) and all three components of the contact force are transmitted through the contact. None of the angular velocity components or moment components are transmitted.

The soft-finger (**SF**) model is used in situations in which the surface friction and the contact patch are large enough to generate significant friction forces and a friction moment about the contact normal. At a contact where this model is enforced, the three translational velocity components of the contact on the hand and the angular velocity component about the contact normal are transmitted (i.e., the first four components of $\mathbf{v}_{i,\text{hnd}}$). Similarly, all three components of contact force and the normal component of the contact moment are transmitted.

Remark. The reader may see a contradiction between the rigid-body assumption and the soft-finger model. The rigid-body assumption is an approximation that simplifies all aspects of the analysis of grasping, but nonetheless it is sufficiently accurate in many real situations and grasp analysis would be impractical without. On the other hand, the need for a soft-finger model is a clear admission that the finger links and object are not rigid. However, it can be usefully applied in situations in which the amount of deformation required to obtain a large contact patch is small. Such situations occur when the local surface geometries are similar. If large finger or body deformations exist in the real sys-

Table 28.2 Selection matrices for three contact models

| Model | ℓ_i | \mathbf{H}_{iF} | \mathbf{H}_{iM} |
|-------|----------|---------------------------|-------------------|
| PwoF | 1 | $(1 \ 0 \ 0)$ | vacuous |
| HF | 3 | $\mathbf{I}_{3 \times 3}$ | vacuous |
| SF | 4 | $\mathbf{I}_{3 \times 3}$ | $(1 \ 0 \ 0)$ |

tem, the rigid-body approach presented in this chapter should be used with caution.

To develop the **PwoF**, **HF**, and **SF** models, define the relative twist at contact i as:

$$\begin{pmatrix} \tilde{\mathbf{J}}_i & -\tilde{\mathbf{G}}_i^\top \end{pmatrix} \begin{pmatrix} \dot{\mathbf{q}} \\ \mathbf{v} \end{pmatrix} = \mathbf{v}_{i,\text{hnd}} - \mathbf{v}_{i,\text{obj}} .$$

A particular contact model is defined through the matrix $\mathbf{H}_i \in \mathbb{R}^{\ell_i \times 6}$, which selects ℓ_i components of the relative contact twist and sets them to zero:

$$\mathbf{H}_i(\mathbf{v}_{i,\text{hnd}} - \mathbf{v}_{i,\text{obj}}) = \mathbf{0} .$$

These components are referred to as transmitted degrees of freedom (**DOF**). Define \mathbf{H}_i as:

$$\mathbf{H}_i = \begin{bmatrix} \mathbf{H}_{iF} & \mathbf{0} \\ \mathbf{0} & \mathbf{H}_{iM} \end{bmatrix} , \quad (28.15)$$

where \mathbf{H}_{iF} and \mathbf{H}_{iM} are the translational and rotational component selection matrices, respectively. Table 28.2 gives the definitions of the selection matrices for the three contact models, where *vacuous* means that the corresponding block row matrix in (28.15) is void (i.e., it has zero rows and columns). Notice that, for the **SF** model, \mathbf{H}_{iM} selects rotation about the contact normal.

After choosing a transmission model for each contact, the contact constraint equations for all n_c contacts can be written in compact form as:

$$\mathbf{H}(\mathbf{v}_{c,\text{hnd}} - \mathbf{v}_{c,\text{obj}}) = \mathbf{0} , \quad (28.16)$$

where

$$\mathbf{H} = \text{Blockdiag}(\mathbf{H}_1, \dots, \mathbf{H}_{n_c}) \in \mathbb{R}^{\ell \times 6n_c} ,$$

and the number of twist components ℓ transmitted through the n_c contacts is given by $\ell = \sum_{i=1}^{n_c} \ell_i$.

Finally, by substituting (28.12) and (28.13) into (28.16) one obtains:

$$\begin{pmatrix} \mathbf{J} & -\mathbf{G}^\top \end{pmatrix} \begin{pmatrix} \dot{\mathbf{q}} \\ \mathbf{v} \end{pmatrix} = \mathbf{0} , \quad (28.17)$$

where the grasp matrix and hand Jacobian are

$$\mathbf{G}^\top = \mathbf{H}\tilde{\mathbf{G}}^\top \in \mathbb{R}^{\ell \times 6} ,$$

$$\mathbf{J} = \mathbf{H}\tilde{\mathbf{J}} \in \mathbb{R}^{\ell \times n_q} . \quad (28.18)$$

Table 28.3 Selection matrices for planar contact models

| Model | ℓ_i | H_{iF} | H_{iM} |
|-------|----------|---------------------------------------|----------|
| PwoF | 1 | $\begin{pmatrix} 1 & 0 \end{pmatrix}$ | vacuous |
| HF/SF | 2 | $I_{2 \times 2}$ | vacuous |

For more details on the construction of \mathbf{H} , the grasp matrix, and the hand Jacobian, readers are referred to [28.10–12] and the references therein.

See Example 1, Part 2 and Example 3, Part 2.

It is worth noting that (28.17) can be written in the following form:

$$\mathbf{J}\dot{\mathbf{q}} = \mathbf{v}_{cc,hnd} = \mathbf{v}_{cc,obj} = \mathbf{G}^\top \mathbf{v}, \quad (28.19)$$

where $\mathbf{v}_{cc,hnd}$ and $\mathbf{v}_{cc,obj}$ contain only the components of the twists that are transmitted by the contacts. Note that this equation implies that grasp *maintenance* is defined as the situation in which all these equations are maintained over time. Thus, when a contact is frictionless, contact maintenance implies continued contact, but sliding is allowed. However, when a contact is of the **HF** type, contact maintenance implies sticking contact, since sliding would violate the **HF** model. Similarly, for an **SF** contact, there may be no sliding or relative rotation about the contact normal.

For the remainder of this chapter, it will be assumed that $\mathbf{v}_{cc,hnd} = \mathbf{v}_{cc,obj}$, so the notation will be shortened to \mathbf{v}_{cc} .

Planar Simplifications

Assume that the plane of motion is the (x, y) -plane of $\{N\}$. The vectors \mathbf{v} and \mathbf{g} reduce in dimension from six to three by dropping components three, four, and five. The dimensions of the vectors \mathbf{c}_i and \mathbf{p} reduce from three to two. The i -th rotation matrix becomes $\mathbf{R}_i = (\hat{\mathbf{n}}_i \ \hat{\mathbf{t}}_i) \in \mathbb{R}^{2 \times 2}$ (where the third components of $\hat{\mathbf{n}}_i$ and $\hat{\mathbf{t}}_i$ are dropped) and (28.4) holds with $\tilde{\mathbf{R}}_i = \text{Blockdiag}(\mathbf{R}_i, 1) \in \mathbb{R}^{3 \times 3}$. Equation (28.2) holds with:

$$\mathbf{P}_i = \begin{pmatrix} I_{2 \times 2} & \mathbf{0} \\ S_2(\mathbf{c}_i - \mathbf{p}) & 1 \end{pmatrix},$$

where S_2 is the analog of the cross-product matrix for two-dimensional vectors, given as

$$S_2(\mathbf{r}) = \begin{pmatrix} -r_y & r_x \end{pmatrix}.$$

Table 28.4 Vectors of contact force and moment components, also known as the wrench intensity vector, transmitted through contact i

| Model | λ_i |
|-------|--------------------------------------|
| PwoF | (f_{in}) |
| HF | $(f_{in} f_{it} f_{io})^\top$ |
| SF | $(f_{in} f_{it} f_{io} m_{in})^\top$ |

Equation (28.7) holds with $\mathbf{d}_{i,j} \in \mathbb{R}^2$ and $\mathbf{l}_{i,j} \in \mathbb{R}$ defined as

$$\mathbf{d}_{i,j} = \begin{cases} \mathbf{0}_{2 \times 1} & \text{if contact force } i \text{ does} \\ & \text{not affect the joint } j, \\ \hat{\mathbf{z}}_j & \text{if joint } j \text{ is prismatic,} \\ \mathbf{S}(\mathbf{c}_i - \boldsymbol{\zeta}_j)^\top & \text{if joint } j \text{ is revolute,} \end{cases}$$

$$\mathbf{l}_{i,j} = \begin{cases} 0 & \text{if contact force } i \text{ does} \\ & \text{not affect joint } j, \\ 0 & \text{if joint } j \text{ is prismatic,} \\ 1 & \text{if joint } j \text{ is revolute.} \end{cases}$$

The complete grasp matrix and hand Jacobian have reduced sizes: $\mathbf{G}^\top \in \mathbb{R}^{3n_c \times 3}$ and $\tilde{\mathbf{J}} \in \mathbb{R}^{3n_c \times n_q}$.

As far as contact constraint is concerned, (28.15) holds with H_{iF} and H_{iM} in Table 28.3.

In planar cases, the **SF** and **HF** models are equivalent, because the object and the hand lie in a plane. Rotations about the contact normals would cause out-of-plane motions. Finally, the dimensions of the grasp matrix and hand Jacobian are reduced to the following sizes: $\mathbf{G}^\top \in \mathbb{R}^{\ell \times 3}$ and $\mathbf{J} \in \mathbb{R}^{\ell \times n_q}$. See Example 1, Part 3 and Example 2, Part 1.

28.2.2 Dynamics and Equilibrium

The dynamic equations of the system can be written as:

$$\begin{aligned} \mathbf{M}_{hnd}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{b}_{hnd}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{J}^\top \boldsymbol{\lambda} &= \boldsymbol{\tau}_{app} \\ \mathbf{M}_{obj}(\mathbf{u})\ddot{\mathbf{v}} + \mathbf{b}_{obj}(\mathbf{u}, \dot{\mathbf{v}}) - \mathbf{G}\boldsymbol{\lambda} &= \mathbf{g}_{app} \\ \text{subject to constraint (28.17),} \end{aligned} \quad (28.20)$$

where $\mathbf{M}_{hnd}(\cdot)$ and $\mathbf{M}_{obj}(\cdot)$ are symmetric positive-definite inertia matrices and $\mathbf{b}_{hnd}(\cdot, \cdot)$ and $\mathbf{b}_{obj}(\cdot, \cdot)$ are the velocity-product terms, \mathbf{g}_{app} is the force and moment applied to the object by gravity and other external sources, $\boldsymbol{\tau}_{app}$ is the vector of external loads and actuator actions, and the vector $\mathbf{G}\boldsymbol{\lambda}$ is the total

wrench applied to the object by the hand. The vector λ contains the contact force and moment components transmitted through the contacts and expressed in the contact frames. Specifically, $\lambda = [\lambda_1^\top \cdots \lambda_{n_c}^\top]^\top$, where $\lambda_i = \mathbf{H}_i [f_{in} f_{it} f_{io} m_{in} m_{it} m_{io}]^\top$. The subscripts indicate one normal (n) and two tangential (t, o) components of contact force f and moment m . For an SF, HF, or PwoF contact, λ_i is defined as in Table 28.4. Finally, it is worth noting that $\mathbf{G}_i \lambda_i = \tilde{\mathbf{G}}_i \mathbf{H}_i \lambda_i$ is the wrench applied through contact i , where $\tilde{\mathbf{G}}_i$ and \mathbf{H}_i are defined in (28.6) and (28.15). The vector λ_i is known as the wrench intensity vector for contact i .

Equation (28.20) represents the dynamics of the hand and object without regard for the kinematic constraints imposed by the contact models. Enforcing them, the dynamic model of the system can be written as:

$$\begin{pmatrix} \mathbf{J}^\top \\ -\mathbf{G} \end{pmatrix} \lambda = \begin{pmatrix} \tau \\ \mathbf{g} \end{pmatrix} \quad (28.21)$$

subject to $\mathbf{J}\dot{\mathbf{q}} = \mathbf{G}^\top \mathbf{v} = \mathbf{v}_{cc}$, where

$$\begin{aligned} \tau &= \tau_{app} - \mathbf{M}_{hnd}(\mathbf{q})\ddot{\mathbf{q}} - \mathbf{b}_{hnd}(\mathbf{q}, \dot{\mathbf{q}}), \\ \mathbf{g} &= \mathbf{g}_{app} - \mathbf{M}_{obj}(\mathbf{u})\ddot{\mathbf{v}} - \mathbf{b}_{obj}(\mathbf{u}, \mathbf{v}). \end{aligned} \quad (28.22)$$

One should notice that the dynamic equations are closely related to the kinematic model in (28.17). Specifically, just as \mathbf{J} and \mathbf{G}^\top transmit only selected

components of contact twists, \mathbf{J}^\top and \mathbf{G} in (28.20) serve to transmit only the corresponding components of the contact wrenches.

When the inertia terms are negligible, as occurs during slow motion, the system is said to be quasistatic. In this case, (28.22) becomes:

$$\begin{aligned} \tau &= \tau_{app}, \\ \mathbf{g} &= \mathbf{g}_{app}, \end{aligned} \quad (28.23)$$

and does not depend on joint and object velocities. Consequently, when the grasp is in static equilibrium or moves quasistatically, one can solve the first equation and the constraint in (28.21) independently to compute λ , $\dot{\mathbf{q}}$, and \mathbf{v} . It is worth noting that such a force/velocity decoupled solution is not possible when dynamic effects are appreciable, since the first equation in (28.21) depends on the third one through (28.22).

Remark. Equation (28.21) highlights an important alternative view of the grasp matrix and the hand Jacobian. \mathbf{G} can be thought of as a mapping from the transmitted contact forces and moments to the set wrenches that the hand can apply to the object, while \mathbf{J}^\top can be thought of as a mapping from the transmitted contact forces and moments to the vector of joint loads. Notice that these interpretations hold for both dynamic and quasistatic conditions.

28.3 Controllable Twists and Wrenches

In hand design and in grasp and manipulation planning, it is important to know the set of twists that can be imparted to the object by movements of the fingers, and conversely, the conditions under which the hand can prevent all possible motions of the object. The dual view is that one needs to know the set of wrenches that the hand can apply to the object and under what conditions any wrench in \mathbb{R}^6 can be applied through the contacts. This knowledge will be gained by studying the various subspaces associated with \mathbf{G} and \mathbf{J} [28.13].

The spaces, shown in Fig. 28.3, are the column spaces and null spaces of \mathbf{G} , \mathbf{G}^\top , \mathbf{J} , and \mathbf{J}^\top . Column space (also known as range) and null space will be denoted by $\mathcal{R}(\cdot)$ and $\mathcal{N}(\cdot)$, respectively. The arrows show the propagation of the various velocity and load quantities through the grasping system. For example, in the left part of Fig. 28.3 it is shown how any vector $\dot{\mathbf{q}} \in \mathbb{R}^{n_q}$ can be decomposed into a sum of two orthogonal vectors in

$\mathcal{R}(\mathbf{J}^\top)$ and in $\mathcal{N}(\mathbf{J})$ and how $\dot{\mathbf{q}}$ is mapped to $\mathcal{R}(\mathbf{J})$ by multiplication by \mathbf{J} .

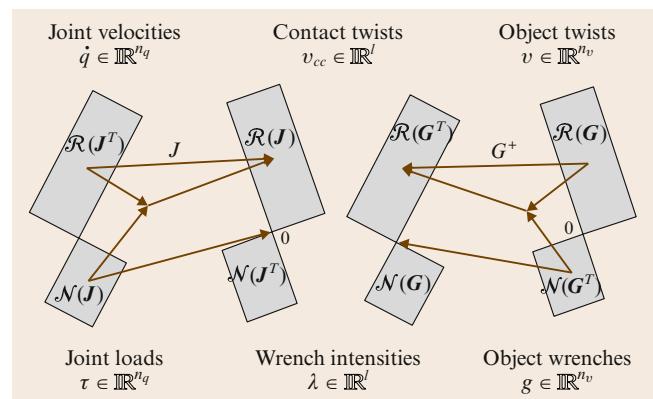

Fig. 28.3 Linear maps relating the twists and wrenches of a grasping system

Table 28.5 Basic grasp classes

| Condition | Class | Many to one |
|---------------------------------------|---------------|------------------------------------------------------------|
| $\mathcal{N}(J) \neq \mathbf{0}$ | Redundant | $\dot{q} \rightarrow v_{cc}$ $\tau \rightarrow \lambda$ |
| $\mathcal{N}(G^\top) \neq \mathbf{0}$ | Indeterminate | $v \rightarrow v_{cc}$ $g \rightarrow \lambda$ |
| $\mathcal{N}(G) \neq \mathbf{0}$ | Graspable | $\lambda \rightarrow g$ $v_{cc} \rightarrow v$ |
| $\mathcal{N}(J^\top) \neq \mathbf{0}$ | Defective | $\lambda \rightarrow \tau$ $v_{cc} \rightarrow \dot{q}$ |

It is important to recall two facts from linear algebra. First, a matrix A maps vectors from $\mathcal{R}(A^\top)$ to $\mathcal{R}(A)$ in a one-to-one and onto fashion, that is, the map A is a bijection. The generalized inverse A^+ of A is a bijection that maps vectors in the opposite direction [28.14]. Also, A maps vectors in $\mathcal{N}(A)$ to zero. Finally, there is no nontrivial vector that A can map into $\mathcal{N}(A^\top)$. This implies that, if $\mathcal{N}(G^\top)$ is nontrivial, then the hand will not be able to control all degrees of freedom of the object's motion. This is certainly true for quasistatic grasping, but when dynamics are important, they may cause the object to move along the directions in $\mathcal{N}(G^\top)$.

28.3.1 Grasp Classifications

The four null spaces motivate a basic classification of grasping systems defined in Table 28.5. Assuming solutions to (28.21) exist, the following force and velocity equations provide insight into the physical meaning of the various null spaces:

$$\dot{q} = J^+ v_{cc} + N(J)\alpha, \quad (28.24)$$

$$v = (G^\top)^+ v_{cc} + N(G^\top)\beta, \quad (28.25)$$

$$\lambda = -G^+ g + N(G)\gamma, \quad (28.26)$$

$$\lambda = (J^\top)^+ \tau + N(J^\top)\eta. \quad (28.27)$$

In these equations, A^+ denotes the generalized inverse, henceforth pseudoinverse, of a matrix A , $N(A)$ denotes a matrix whose columns form a basis for $\mathcal{N}(A)$, and α , β , γ , and η are arbitrary vectors that parameterize the solution sets. If not otherwise specified, the context will make clear whether the generalized inverse is left or right.

If the null spaces represented in the equations are nontrivial, then one immediately sees the first many-to-one mapping in the Table 28.5. To see the other many-to-one mappings, and in particular the defective class, consider (28.24). It can be rewritten with v_{cc} de-

composed into components v_{rs} and v_{lins} in $\mathcal{R}(J)$ and $\mathcal{N}(J^\top)$, respectively, as follows:

$$\dot{q} = J^+(v_{rs} + v_{lins}) + N(J)\alpha. \quad (28.28)$$

Recall that every vector in $\mathcal{N}(A^\top)$ is orthogonal to every row of A^+ . Therefore $J^+ v_{lins} = \mathbf{0}$. If α and v_{rs} are fixed in (28.28), then \dot{q} is unique. Thus it is clear that, if $\mathcal{N}(J^\top)$ is nontrivial, then a subspace of twists of the hand at the contacts will map to a single joint velocity vector. Applying the same approach to the other three equations (28.25–28.27) yields the other many-to-one mappings listed in Table 28.5.

Equations (28.21) and (28.24–28.27), motivate the following definitions.

Definition 28.1 Redundant

A grasping system is said to be *redundant* if $\mathcal{N}(J)$ is nontrivial.

Joint velocities \dot{q} in $\mathcal{N}(J)$ are referred to as *internal hand velocities*, since they correspond to finger motions, but do not generate motion of the hand in the constrained directions at the contact points. If the quasistatic model applies, it can be shown that these motions are not influenced by the motion of the object and vice versa.

Definition 28.2 Indeterminate

A grasping system is said to be *indeterminate* if $\mathcal{N}(G^\top)$ is nontrivial.

Object twists v in $\mathcal{N}(G^\top)$ are called *internal object twists*, since they correspond to motions of the object, but do not cause motion of the object in the constrained directions at the contacts. If the static model applies, it can be shown that these twists cannot be controlled by finger motions.

Definition 28.3 Graspable

A grasping system is said to be *graspable* if $\mathcal{N}(G)$ is nontrivial.

Wrench intensities λ in $\mathcal{N}(G)$ are referred to as *internal object forces*. These wrenches are *internal* because they do not contribute to the acceleration of the object, i.e., $G\lambda = \mathbf{0}$. Instead, these wrench intensities affect the tightness of the grasp. Thus, internal wrench intensities play a fundamental role in maintaining grasps that rely on friction (Sect. 28.5.2).

Definition 28.4 Defective

A grasping system is said to be *defective* if $\mathcal{N}(\mathbf{J}^\top)$ is nontrivial.

Wrench intensities λ in $\mathcal{N}(\mathbf{J}^\top)$ are called *internal hand forces*. These forces do not influence the hand joint dynamics given in (28.20). If the static model is considered, it can be easily shown that wrench intensities belonging to $\mathcal{N}(\mathbf{J}^\top)$ cannot be generated by joint actions, but can be resisted by the structure of the hand.

See Example 1, Part 4; Example 2, Part 2; and Example 3, Part 3.

28.3.2 Limitations of Rigid-Body Assumption

The rigid-body dynamics equation (28.20) can be rewritten with Lagrange multipliers associated with the contact constraints as:

$$\mathbf{M}_{\text{dyn}} \begin{pmatrix} \ddot{\mathbf{q}} \\ \dot{\mathbf{v}} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \boldsymbol{\tau} - \mathbf{b}_{\text{hnd}} \\ \mathbf{v} - \mathbf{b}_{\text{obj}} \\ \mathbf{b}_c \end{pmatrix}, \quad (28.29)$$

where $\mathbf{b}_c = [\partial(\mathbf{J}\dot{\mathbf{q}})/\partial\mathbf{q}] \dot{\mathbf{q}} - [\partial(\mathbf{G}\mathbf{v})/\partial\mathbf{u}] \dot{\mathbf{u}}$ and

$$\mathbf{M}_{\text{dyn}} = \begin{pmatrix} \mathbf{M}_{\text{hnd}} & \mathbf{0} & \mathbf{J}^\top \\ \mathbf{0} & \mathbf{M}_{\text{obj}} & -\mathbf{G} \\ \mathbf{J} & -\mathbf{G}^\top & \mathbf{0} \end{pmatrix}.$$

In order for this equation to determine the motion of the system completely, it is necessary that the matrix \mathbf{M}_{dyn} be invertible. This case is considered in detail in [28.15], where the dynamics of multifinger manipulation is studied under the hypothesis that the hand Jacobian is full row rank, $\mathcal{N}(\mathbf{J}^\top) = \mathbf{0}$. For all manipulation systems with noninvertible \mathbf{M}_{dyn} , rigid-body dynamics fails to determine the motion and the wrench intensity vector. By observing that:

$$\begin{aligned} \mathcal{N}(\mathbf{M}_{\text{dyn}}) \\ = \{(\ddot{\mathbf{q}}, \dot{\mathbf{v}}\boldsymbol{\lambda})^\top \mid \ddot{\mathbf{q}} = \mathbf{0}, \dot{\mathbf{v}} = \mathbf{0}, \boldsymbol{\lambda} \in \mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G})\}, \end{aligned}$$

the same arguments apply under the quasistatic conditions defined by (28.21) and (28.23). When $\mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G}) \neq \mathbf{0}$, the rigid-body approach fails to solve the first equation in (28.21), thus leaving $\boldsymbol{\lambda}$ indeterminate.

Definition 28.5 Hyperstatic

A grasping system is said to be *hyperstatic* if $\mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G})$ is nontrivial.

In such systems there are internal forces (Definition 28.3) belonging to $\mathcal{N}(\mathbf{J}^\top)$ that are not controllable as discussed for defective grasps. Rigid-body dynamics is not satisfactory for hyperstatic grasps since the rigid-body assumption leads to undetermined contact wrenches [28.16].

See Example 3, Part 3.

28.3.3 Desirable Properties

For a general-purpose grasping system, there are three main desirable properties: control of the object twist \mathbf{v} , control of object wrench \mathbf{g} , and control of the internal forces. Control of these quantities implies that the hand can deliver the desired \mathbf{v} and \mathbf{g} with specified grip pressure by the appropriate choice of joint velocities and actions. The conditions on \mathbf{J} and \mathbf{G} equivalent to these properties are given in Table 28.6.

We derive the associated conditions in two steps. First, we ignore the structure and configuration of the hand (captured in \mathbf{J}) by assuming that the contact point on the finger can be commanded to move in any direction transmitted by the chosen contact model. An important perspective here is that \mathbf{v}_{cc} is seen as the independent input variable and \mathbf{v} is seen as the output. The dual interpretation is that the actuators can generate any contact force and moment in the constrained directions. Similarly, $\boldsymbol{\lambda}$ is seen as the input and \mathbf{g} is seen as the output. The preliminary property of interest under this assumption is whether or not the arrangement and types of contacts on the object (captured in \mathbf{G}) are such that a sufficiently dexterous hand could control its fingers so as to impart any twist $\mathbf{v} \in \mathbb{R}^6$ to the object and, similarly, to apply any wrench $\mathbf{g} \in \mathbb{R}^6$ to the object.

All Object Twists Possible

Given a set of contact locations and types, by solving (28.19) for \mathbf{v} or observing the map \mathbf{G} on the right side of Fig. 28.3, one sees that the achievable object twists are those in $\mathcal{R}(\mathbf{G})$. Those in $\mathcal{N}(\mathbf{G}^\top)$ could not be achieved by any hand using the given grasp. Therefore, to achieve any object twist, we must have: $\mathcal{N}(\mathbf{G}^\top) = \mathbf{0}$, or equivalently:

Table 28.6 Desirable properties of a grasp

| Task requirement | Required conditions |
|-------------------------------------|----------------------------------------------------------------------------------------------------------------|
| All wrenches possible, \mathbf{g} | $\text{rank}(\mathbf{G}) = n_v$ |
| All twists possible, \mathbf{v} | $\left\{ \begin{array}{l} \text{rank}(\mathbf{G}) = n_v \\ \text{rank}(\mathbf{GJ}) = n_v \end{array} \right.$ |
| Control all wrenches, \mathbf{g} | $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^\top) = \mathbf{0}$ |
| Control all twists, \mathbf{v} | |
| Control all internal forces | |

Fig. 28.4 The Salisbury hand

lently, $\text{rank}(\mathbf{G}) = n_v$. Any grasp with three non-collinear hard contacts or two distinct soft contacts satisfies this condition.

All Object Wrenches Possible

This case is the dual of the previous case, so we expect the same condition. From (28.21), one immediately obtains the condition $\mathcal{N}(\mathbf{G}^\top) = \mathbf{0}$, so again we have $\text{rank}(\mathbf{G}) = n_v$.

To obtain the conditions needed to control the various quantities of interest, the structure of the hand cannot be ignored. Recall that the only achievable contact twists on the hand are in $\mathcal{R}(\mathbf{J})$, which is not necessarily equal to \mathbb{R}^ℓ .

Control All Object Twists

By solving (28.17) for v , one sees that, in order to cause any object twist v by choice of joint velocities $\dot{\mathbf{q}}$, we must have $\mathcal{R}(\mathbf{GJ}) = \mathcal{R}(\mathbf{G})$ and $\mathcal{N}(\mathbf{G}^\top) = \mathbf{0}$. These conditions are equivalent to $\text{rank}(\mathbf{GJ}) = \text{rank}(\mathbf{G}) = n_v$.

Control All Object Wrenches

This property is dual to the previous one. Analysis of (28.21) yields the same conditions: $\text{rank}(\mathbf{GJ}) = \text{rank}(\mathbf{G}) = n_v$.

Control All Internal Forces

Equation (28.20) shows that wrench intensities with no effect on object motion are only those in $\mathcal{N}(\mathbf{G})$. In general, not all the internal forces may be actively controlled by joint actions. In [28.12, 17] it has been shown that all internal forces in $\mathcal{N}(\mathbf{G})$ are controllable if and only if $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^\top) = \mathbf{0}$.

See Example 1, Part 5 and Example 2, Part 3.

Design Considerations of the Salisbury Hand

The Salisbury hand in Fig. 28.4 was designed to have the smallest number of joints that would meet all the task requirements in Table 28.6. Assuming HF contacts, three non-collinear contacts is the minimum number such that $\text{rank}(\mathbf{G}) = n_v = 6$. In this case, \mathbf{G} has six rows and nine columns and the dimension of $\mathcal{N}(\mathbf{G})$ is three [28.1, 4]. The ability to control all internal forces and apply an arbitrary wrench to the object requires that $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^\top) = \mathbf{0}$, so the minimum dimension of the column space of \mathbf{J} is nine. To achieve this, the hand must have at least nine joints, which Salisbury implemented as three fingers, each with three revolute joints.

The intended way to execute a dexterous manipulation task with the Salisbury hand is to grasp the object at three non-collinear points with the fingertips, forming a grasp triangle. To secure the grasp, the internal forces are controlled so that the contact points are maintained without sliding. Dexterous manipulation can be thought of as moving the fingertips to control the positions of the vertices of the grasp triangle.

28.4 Restraint Analysis

The most fundamental requirements in grasping and dexterous manipulation are the abilities to hold an object in equilibrium and control the position and orientation of the grasped object relative to the palm of the hand. The two most useful characterizations of grasp restraint are *force closure* and *form closure*. These names were in use over 125 years ago in the field of machine design to distinguish between joints that required an external force to maintain contact, and those that did not [28.18]. For example, some water wheels had a cylindrical axle that

was laid in a horizontal semicylindrical groove split on either side of the wheel. During operation, the weight of the wheel acted to *close* the groove–axle contacts, hence the term *force closure*. By contrast, if the grooves were replaced by cylindrical holes just long enough to accept the axle, then the contacts would be closed by the geometry (even if the direction of the gravitational force was reversed), hence the term *form closure*.

When applied to grasping, form and force closure have the following interpretations. Assume that a hand

Fig. 28.5 The palm, fingers, wrist, and watch band combine to create a very secure form closure grasp of a TV remote controller

grasping an object has its joint angles locked and its palm fixed in space; then the grasp has *form closure*, or the object is *form closed*, if it is impossible to move the object, even infinitesimally. Under the same conditions, the grasp has *force closure*, or the object is *force closed*, if for any noncontact wrench experienced by the object, contact wrench intensities exist that satisfy (28.20) and are consistent with the constraints imposed by the friction models applicable at the contact points. Notice that all form closure grasps are also force closure grasps. When under form closure, the object cannot move at

Fig. 28.7 In the grasp depicted, contact with the ridges on the gasoline cap creates partial form closure in the direction of cap rotation (when screwing it in) and also in the directions of translation perpendicular to the axis of rotation. To achieve complete control over the cap, the grasp achieves force closure over the other three degrees of freedom

all, regardless of the noncontact wrench. Therefore, the hand maintains the object in equilibrium for any external wrench, which is the force closure requirement.

Roughly speaking, form closure occurs when the palm and fingers wrap around the object forming a cage with no *wiggle room* such as the grasp shown in Fig. 28.5. This kind of grasp is also called a *power grasp* [28.19] or an *enveloping grasp* [28.20]. However, force closure is possible with fewer contacts, as shown in Fig. 28.6, but in this case force closure requires the ability to control internal forces. It is also possible for a grasp to have partial form closure, indicating that only a subset of the possible degrees of freedom are restrained by form closure [28.21]. An example of such a grasp is shown in Fig. 28.7. In this grasp, fingertip placement between the ridges around the periphery of the gasoline cap provide form closure against relative rotation about the axis of the helix of the threads and also against translation perpendicular to that axis, but the other three degrees of freedom are restrained through force closure. Strictly speaking, given a grasp of a real object by a human hand, it is impossible to prevent relative motion of the object with respect to the palm due to the compliance of the hand and object. Preventing all motion is possible only if the contacting bodies are rigid, as is assumed in most mathematical models employed in grasp analysis.

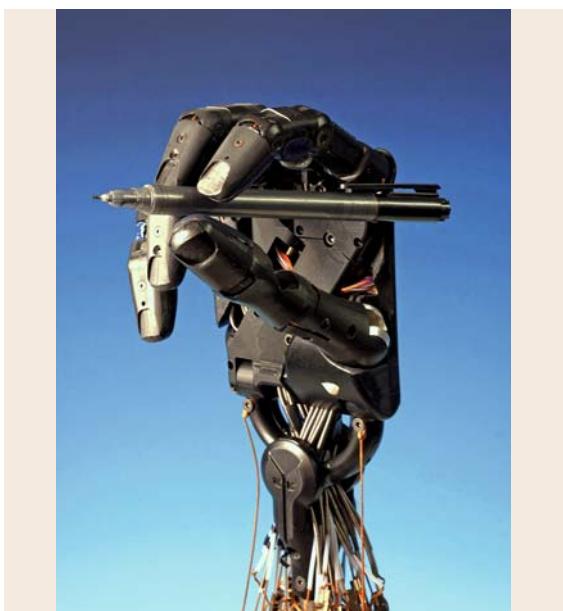

Fig. 28.6 This grasp has a force closure grasp appropriate for dexterous manipulation (Image of Shadow Dexterous Hand © Shadow Robot Company 2008)

28.4.1 Form Closure

To make the notion of form closure precise, introduce a gap function denoted by $\psi_i(\mathbf{u}, \mathbf{q})$ at each of the n_c contact points between the object and the hand. The gap function is zero at each contact, becomes positive if contact breaks, and negative if penetration occurs. The

gap function can be thought of as the distance between the contact points. In general, this function is dependent on the shapes of the contacting bodies. Let $\bar{\mathbf{u}}$ and $\bar{\mathbf{q}}$ represent the configurations of the object and hand for a given grasp; then:

$$\psi_i(\bar{\mathbf{u}}, \bar{\mathbf{q}}) = 0 \quad \forall i = 1, \dots, n_c. \quad (28.30)$$

The form closure condition can now be stated in terms of a differential change $d\mathbf{u}$ of $\bar{\mathbf{u}}$:

Definition 28.6

A grasp $(\bar{\mathbf{u}}, \bar{\mathbf{q}})$ has *form closure* if and only if the following implication holds:

$$\psi(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) \geq 0 \Rightarrow d\mathbf{u} = 0, \quad (28.31)$$

where ψ is the n_c -dimensional vector of gap functions with i -th component equal to $\psi_i(\mathbf{u}, \mathbf{q})$. By definition, inequalities between vectors imply that the inequality is applied between corresponding components of the vectors.

Expanding the gap function vector in a Taylor series about $\bar{\mathbf{u}}$ yields infinitesimal form closure tests of various orders. Let ${}^{\beta}\psi(\mathbf{u}, \mathbf{q})$, $\beta = 1, 2, 3, \dots$ denote the Taylor series approximation truncated after the terms of order β in $d\mathbf{u}$. From (28.30), it follows that the first-order approximation is:

$${}^1\psi(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) = \frac{\partial \psi(\mathbf{u}, \mathbf{q})}{\partial \mathbf{u}} \Big|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})} d\mathbf{u},$$

where $\partial \psi(\mathbf{u}, \mathbf{q})/\partial \mathbf{u}|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})}$ denotes the partial derivative of ψ with respect to \mathbf{u} evaluated at $(\bar{\mathbf{u}}, \bar{\mathbf{q}})$. Replacing ψ with its approximation of order β in (28.31) implies three relevant cases of order β :

1. if there exists $d\mathbf{u}$ such that ${}^{\beta}\psi(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}})$ has at least one strictly positive component, then the grasp does not have form closure of order β ;
2. if for every nonzero $d\mathbf{u}$, ${}^{\beta}\psi(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}})$ has at least one strictly negative component, then the grasp has form closure of order β ;
3. if neither case 1 nor case 2 applies for all ${}^{\alpha}\psi(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) \forall \alpha \leq \beta$, then higher-order analysis is required to determine the existence of form closure.

Figure 28.8 illustrates form closure concepts using several planar grasps of gray objects by fingers shown as dark disks. The concepts are identical for grasps of three-dimensional objects, but are more clearly illustrated in a plane. The grasp on the left has first-order form closure. Note that first-order form closure only involves

the first derivatives of the distance functions. This implies that the only relevant geometry in first-order form closure are the locations of the contacts and the directions of the contact normals. The grasp in the center has form closure of higher order, with the specific order depending on the degrees of the curves defining the surfaces of the object and fingers in the neighborhoods of the contacts [28.22]. Second-order form closure analysis depends on the curvatures of the two contacting bodies in addition to the geometric information used to analyze first-order form closure. The grasp on the right does not have form closure of any order, because the object can translate horizontally and rotate about its center.

First-Order Form Closure

First-order form closure exists if and only if the following implication holds:

$$\left. \frac{\partial \psi(\mathbf{u}, \mathbf{q})}{\partial \mathbf{u}} \right|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})} d\mathbf{u} \geq 0 \Rightarrow d\mathbf{u} = 0.$$

The first-order form closure condition can be written in terms of the object twist \mathbf{v} :

$$\mathbf{G}_n^\top \mathbf{v} \geq 0 \Rightarrow \mathbf{v} = 0, \quad (28.32)$$

where $\mathbf{G}_n^\top = \partial \psi / \partial \mathbf{u} V \in \mathbb{R}^{n_c \times 6}$. Because the gap functions only quantify distances, the product $\mathbf{G}_n^\top \mathbf{v}$ is the vector of normal components of the instantaneous velocities of the object at the contact points (which must be nonnegative to prevent interpenetration). This in turn implies that the grasp matrix is the one that would result from the assumption that all contacts are of the type PwoF.

An equivalent condition in terms of the contact wrench intensity vector $\lambda_n \in \mathbb{R}^{n_c}$ can be stated as follows. A grasp has first-order form closure if and only

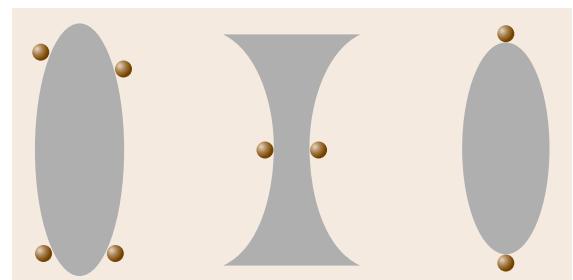

Fig. 28.8 Three planar grasps: two with form closure of different orders and one without form closure

if:

$$\left. \begin{array}{l} \mathbf{G}_n \boldsymbol{\lambda}_n = -\mathbf{g} \\ \boldsymbol{\lambda}_n \geq \mathbf{0} \end{array} \right\} \forall \mathbf{g} \in \mathbb{R}^6. \quad (28.33)$$

The physical interpretation of this condition is that equilibrium can be maintained under the assumption that the contacts are frictionless. Note that the components of $\boldsymbol{\lambda}_n$ are the magnitudes of the normal components of the contact forces. The subscript $(.)_n$ is used to emphasize that $\boldsymbol{\lambda}_n$ contains no other force or moment components.

Since \mathbf{g} must be in the range of \mathbf{G}_n for equilibrium to be satisfied, and since \mathbf{g} is an arbitrary element of \mathbb{R}^6 , then in order for condition (28.33) to be satisfied, the rank of \mathbf{G}_n must be six. Assuming $\text{rank}(\mathbf{G}_n) = 6$, another equivalent mathematical statement of first-order form closure is: there exists $\boldsymbol{\lambda}_n$ such that the following two conditions hold [28.23]:

$$\left. \begin{array}{l} \mathbf{G}_n \boldsymbol{\lambda}_n = \mathbf{0}, \\ \boldsymbol{\lambda}_n > \mathbf{0}. \end{array} \right\} \quad (28.34)$$

This means that there exists a set of strictly compressive normal contact forces in the null space of \mathbf{G}_n . In other words, one can squeeze the object as tightly as desired while maintaining equilibrium. A second interpretation of this condition is that the nonnegative span of the columns of \mathbf{G}_n must equal \mathbb{R}^6 . As will be seen, this interpretation will provide a conceptual link called *frictional form closure* that lies between form closure and force closure.

The duality of conditions (28.32) and (28.33) can be seen clearly by examining the set of wrenches that can be applied by frictionless contacts and the corresponding set of possible object twists. For this discussion, it is useful to give definitions of cones and their duals.

Definition 28.7

A cone \mathcal{C} is a set of vectors $\boldsymbol{\varsigma}$ such that, for every $\boldsymbol{\varsigma}$ in \mathcal{C} , every nonnegative scalar multiple of $\boldsymbol{\varsigma}$ is also in \mathcal{C} .

Equivalently, a cone is a set of vectors closed under addition and nonnegative scalar multiplication.

Table 28.7 Minimum number of contacts n_c required to form close an object with n_v degrees of freedom

| n_v | n_c |
|-------------------|-----------|
| 3 (planar grasp) | 4 |
| 6 (spatial grasp) | 7 |
| n_v (general) | $n_v + 1$ |

Definition 28.8

Given a cone \mathcal{C} with elements $\boldsymbol{\varsigma}$, the *dual cone* \mathcal{C}^* with elements $\boldsymbol{\varsigma}^*$ is the set of vectors such that the dot product of $\boldsymbol{\varsigma}^*$ with each vector in \mathcal{C} is nonnegative. Mathematically:

$$\mathcal{C}^* = \{\boldsymbol{\varsigma}^* | \boldsymbol{\varsigma}^* \boldsymbol{\varsigma} \geq 0, \forall \boldsymbol{\varsigma} \in \mathcal{C}\}. \quad (28.35)$$

See Example 4.

First-Order Form Closure Requirements

Several useful necessary conditions for form closure are known. In 1897 *Somov* proved that at least seven contacts are necessary to form close a rigid object with six degrees of freedom [28.24]. *Lakshminarayana* generalized this to prove that $n_v + 1$ contacts are necessary to form close an object with n_v degrees of freedom [28.21] (based on *Goldman* and *Tucker* 1956 [28.25]), see Table 28.7. This led to the definition of partial form closure that was mentioned above in the discussion of the hand grasping the gasoline cap. *Markenscoff* and *Papadimitriou* determined a tight upper bound, showing that, for all objects whose surfaces are not surfaces of revolution, at most $n_v + 1$ contacts are necessary [28.26]. Form closure is impossible to achieve for surfaces of revolution.

To emphasize the fact that $n_v + 1$ contacts are necessary and *not* sufficient, consider grasping a cube with seven or more points of contact. If all contacts are on one face, then clearly the cube is not form closed.

First-Order Form Closure Tests

Because form closure grasps are very secure, it is desirable to design or synthesize such grasps. To do this, one needs a way to test candidate grasps for form closure, and rank them so that the *best* grasp can be chosen. One reasonable measure of form closure can be derived from the geometric interpretation of the condition (28.34). The null space constraint and the positivity of $\boldsymbol{\lambda}_n$ represent the addition of the columns of \mathbf{G}_n scaled by the components of $\boldsymbol{\lambda}_n$. Any choice of $\boldsymbol{\lambda}_n$ closing this loop is in $\mathcal{N}(\mathbf{G}_n)$. For a given loop, if the magnitude of the smallest component of $\boldsymbol{\lambda}_n$ is positive, then the grasp has form closure, otherwise it does not. Let us denote this smallest component by d . Since such a loop, and hence d , can be scaled arbitrarily, $\boldsymbol{\lambda}_n$ should be bounded for computational expediency.

After verifying that \mathbf{G}_n has full row rank, a quantitative form closure test based on the above observations can be formulated as a linear program (LP) in the

unknowns d and λ_n as follows:

$$LP1: \text{ maximize : } d \quad (28.36)$$

$$\text{subject to: } G_n \lambda_n = \mathbf{0} \quad (28.37)$$

$$I \lambda_n - Id \geq \mathbf{0} \quad (28.38)$$

$$d \geq 0 \quad (28.39)$$

$$I^\top \lambda_n \leq n_c, \quad (28.40)$$

where $I \in \mathbb{R}^{n_c \times n_c}$ is the identity matrix and $I \in \mathbb{R}_c^n$ is a vector with all components equal to 1. The last inequality is designed to prevent this LP from becoming unbounded. A typical LP solution algorithm determines infeasibility or unboundedness of the constraints in the, so-called, phase I of the algorithm, and considers the result before attempting to calculate an optimal value [28.27]. If LP1 is infeasible, or if the optimal value d^* is zero, then the grasp is not form closed.

The quantitative form closure test (28.36–28.40) has $n_c + 8$ constraints and $n_c + 1$ unknowns. For a typical grasp with $n_c < 10$, this is a small linear program that can be solved very quickly using the simplex method. However, one should note that the metric d^* is dependent on the choice of units used when forming G_n . It would be advisable to nondimensionalize the components of the wrenches to avoid dependence of the optimal d on ones choice of units. This could be done by dividing the first three rows of G by a characteristic force and the last three rows by a characteristic moment.

However, if one desires a binary test, LP1 can be converted into one by dropping the last constraint (28.40) and applying only phase I of the simplex algorithm.

In summary, form closure testing is a two-step process:

Form Closure Test

1. Compute rank(G_n).
 - a) If $\text{rank}(G_n) \neq n_v$, then form closure does not exist. Stop.
 - b) If $\text{rank}(G_n) = n_v$, continue.
2. Solve LP1.
 - a) If $d^* = 0$, then form closure does not exist.
 - b) If $d^* > 0$, then form closure exists and d^* is a crude measure of how far the grasp is from losing form closure.

Variations of the Test

If the rank test fails, then the grasp could have partial form closure over as many as $\text{rank}(G_n)$ degrees of freedom. If one desires to test this, then LP1 must be solved using a new G_n formed by retaining only the rows cor-

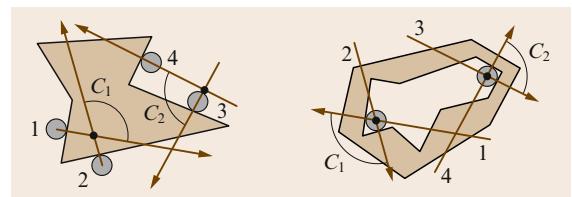

Fig. 28.9 Planar grasps with first-order form closure

responding to the degrees of freedom for which partial form closure is to be tested. If $d^* > 0$, then partial form closure exists. A second variation is to constrain d to be greater than some large negative value. If this is done, then $d^* < 0$ is a crude measure of how far a grasp is from achieving form closure.

See Example 5.

Planar Simplifications

In the planar case, Nguyen [28.28] developed a graphical qualitative test for form closure. Figure 28.9 shows two form closure grasps with four contacts. To test form closure one partitions the normals into two groups of two. Let C_1 be the nonnegative span of two normals in one pair and C_2 be the nonnegative span of the other pair. A grasp has form closure if and only if C_1 and C_2 or $-C_1$ and $-C_2$ see each other for any pairings. Two cones see each other if the open line segment defined by the vertices of the cones lies in the interior of both cones. In the presence of more than four contacts, if any set of four contacts satisfies this condition, then the grasp has form closure. Notice that this graphical test can be difficult to execute for grasps with more than four contacts. Also, it does not extend to grasps of three-dimensional (3-D) objects and does not provide a closure measure.

28.4.2 Force Closure

A grasp has force closure, or is force closed, if the grasp can be maintained in the face of any object wrench. Force closure is similar to form closure, but relaxed to allow friction forces to help balance the object wrench. A benefit of including friction in the analysis is the reduction in the number of contact points needed for closure. A three-dimensional object with six degrees of freedom requires seven contacts for form closure, but for force closure, only two contacts are needed if they are modeled as soft fingers, and only three (non-collinear) contacts are needed if they are modeled as hard fingers.

Force closure relies on the ability of the hand to squeeze arbitrarily tightly in order to compensate for large applied wrenches that can only be resisted by

Table 28.8 Norms for the three main contact models

| Model | $\ \lambda_i\ _w$ |
|-------|------------------------------------------------------------------------|
| PwoF | 0 |
| HF | $\frac{1}{\mu_i} \sqrt{f_{it}^2 + f_{io}^2}$ |
| SF | $\frac{1}{\mu_i} \sqrt{f_{it}^2 + f_{io}^2} + \frac{1}{av_i} m_{in} $ |

friction. Figure 28.14 shows a grasped polygon (see Example 2). Consider applying a wrench to the object that is a pure force acting upward along the y -axis of the inertial frame. It seems intuitive that, if there is enough friction, the hand will be able to squeeze the object with friction forces preventing the object's upward escape. Also, as the applied force increases in magnitude, the magnitude of the squeezing force will have to increase accordingly.

Since force closure is dependent on the friction models, common models will be introduced before giving formal definitions of force closure.

Friction Models

Recall the components of force and moment transmitted through contact i under the various contact models given earlier (Table 28.4). At contact point i , the friction law imposes constraints on the components of the contact force and moment. Specifically, the frictional components of λ_i are constrained to lie inside a limit surface, denoted by \mathcal{L}_i , that scales linearly with the product $\mu_i f_{in}$, where μ_i is the coefficient of friction at contact i . In the case of Coulomb friction, the limit surface is a circle of radius $\mu_i f_{in}$. The Coulomb friction cone \mathcal{F}_i is a subset of \mathbb{R}^3 :

$$\mathcal{F}_i = \left\{ (f_{in}, f_{it}, f_{io}) \mid \sqrt{f_{it}^2 + f_{io}^2} \leq \mu_i f_{in} \right\}. \quad (28.41)$$

More generally, the friction laws of interest have limit surfaces defined in the space of friction components, \mathbb{R}^{ℓ_i-1} , and friction cones \mathcal{F}_i defined in the space of λ_i , \mathbb{R}^{ℓ_i} . They can be written as

$$\mathcal{F}_i = \{ \lambda_i \in \mathbb{R}^{\ell_i} \mid \|\lambda_i\|_w \leq f_{in} \}, \quad (28.42)$$

where $\|\lambda_i\|_w$ denotes a weighted quadratic norm of the friction components at contact i . The limit surface is defined by $\|\lambda_i\|_w = f_{in}$.

Table 28.8 defines useful weighted quadratic norms for the three contact models: PwoF, HF, and SF. The parameter μ_i is the friction coefficient for the tangential forces, v_i is the torsional friction coefficient, and a is the characteristic length of the object that is used to ensure consistent units in the terms of the norm of the SF model.

Remark. There are several noteworthy points to be made about the friction cones. First, all of them implicitly or explicitly constrain the normal component of the contact force to be nonnegative. The cone for SF contacts has a cylindrical limit surface with circular cross section in the (f_{it}, f_{io}) -plane and rectangular cross section in the (f_{it}, m_{in}) -plane. With this model, the amount of torsional friction that can be transmitted is independent of the lateral friction load. An improved model that couples the torsional friction limit with the tangential limit was studied by Howe and Cutkosky [28.29].

A Force Closure Definition

One common definition of force closure can be stated simply by modifying condition (28.33) to allow each contact force to lie in its friction cone rather than along the contact normal. Because this definition does not consider the hand's ability to control contact forces, this definition will be referred to as *frictional form closure*. A grasp will be said to have frictional form closure if and only if the following conditions are satisfied:

$$\begin{aligned} G\lambda &= -g \\ \lambda &\in \mathcal{F} \end{aligned} \quad \left\{ \forall g \in \mathbb{R}^{n_v}, \lambda \in \mathcal{F} \right\}$$

where \mathcal{F} is the composite friction cone defined as: $\mathcal{F} = \mathcal{F}_1 \times \dots \times \mathcal{F}_{n_c} = \{ \lambda \in \mathbb{R}^m \mid \lambda_i \in \mathcal{F}_i; i = 1, \dots, n_c \}$, and each \mathcal{F}_i is defined by (28.42) and one of the models listed in Table 28.8.

Letting $\text{Int}(\mathcal{F})$ denote the interior of the composite friction cone, Murray et al. give the following equivalent definition [28.15]:

Definition 28.9

(Proposition 5.2, Murray et al.) A grasp has *frictional form closure* if and only if the following conditions are satisfied:

1. $\text{rank}(G) = n_v$
2. $\exists \lambda$ such that $G\lambda = \mathbf{0}$ and $\lambda \in \text{Int}(\mathcal{F})$.

These conditions define what Murray et al. call *force closure*. The force closure definition adopted here is stricter than frictional form closure; it additionally requires that the hand be able to control the internal object forces.

Definition 28.10

A grasp has *force closure* if and only if $\text{rank}(G) = n_v$, $\mathcal{N}(G) \cap \mathcal{N}(J^\top) = \mathbf{0}$, and there exists λ such that $G\lambda = \mathbf{0}$ and $\lambda \in \text{Int}(\mathcal{F})$.

The full row rank condition on the matrix \mathbf{G} is the same condition required for form closure, although \mathbf{G} is different from \mathbf{G}_n used to determine form closure. If the rank test passes, then one must still find λ satisfying the remaining three conditions. Of these, the null space intersection test can be performed easily by linear programming techniques, but the friction cone constraint is quadratic, and thus forces one to use nonlinear programming techniques. While exact nonlinear tests have been developed [28.30], only approximate tests will be presented here.

Approximate Force Closure Tests

Any of the friction cones discussed can be approximated as the nonnegative span of a finite number n_g of generators s_{ij} of the friction cone. Given this, one can represent the set of applicable contact wrenches at contact i as follows:

$$\mathbf{G}_i \boldsymbol{\lambda}_i = \mathbf{S}_i \boldsymbol{\sigma}_i, \quad \boldsymbol{\sigma}_i \geq 0,$$

where $\mathbf{S}_i = (s_{i1} \cdots s_{in_g})$ and $\boldsymbol{\sigma}_i$ is a vector of nonnegative generator weights. If contact i is frictionless, then $n_g = 1$ and $\mathbf{S}_i = [\hat{\mathbf{n}}_i^\top \quad (\mathbf{c}_i - \mathbf{p}) \times \hat{\mathbf{n}}_i]^\top$.

If contact i is of type **HF**, we represent the friction cone by the nonnegative sum of uniformly spaced contact force generators (Fig. 28.10) whose nonnegative span approximates the Coulomb cone with an inscribed regular polyhedral cone. This leads to the following definition of \mathbf{S}_i :

$$\mathbf{S}_i = \begin{pmatrix} \dots & 1 & \dots \\ \dots & \mu_i \cos(2k\pi/n_g) & \dots \\ \dots & \mu_i \sin(2k\pi/n_g) & \dots \end{pmatrix}, \quad (28.43)$$

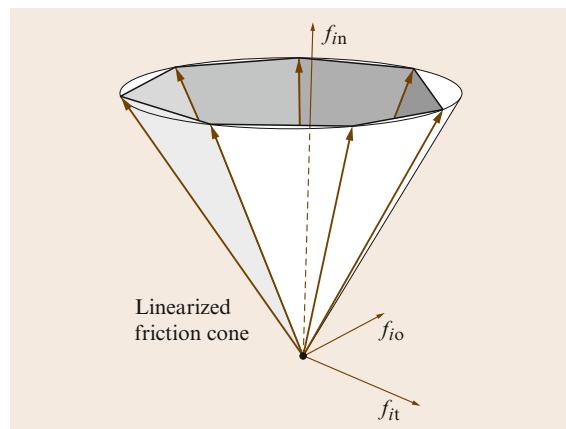

Fig. 28.10 Quadratic cone approximated as a polyhedral cone with seven generators

where the index k varies from 1 to n_g . If one prefers to approximate the quadratic friction cone by a circumscribing polyhedral cone, one simply replaces μ_i in the above definition with $\mu_i / \cos(\pi n_g)$.

The adjustment needed for the **SF** model is quite simple. Since the torsional friction in this model is decoupled from the tangential friction, its generators are given by $[1 \ 0 \ 0 \ \pm bv_i]^\top$. Thus \mathbf{S}_i for the **SF** model is:

$$\mathbf{S}_i = \begin{pmatrix} \dots & 1 & \dots & 1 & 1 \\ \dots & \mu_i \cos(2k\pi/n_g) & \dots & 0 & 0 \\ \dots & \mu_i \sin(2k\pi/n_g) & \dots & 0 & 0 \\ \dots & 0 & \dots & bv_i & -bv_i \end{pmatrix}, \quad (28.44)$$

where b is the characteristic length used to unify units. The set of total contact wrenches that may be applied by the hand without violating the contact friction law at any contact can be written as:

$$\mathbf{G}\boldsymbol{\lambda} = \mathbf{S}\boldsymbol{\sigma}, \quad \boldsymbol{\sigma} \geq \mathbf{0},$$

where $\mathbf{S} = (\mathbf{S}_1, \dots, \mathbf{S}_{n_g})$ and $\boldsymbol{\sigma} = (\boldsymbol{\sigma}_1^\top \dots \boldsymbol{\sigma}_{n_g}^\top)^\top$.

It is convenient to reformulate the friction constraints in a dual form:

$$\mathbf{F}_i \boldsymbol{\lambda}_i \geq \mathbf{0}. \quad (28.45)$$

In this form, each row of \mathbf{F}_i is normal to a face formed by two adjacent generators of the approximate cone. For an **HF** contact, row i of \mathbf{F}_i can be computed as the cross product of \mathbf{s}_i and \mathbf{s}_{i+1} . In the case of an **SF** contact, the generators are of dimension four, so simple cross products will not suffice. However, general methods exist to perform the conversion from the generator form to the face normal form [28.25].

The face normal constraints for all contacts can be combined into the following compact form:

$$\mathbf{F}\boldsymbol{\lambda} \geq \mathbf{0}, \quad (28.46)$$

where $\mathbf{F} = \text{Blockdiag}(\mathbf{F}_1, \dots, \mathbf{F}_{n_c})$.

Let $\mathbf{e}_i \in \mathbb{R}^{\ell_i}$ be the first row of \mathbf{H}_i . Further let $\mathbf{e} = (\mathbf{e}_1, \dots, \mathbf{e}_{n_c}) \in \mathbb{R}^\ell$ and let $\mathbf{E} = \text{Blockdiag}(\mathbf{e}_1, \dots, \mathbf{e}_{n_c}) \in \mathbb{R}^{\ell \times n_c}$. The following linear program is a quantitative test for frictional form closure. The optimal objective function value d^* is a measure of the distance the contact forces are from the boundaries of their friction cones, and hence a crude measure of how far a grasp is from

losing frictional form closure.

$$\begin{aligned} LP2: \quad & \text{maximize :} && d \\ & \text{subject to:} && \mathbf{G}\lambda = \mathbf{0} \\ & && \mathbf{F}\lambda - \mathbf{Id} \geq \mathbf{0} \\ & && d \geq 0 \\ & && e\lambda \leq n_c . \end{aligned}$$

The last inequality in *LP2* is simply the sum of the magnitudes of the normal components of the contact forces. After solving *LP2*, if $d^* = 0$ frictional form closure does not exist, but if $d^* > 0$, then it does.

If the grasp has frictional form closure, the last step to determine the existence of force closure is to verify the condition $\mathcal{N}(G) \cap \mathcal{N}(J^\top) = \mathbf{0}$. If it holds, then the grasp has force closure. This condition is easy to verify with another linear program *LP3*.

$$\begin{aligned} LP3: \quad & \text{maximize :} && d \\ & \text{subject to:} && \mathbf{G}\lambda = \mathbf{0} \\ & && \mathbf{J}^\top \lambda = \mathbf{0} \\ & && \mathbf{E}\lambda - \mathbf{Id} \geq \mathbf{0} \\ & && d \geq 0 \\ & && e\lambda \leq n_c . \end{aligned}$$

In summary, force closure testing is a three-step process:

Approximate Force Closure Test

1. Compute $\text{rank}(G)$.
 - a) If $\text{rank}(G) \neq n_v$, then force closure does not exist. Stop.

2. Solve *LP2*: *Test frictional form closure*.
 - a) If $d^* = 0$, then frictional form closure does not exist. Stop.
 - b) If $d^* > 0$, then frictional form closure exists and d^* is a crude measure of how far the grasp is from losing frictional form closure.
3. Solve *LP3*. *Test control of internal force*.
 - a) If $d^* > 0$, then force closure does not exist.
 - b) If $d^* = 0$, then force closure exists.

See Example 1, Part 6.

Planar Simplifications

In planar grasping systems, the approximate method described above is exact. This is because the SF models are meaningless, since rotations about the contact normal would cause motions out of the plane. With regard to the HF model, for planar problems, the quadratic friction cone becomes linear, with its cone represented exactly as:

$$\mathbf{F}_i = \frac{1}{\sqrt{1+\mu_i^2}} \begin{pmatrix} \mu_i & 1 \\ \mu_i & -1 \end{pmatrix}. \quad (28.47)$$

Nguyen's graphical form closure test can be applied to planar grasps with two frictional contacts [28.28]. The only change is that the four contact normals are replaced by the four generators of the two friction cones. However, the test can only determine frictional form closure, since it does not incorporate the additional information needed to determine force closure.

28.5 Examples

28.5.1 Example 1: Grasped Sphere

Part 1: $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{J}}$

Figure 28.11 shows a planar projection of a three-dimensional sphere of radius r grasped by two fingers, which make two contacts at angles θ_1 and θ_2 . The frames $\{C\}_1$ and $\{C\}_2$ are oriented so that their $\hat{\mathbf{o}}$ -directions point out of the plane of the figure (as indicated by the small bold circle). The axes of the frames $\{N\}$ and $\{B\}$ were chosen to be axis-aligned with coincident origins located at the center of the sphere. The z -axes are pointing out of the page. Observe that, since the two joint axes of the left finger are perpendicular to the (x, y) -plane, it operates in that plane for all time. The other finger has three

revolute joints. Because its first and second axes, $\hat{\mathbf{z}}_3$ and $\hat{\mathbf{z}}_4$, currently lie in the plane, rotation about $\hat{\mathbf{z}}_3$ will cause $\hat{\mathbf{z}}_4$ to attain an out-of-plane component and would cause the finger tip at contact 2 to leave the plane.

In the current configuration, the rotation matrix for the i -th contact frame is defined as

$$\mathbf{R}_i = \begin{pmatrix} -\cos(\theta_i) & \sin(\theta_i) & 0 \\ -\sin(\theta_i) & -\cos(\theta_i) & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (28.48)$$

The vector from the origin of $\{N\}$ to the i -th contact point is given by

$$\mathbf{c}_i - \mathbf{p} = r \begin{pmatrix} \cos(\theta_i) & \sin(\theta_i) & 0 \end{pmatrix}^\top. \quad (28.49)$$

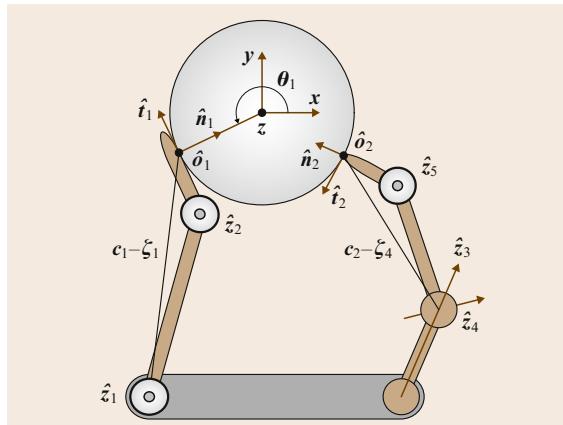

Fig. 28.11 A sphere grasped by a two-fingered hand with five revolute joints

Substituting into (28.3) and (28.6) yields the complete grasp matrix for contact i :

$$\tilde{\mathbf{G}}_i = \begin{pmatrix} -c_i & s_i & 0 & & \\ -s_i & -c_i & 0 & & \mathbf{0} \\ 0 & 0 & 1 & & \\ 0 & 0 & rs_i & -c_i & s_i & 0 \\ 0 & 0 & -rc_i & -s_i & -c_i & 0 \\ 0 & -r & 0 & 0 & 0 & 1 \end{pmatrix}, \quad (28.50)$$

where $\mathbf{0} \in \mathbb{R}^{3 \times 3}$ is the zero matrix and c_i and s_i are abbreviations for $\cos(\theta_i)$ and $\sin(\theta_i)$, respectively. The complete grasp matrix is defined as: $\tilde{\mathbf{G}} = (\tilde{\mathbf{G}}_1 \ \tilde{\mathbf{G}}_2) \in \mathbb{R}^{6 \times 12}$.

The accuracy of this matrix can be verified by inspection; for example, the first column is the unit wrench of the unit contact normal, the first three components are the direction cosines of $\hat{\mathbf{n}}_i$, and the last three are $(\mathbf{c}_i - \mathbf{p}) \times \hat{\mathbf{n}}_i$. Since $\hat{\mathbf{n}}_i$ is collinear with $(\mathbf{c}_i - \mathbf{p})$, the cross products (the last three components of the column) are zero. The last three components of the second column represent the moment of $\hat{\mathbf{t}}_i$ about the x -, y -, and z -axes of $\{N\}$. Since $\hat{\mathbf{t}}_i$ lies in the (x, y) -plane, the moments with the x - and y -axes are zero. Clearly $\hat{\mathbf{t}}_i$ produces a moment of $-r$ about the z -axis.

Construction of the complete hand Jacobian $\tilde{\mathbf{J}}_i$ for contact i requires knowledge of the joint axis directions and the origins of the frames fixed to the links of

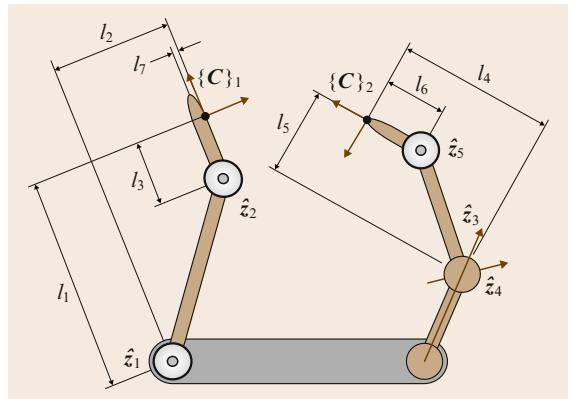

Fig. 28.12 Relevant data for the hand Jacobian

each finger. Figure 28.12 shows the hand in the same configuration as in Fig. 28.11, but with some additional data needed to construct the hand Jacobian. Assume that the origins of the joint frames lie in the plane of the figure.

In the current configuration, the quantities of interest for contact 1, expressed in $\{C\}_1$ are:

$$\mathbf{c}_1 - \boldsymbol{\xi}_1 = (l_2 \ l_1 \ 0)^\top, \quad (28.51)$$

$$\mathbf{c}_1 - \boldsymbol{\xi}_2 = (l_7 \ l_3 \ 0)^\top, \quad (28.52)$$

$$\hat{\mathbf{z}}_1 = \hat{\mathbf{z}}_2 = (0 \ 0 \ 1)^\top. \quad (28.53)$$

The quantities of interest for contact 2, in $\{C\}_2$ are:

$$\mathbf{c}_2 - \boldsymbol{\xi}_3 = \mathbf{c}_2 - \boldsymbol{\xi}_4 = (l_4 \ -l_5 \ 0)^\top, \quad (28.54)$$

$$\mathbf{c}_2 - \boldsymbol{\xi}_5 = (l_6 \ 0 \ 0)^\top, \quad (28.55)$$

$$\hat{\mathbf{z}}_3 = (0 \ -1 \ 0)^\top, \quad (28.56)$$

$$\hat{\mathbf{z}}_4(q_3) = \frac{\sqrt{2}}{2} (-1 \ -1 \ 0)^\top, \quad (28.57)$$

$$\hat{\mathbf{z}}_5(q_3, q_4) = (0 \ 0 \ 1)^\top. \quad (28.58)$$

Generally all of the components of the $\mathbf{c} - \boldsymbol{\xi}$ and $\hat{\mathbf{z}}$ vectors (including the components that are zero in the current configuration) are functions of \mathbf{q} and \mathbf{u} . The dependencies of the $\hat{\mathbf{z}}$ vectors are shown explicitly.

Substituting into (28.14), (28.11), and (28.8) yields the complete hand Jacobian $\tilde{\mathbf{J}} \in \mathbb{R}^{12 \times 5}$:

$$\tilde{\mathbf{J}} = \begin{pmatrix} -l_1 & -l_3 \\ l_2 & l_7 \\ 0 & 0 \\ 0 & 0 & \mathbf{0} \\ 0 & 0 \\ 1 & 1 \\ \hline 0 & 0 & 0 \\ 0 & 0 & l_6 \\ l_4 & \frac{\sqrt{2}}{2}(l_4+l_5) & 0 \\ \mathbf{0} & 0 & -\frac{\sqrt{2}}{2} \\ -1 & -\frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The horizontal dividing line partitions $\tilde{\mathbf{J}}$ into $\tilde{\mathbf{J}}_1$ (on top) and $\tilde{\mathbf{J}}_2$ (on the bottom). The columns correspond to joints 1–5. The block diagonal structure is a result of the fact that finger i directly affects only contact i .

Example 1, Part 2: \mathbf{G} and \mathbf{J}

Assume that the contacts in Fig. 28.11 are both of type SF. Then the selection matrix \mathbf{H} is given by

$$\mathbf{H} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ \hline & & 1 & 0 & 0 & 0 & 0 \\ & & 0 & 1 & 0 & 0 & 0 \\ & \mathbf{0} & 0 & 0 & 1 & 0 & 0 \\ & & 0 & 0 & 0 & 1 & 0 \end{pmatrix},$$

thus the matrices $\mathbf{G}^\top \in \mathbb{R}^{8 \times 6}$ and $\mathbf{J} \in \mathbb{R}^{8 \times 5}$ are constructed by removing rows 5, 6, 11, and 12 from $\tilde{\mathbf{G}}^\top$ and $\tilde{\mathbf{J}}$:

$$\mathbf{G}^\top = \begin{pmatrix} -c_1 & -s_1 & 0 & 0 & 0 & 0 \\ s_1 & -c_1 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_1 & -rc_1 & 0 \\ 0 & 0 & 0 & -c_1 & -s_1 & 0 \\ -c_2 & -s_2 & 0 & 0 & 0 & 0 \\ s_2 & -c_2 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_2 & -rc_2 & 0 \\ 0 & 0 & 0 & -c_2 & -s_2 & 0 \end{pmatrix}, \quad (28.59)$$

$$\mathbf{J} = \left(\begin{array}{cc|ccc} -l_1 & -l_3 & & & & \\ l_2 & l_7 & & & & \mathbf{0} \\ 0 & 0 & & & & \\ 0 & 0 & & & & \\ \hline 0 & 0 & 0 & 0 & 0 & \\ 0 & 0 & 0 & 0 & l_6 & \\ \mathbf{0} & d & \frac{\sqrt{2}}{2}(l_4+l_5) & 0 & 0 & \\ 0 & -\frac{\sqrt{2}}{2} & 0 & 0 & 0 & \end{array} \right). \quad (28.60)$$

Notice that changing the contact models is easily accomplished by removing more rows. Changing contact 1 to HF would eliminate the fourth rows from \mathbf{G}^\top and \mathbf{J} , while changing it to PwoF would eliminate the second, third, and fourth rows of \mathbf{G}^\top and \mathbf{J} . Changing the model at contact 2 would remove either just the eighth row or the sixth, seventh, and eighth rows.

Example 1, Part 3: Reduction to the Planar Case

The grasp shown in Fig. 28.11 can be reduced to a planar problem by following the explicit formulas given above, but it can also be done by understanding the physical interpretations of the various rows and columns of the matrices. Proceed by eliminating velocities and forces that are out of the plane. This can be done by removing the z -axes from $\{N\}$ and $\{B\}$, and the \hat{o} -directions at the contacts. Further, joints 3 and 4 must be locked. The resulting \mathbf{G}^\top and \mathbf{J} are constructed eliminating certain rows and columns. \mathbf{G}^\top is formed by removing rows 3, 4, 7, and 8 and columns 3, 4, and 5. \mathbf{J} is formed by removing rows 3, 4, 7, and 8 and columns 3 and 4,

Table 28.9 Dimensions of the main subspaces and classifications of the grasp studied in Example 1

| Models | Dimension | Class |
|--------|-----------------------------------------|---------------|
| HF,HF | $\dim \mathcal{N}(\mathbf{J}) = 1$ | Redundant |
| | $\dim \mathcal{N}(\mathbf{G}^\top) = 1$ | Indeterminate |
| | $\dim \mathcal{N}(\mathbf{G}) = 1$ | Graspable |
| | $\dim \mathcal{N}(\mathbf{J}^\top) = 2$ | Defective |
| SF,HF | $\dim \mathcal{N}(\mathbf{J}) = 1$ | Redundant |
| | $\dim \mathcal{N}(\mathbf{G}) = 1$ | Graspable |
| | $\dim \mathcal{N}(\mathbf{J}^\top) = 3$ | Defective |
| HF,SF | $\dim \mathcal{N}(\mathbf{G}) = 1$ | Graspable |
| | $\dim \mathcal{N}(\mathbf{J}^\top) = 2$ | Defective |
| SF,SF | $\dim \mathcal{N}(\mathbf{G}) = 2$ | Graspable |
| | $\dim \mathcal{N}(\mathbf{J}^\top) = 3$ | Defective |

yielding:

$$\mathbf{G}^\top = \begin{pmatrix} -c_1 & -s_1 & 0 \\ s_1 & -c_1 & -r \\ -c_2 & -s_2 & 0 \\ s_2 & -c_2 & -r \end{pmatrix}, \quad (28.61)$$

$$\mathbf{J} = \begin{pmatrix} -l_1 & -l_3 & 0 \\ l_2 & l_7 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & l_6 \end{pmatrix}. \quad (28.62)$$

Example 1, Part 4: Grasp Classes

The first column of Table 28.9 reports the dimensions of the main subspaces of \mathbf{J} and \mathbf{G} for the sphere grasping example with different contact models. Only nontrivial null spaces are listed.

In the case of two **HF** contact models, all four null spaces are nontrivial, so the system satisfies the conditions for all four grasp classes. The system is graspable because there is an internal force along the line segment connecting the two contact points. Indeterminacy is manifested in the fact that the hand cannot resist a moment acting about that line. Redundancy is seen to exist since joint 3 can be used to move contact 2 out of the plane of the figure, but joint 4 can be rotated in the opposite direction to cancel this motion. Finally, the grasp is defective, because the contact forces and the instantaneous velocities along the $\hat{\mathbf{o}}_1$ and $\hat{\mathbf{n}}_2$ directions of contact 1 and 2, respectively, cannot be controlled through the joint torques and velocities. These interpretations are borne out in the null space basis matrices below, computed using $r = 1$, $\cos(\theta_1) = -0.8 = -\cos(\theta_2)$, $\sin(\theta_1) = \cos(\theta_2) = -0.6$, and $l_7 = 0$:

$$N(\mathbf{J}) \approx \begin{pmatrix} 0 \\ 0 \\ -0.73 \\ 0.69 \\ 0 \end{pmatrix}, \quad N(\mathbf{G}^\top) \approx \begin{pmatrix} 0 \\ 0 \\ 0.51 \\ 0.86 \\ 0 \\ 0 \end{pmatrix}, \quad (28.63)$$

$$N(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ -0.42 \\ 0 \\ 0.57 \\ 0.42 \\ 0 \end{pmatrix}, \quad N(\mathbf{J}^\top) = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 0 & -1 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}. \quad (28.64)$$

Notice that changing either contact to **SF** makes it possible for the hand to resist external moments applied about the line containing the contacts, so the grasp loses indeterminacy, but retains graspability (with squeezing still possible along the line of the contacts). However, if contact 2 is the **SF** contact, the grasp loses its redundancy. While the second contact point can still be moved out of the plane by joint 3 and back in by joint 4, this canceled translation of the contact point yields a net rotation about $\hat{\mathbf{n}}_2$ (this also implies that the hand can control the moment applied to the object along the line containing the contacts). Changing to **SF** at contact 2 does *not* affect the hand's inability to move contact 1 and contact 2 in the $\hat{\mathbf{o}}_1$ and $\hat{\mathbf{n}}_2$ directions, so the defectivity property is retained.

Example 1, Part 5: Desirable Properties

Assuming contact model types of **SF** and **HF** at contacts 1 and 2, respectively, \mathbf{G} is full row rank and so $N(\mathbf{G}^\top) = \mathbf{0}$ (Table 28.9). Therefore, as long as the hand is sufficiently dexterous, it can apply any wrench in \mathbb{R}^6 to the object. Also, if the joints are locked, object motion will be prevented. Assuming the same problem values used in the previous part of this problem, the matrix \mathbf{G}^\top is:

$$\mathbf{G}^\top = \begin{pmatrix} -c_1 & -s_1 & 0 & 0 & 0 & 0 \\ s_1 & -c_1 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_1 & -rc_1 & 0 \\ 0 & 0 & 0 & -c_1 & -s_1 & 0 \\ -c_2 & -s_2 & 0 & 0 & 0 & 0 \\ s_2 & -c_2 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_2 & -rc_2 & 0 \end{pmatrix}. \quad (28.65)$$

Bases for the three nontrivial null spaces are:

$$N(\mathbf{J}^\top) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (28.66)$$

$$N(\mathbf{J}) \approx \begin{pmatrix} 0 \\ 0 \\ -0.73 \\ 0.69 \\ 0 \end{pmatrix},$$

$$\mathcal{N}(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ -0.42 \\ 0 \\ 0 \\ 0.57 \\ 0.42 \\ 0 \end{pmatrix}. \quad (28.67)$$

Since $\mathcal{R}(\mathbf{J})$ is four dimensional and $\mathcal{N}(\mathbf{G})$ is one dimensional, the maximum dimension of $\mathcal{R}(\mathbf{J}) + \mathcal{N}(\mathbf{G})$ cannot be more than five, and therefore, the hand cannot control all possible object velocities, for example, the contact velocity $\mathbf{v}_{cc} = (0\ 0\ 0\ 0\ 0.8\ 0\ 0\ 0)^T$ is in $\mathcal{N}(\mathbf{J}^\top)$, and so cannot be controlled by the fingers. It is also equal to 0.6 times the third column of \mathbf{G}^\top plus the fourth column of \mathbf{G}^\top and therefore is in $\mathcal{R}(\mathbf{G}^\top)$. Since the mapping between $\mathcal{R}(\mathbf{G})$ and $\mathcal{R}(\mathbf{G}^\top)$ is one to one and onto, this uncontrollable contact velocity corresponds to a unique uncontrollable object velocity, $\mathbf{v} = (0\ 0\ 0.6\ 1\ 0\ 0)$. In other words, the hand cannot cause the center of the sphere to translate in the z -direction, while also rotating about the x -axis (and not other axes simultaneously).

On the question of controlling all internal object forces, the answer is yes, since $\mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G}) = \mathbf{0}$. This conclusion is clear from the fact that $\mathcal{N}(\mathbf{G})$ has nonzero values in the first, second, and sixth positions, while all columns of $\mathcal{N}(\mathbf{J}^\top)$ have zeros in those positions.

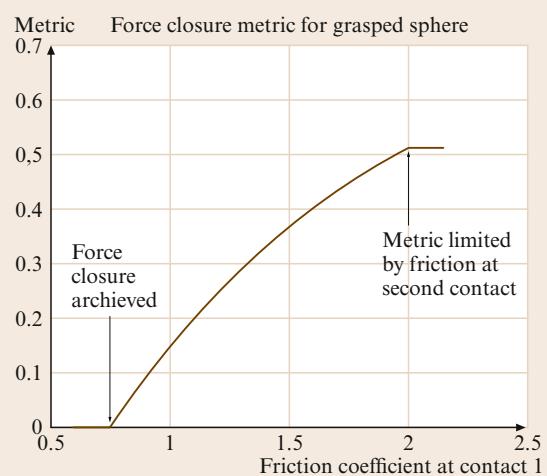

Fig. 28.13 Plot of the force closure metric versus the friction coefficient on contact 1

Example 1, Part6: Force Closure

Again assume that contacts 1 and 2 on the grasped sphere were modeled as SF and HF contacts, respectively. Under this assumption, \mathbf{G} is full row rank, and the internal force corresponds to equal and opposite contact forces. For frictional form closure to exist, the internal force must lie within the friction cones. Choosing r and the sines and cosines of θ_1 and θ_2 as in example 1, part 4, frictional form closure can be shown to exist if both friction coefficients are greater than 0.75. For this grasp, since $\mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G}) = \mathbf{0}$, frictional form closure is equivalent to force closure.

The plot in Fig. 28.13 was generated by fixing $\mu_2 = 2.0$ and varying μ_1 . Notice that, for $\mu_1 < 0.75$, force closure does not exist. The metric increases smoothly until μ_1 becomes equal to μ_2 . At this point, increasing μ_1 further does not improve force closure, since contact 2 becomes the limiting factor. To increase the metric further, both friction coefficients must be increased.

28.5.2 Example 2: Grasped Polygon in the Plane

Part 1: \mathbf{G} and \mathbf{J}

Figure 28.14 shows a planar hand grasping a polygon. Finger 1 (on the right) contains two joints numbered 1 and 2. Finger 2 contains joints 3–7, which are numbered in increasing order moving from the palm distally. The inertial frame has been chosen to lie inside the object, with its x -axis passing through contacts 1 and 2, and collinear with the normal vector of contact 2.

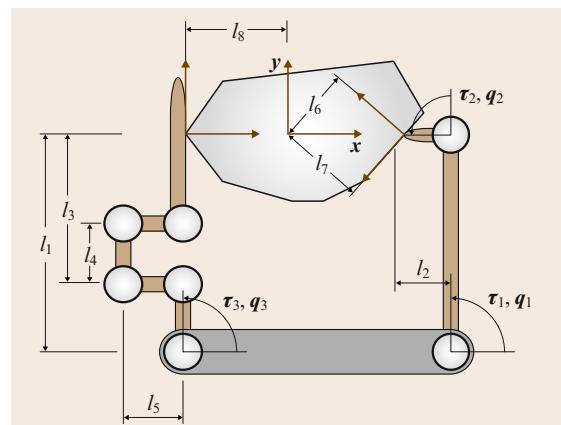

Fig. 28.14 Planar hand with two fingers and seven joints grasping a polygonal object

The rotation matrices are given by

$$\mathbf{R}_1 = \begin{pmatrix} -0.8 & -0.6 \\ 0.6 & -0.8 \end{pmatrix}, \quad \mathbf{R}_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (28.68)$$

Assuming HF contacts, \mathbf{G} is given as

$$\mathbf{G} = \left(\begin{array}{cc|cc} -0.8 & -0.6 & 1 & 0 \\ 0.6 & -0.8 & 0 & 1 \\ \hline l_6 & -l_7 & 0 & -l_8 \end{array} \right). \quad (28.69)$$

Notice that the first two columns of \mathbf{G} correspond to the normal and tangential unit vectors at contact 1. The third and fourth columns correspond to contact 2.

Assuming HF contacts and that all joints are active (i.e., not locked), \mathbf{J} is

$$\mathbf{J}^\top = \left(\begin{array}{cc|c} 0.8l_1 & 0.6l_1 & \mathbf{0} \\ -0.6l_2 & 0.8l_2 & \hline -l_1 & 0 \\ \hline \mathbf{0} & -l_3 & 0 \\ & -l_3 & l_5 \\ & -l_3 + l_4 & l_5 \\ & -l_3 + l_4 & 0 \end{array} \right). \quad (28.70)$$

The first two columns of \mathbf{J}^\top are the torques required to produce a unit force in the $\hat{\mathbf{n}}_1$ and $\hat{\mathbf{t}}_1$ directions at contact 1. The horizontal line through the matrix partitions the contributions for the first finger (the upper part) and second finger. Notice that both \mathbf{J}^\top and \mathbf{G} are full column rank.

Example 2, Part 2: Grasp Classes

This example clearly illustrates the physical qualities of the various grasp classes without introducing features that can cloud the descriptions.

We now discuss the details of the four grasp classes using the previous planar example. During these discussions it is useful to choose nondimensional values for the parameters in the grasping system. Assume l_4 is the unit length. The other lengths as fractions of l_4 are:

$$l_1 = 2.7, \quad l_2 = 1.0, \quad l_3 = 1.7, \quad (28.71)$$

$$l_4 = 1.0, \quad l_5 = 1.0, \quad l_6 = 1.0, \quad (28.72)$$

$$l_7 = 1.3, \quad l_8 = 1.5. \quad (28.73)$$

Redundant

Redundancy exists if $\mathcal{N}(\mathbf{J})$ is nontrivial. Assuming that both contacts are hard contacts and that all the joints

are active, $\text{rank}(\mathbf{J}) = 4$, so $\mathcal{N}(\mathbf{J})$ is three dimensional.

A basis for $\mathcal{N}(\mathbf{J})$ was obtained as

$$\mathcal{N}(\mathbf{J}) \approx \left(\begin{array}{ccc} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \hline -0.50 & -0.24 & -0.18 \\ 0.53 & 0.67 & -0.10 \\ 0.48 & -0.49 & -0.02 \\ -0.48 & 0.49 & 0.02 \\ -0.02 & 0.01 & 0.98 \end{array} \right). \quad (28.74)$$

Since the first two rows are zero, $\mathcal{N}(\mathbf{J})$ does not include motions of the first finger (on the right of the palm). To understand this, assume that the object is fixed in the plane. Then the first finger cannot maintain sticking contact at contact 1 unless its joints are also fixed.

The three nonzero columns corresponding to finger 2 show that there are three basis motions of its joints that allow the finger contact to stick to the object contact. For example, the first column shows that, if joint 3 moves roughly as much as joints 4, 5, and 6, but in the opposite direction as joints 4 and 5 and in the same direction as joint 6, while joint 7 is more or less fixed, then contact 2 will be maintained.

Notice that finger 2 contains a parallelogram. Because of this geometry, one can see that the vector $(0\ 0\ 0\ -1\ 1\ -1\ 1)^\top$ is an element of $\mathcal{N}(\mathbf{J})$. The velocity interpretation of this vector is that the link of the finger connected to the palm, and the link touching the object remain fixed in space, while the parallelogram moves as a simple four-bar mechanism. Similarly, joint actions in $\mathcal{N}(\mathbf{J})$ do not affect the contact forces, but cause internal hand velocities. Also, notice that, since $\mathcal{N}(\mathbf{J}^\top) = \mathbf{0}$, the entire space of possible generalized velocities and forces at the contacts can be generated by the joints.

Indeterminate

As noted above, with HF contact models, the system is graspable. However, replacing the HF models with PwoF models removes the tangent force components in the $\hat{\mathbf{t}}_1$ and $\hat{\mathbf{t}}_2$ directions. This effectively removes columns 2 and 4 from \mathbf{G} , which guarantees that the system will be indeterminate. The reduced matrix is denoted by $\mathbf{G}_{(1,3)}$. In this case $\mathcal{N}(\mathbf{G}_{(1,3)}^\top)$ is

$$\mathcal{N}(\mathbf{G}_{(1,3)}^\top) \approx \left(\begin{array}{c} 0 \\ -0.86 \\ 0.51 \end{array} \right). \quad (28.75)$$

Physically, this basis vector corresponds to moving the object such that the point coincident with the origin of $\{N\}$ moves directly downward, while the object rotates counterclockwise. Also, if the analogous force and moment were applied to the object, the frictionless contacts could not maintain equilibrium.

Graspable

With two HF contact models in force, $\text{rank}(\mathbf{G}) = 3$, so $\mathcal{N}(\mathbf{G})$ is one dimensional and the system is graspable. The null space basis vector of the grasp matrix is:

$$\mathbf{N}(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ 0.42 \\ 0.71 \\ 0 \end{pmatrix}. \quad (28.76)$$

The physical interpretation of this basis vector is two opposing forces acting through the two contact points. Recall that, because the contact model is kinematic, there is no consideration of contact friction. However, given the direction of the contact normal relative to the line of the internal force, one can see that if the coefficient of friction is not greater than 0.75, squeezing tightly will cause sliding at contact 1, thus violating the kinematic contact model.

Defective

In a defective grasp, $\mathcal{N}(\mathbf{J}^\top) \neq \mathbf{0}$. Given that the original \mathbf{J} is full row rank, the grasp is *not* defective. However, it can be made defective by locking a number of joints and/or changing the hand's configuration so that \mathbf{J} is no longer full rank. For example, locking joints 4, 5, 6, and 7 makes finger 2 a single-link finger with only joint 3 active. In this new grasping system, $\mathbf{J}_{(1,2,3)}^\top$ is simply the first three rows of the original \mathbf{J}^\top given in (28.70), where the subscript is the list of indices of active joints. The null space basis vector is:

$$\mathbf{N}(\mathbf{J}_{(1,2,3)}^\top) = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \quad (28.77)$$

This grasp is defective, since there is a subspace of contact velocities and forces that cannot be controlled by joint generalized velocities and forces. Since only the last component of $\mathbf{N}(\mathbf{J}_{(1,2,3)}^\top)$ is nonzero, it

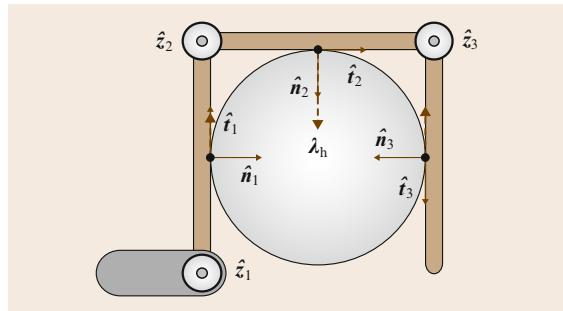

Fig. 28.15 A sphere grasped by a finger with three revolute joints. The force direction λ_h (dashed line) is a force that belongs to both $\mathcal{N}(\mathbf{G})$ and $\mathcal{N}(\mathbf{J}^\top)$ and causes hyperstaticity

would be impossible for the hand to give the contact point 2 on the object a velocity in the $\hat{\mathbf{t}}_2$ -direction while maintaining the contact. This is also clear from the arrangement of joint 3, contact 2, and the direction of the contact normal. The dual interpretation is that forces in $\mathcal{N}(\mathbf{J}^\top)$ are resisted by the structure and the corresponding joint loads is zero, or equivalently that those forces are not controllable by the hand. Notice that if the model of contact 2 were changed to point without friction, then $\mathbf{N}(\mathbf{J}_{(1,2,3)}^\top) = \mathbf{0}$ and the system would no longer be defective.

28.5.3 Example 3: Hyperstatic Grasps

Part 1: $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{J}}$

Figure 28.15 shows a planar projection of a three-dimensional sphere of radius l grasped by one finger only, with three revolute joints, through three contacts. The frames $\{C\}_1$, $\{C\}_2$, and $\{C\}_3$ are oriented so that their $\hat{\mathbf{o}}$ -directions point out of the plane of the figure (as indicated by the small bold circle). The axes of the frames $\{N\}$ and $\{B\}$ were chosen to be axis-aligned with coincident origins located at the center of the sphere. The z -axes are pointing out of the page. Observe that since the three joint axes of the finger are perpendicular to the (x, y) -plane, the grasp operates in that plane for all time.

Assume that the width of all the links of the robotic hand is zero. Rotation matrices \mathbf{R}_i and vectors $\mathbf{c}_i - \mathbf{p}$ for $i = 1, \dots, 3$, can be computed as in (28.48) and (28.49) considering that $\theta_1 = \pi$, for contact 1, $\theta_2 = \pi/2$ and $\theta_3 = 0$, for contacts 2 and 3, respectively. Finally, the complete grasp matrix is $\tilde{\mathbf{G}}^\top = (\tilde{\mathbf{G}}_1 \ \tilde{\mathbf{G}}_2 \ \tilde{\mathbf{G}}_3)^\top \in \mathbb{R}^{18 \times 6}$

where $\tilde{\mathbf{G}}_i$ is as defined in (28.50):

$$\tilde{\mathbf{G}}^\top = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & l & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \hline 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & l & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \hline -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & -l & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

Construction of the complete hand Jacobian $\tilde{\mathbf{J}}_i$ for contact i requires knowledge of the joint axis directions and the origins of the frames fixed to the links of each finger. Assume that the origins of the DH frames lie in the plane of the figure. In the current configuration, the quantities of interest for contact 1, expressed directly in $\{N\}$, are

$$\begin{aligned} \mathbf{c}_1 - \boldsymbol{\xi}_1 &= \begin{pmatrix} 0 & l & 0 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_1 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top. \end{aligned}$$

The quantities of interest for contact 2, in $\{N\}$, are

$$\begin{aligned} \mathbf{c}_2 - \boldsymbol{\xi}_1 &= \begin{pmatrix} l & 2l & 0 \end{pmatrix}^\top, \\ \mathbf{c}_2 - \boldsymbol{\xi}_2 &= \begin{pmatrix} l & 0 & 0 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_1 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_2 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top. \end{aligned}$$

The quantities of interest for contact 3, in $\{N\}$, are

$$\begin{aligned} \mathbf{c}_3 - \boldsymbol{\xi}_1 &= \begin{pmatrix} 2l & l & 0 \end{pmatrix}^\top, \\ \mathbf{c}_3 - \boldsymbol{\xi}_2 &= \begin{pmatrix} 2l & -l & 0 \end{pmatrix}^\top, \end{aligned}$$

$$\begin{aligned} \mathbf{c}_3 - \boldsymbol{\xi}_3 &= \begin{pmatrix} 0 & -l & 0 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_1 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_2 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top, \\ \hat{\mathbf{z}}_3 &= \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^\top. \end{aligned}$$

The complete hand Jacobian $\tilde{\mathbf{J}} \in \mathbb{R}^{18 \times 3}$ (contact velocities are expressed in $\{\mathbf{C}_i\}$) is:

$$\tilde{\mathbf{J}} = \begin{pmatrix} -l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ \hline -l & -l & 0 \\ -2l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 0 \\ \hline l & -l & -l \\ -2l & -2l & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \end{pmatrix}.$$

The horizontal dividing line partitions $\tilde{\mathbf{J}}$ into $\tilde{\mathbf{J}}_1$ (on top), $\tilde{\mathbf{J}}_2$, and $\tilde{\mathbf{J}}_3$ (on the bottom). The columns correspond to joints 1–3.

Example 3, Part 2: \mathbf{G} and \mathbf{J}

Assume that the three contacts in Fig. 28.15 are of type HF. Then the selection matrix \mathbf{H} is given by

$$\mathbf{H} = \begin{pmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \end{pmatrix}, \quad (28.78)$$

where \mathbf{I} and $\mathbf{0}$ are in $\mathbb{R}^{3 \times 3}$, thus the matrices $\mathbf{G}^\top \in \mathbb{R}^{9 \times 6}$ and $\mathbf{J} \in \mathbb{R}^{9 \times 3}$ are obtained by removing rows related to

rotations from $\tilde{\mathbf{G}}^\top$ and $\tilde{\mathbf{J}}$:

$$\mathbf{G}^\top = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & l & 0 \\ \hline 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & l & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & -l & 0 \end{pmatrix},$$

$$\mathbf{J} = \begin{pmatrix} l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ \hline l & l & 0 \\ 2l & 0 & 0 \\ 0 & 0 & 0 \\ \hline l & l & l \\ 2l & 2l & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Example 3, Part 3: Grasp Classes

The first column of Table 28.10 reports the dimensions of the main subspaces of \mathbf{J}^\top and \mathbf{G} for the sphere grasping example with three hard-finger contacts. Only nontrivial null spaces are listed.

The system is defective because there are generalized contact forces belonging to the subspace that are resisted by the structure, which correspond to zero joint actions:

$$\mathbf{N}(\mathbf{J}^\top) = \begin{pmatrix} 0 & 0 & 0 & -2 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The first three columns represent generalized forces acting at the three contact points in a direction perpendicular to the plane of the Fig. 28.15. The fourth column corresponds to a contact force applied only along the $\hat{\mathbf{t}}_1$ direction.

Table 28.10 Dimensions of the main subspaces and classifications of the grasp given in Example 3

| Dimension | Class |
|----------------------------------------------------------------------|-------------|
| $\dim \mathcal{N}(\mathbf{J}^\top) = 6$ | Defective |
| $\dim \mathcal{N}(\mathbf{G}) = 3$ | Graspable |
| $\dim \mathcal{N}(\mathbf{J}^\top) \cap \mathcal{N}(\mathbf{G}) = 1$ | Hyperstatic |

The system is graspable because the subspace of internal forces is three dimensional; a possible basis matrix is:

$$\mathbf{N}(\mathbf{G}) = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 0 & 0 \\ \hline 1 & 0 & 2 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The three force vectors of the subspace $\mathbf{N}(\mathbf{G})$ are easily identified from Fig. 28.15. Note that all forces are expressed in local contact frames. The first column vector of $\mathbf{N}(\mathbf{G})$ represents opposed forces at contacts 1 and 2 along the line joining contacts 1 and 2. The second column vector parameterizes opposed forces at contacts 1 and 3 along the line joining contacts 1 and 3. The last vector represents forces along direction λ_h , shown as the dashed lines in Fig. 28.15. Note that this direction (in wrench intensity space) corresponds to two upward friction forces at the left and right contacts and one downward with double the magnitude from the center of the top link in the work space.

Finally, the grasp is hyperstatic because

$$\mathbf{N}(\mathbf{G}) \cap \mathbf{N}(\mathbf{J}^\top) = \begin{pmatrix} 0 \\ 1 \\ 0 \\ \hline 2 \\ 0 \\ 0 \\ \hline 0 \\ -1 \\ 0 \end{pmatrix} \neq 0.$$

Hyperstatic forces in this subspace are internal forces that cannot be controlled through the hand joints. In

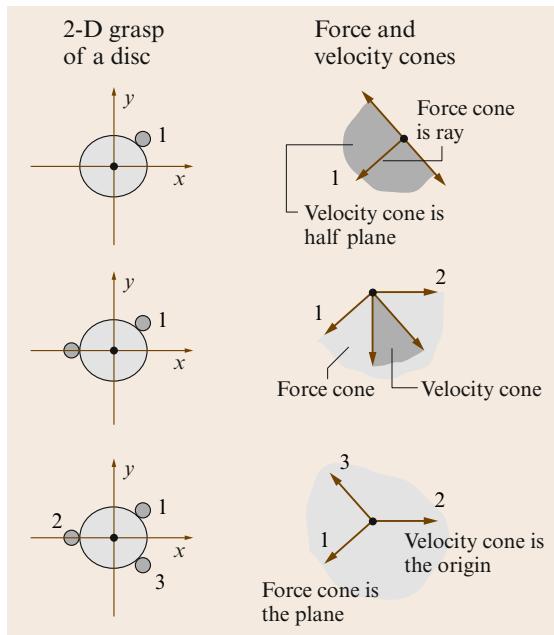

Fig. 28.16 The case of a translating disc in the plane: relationship between frictionless contacts and possible disc velocities and net contact forces

Fig. 28.15 the internal force λ_h that is also in $N(\mathbf{J}^\top)$ is reported.

The grasp in Fig. 28.15 is an example of a *power grasp*, a style of grasp mentioned earlier that uses many contact points not only on the fingertips but also on the links of fingers and the palm [28.4, 20, 31].

All power grasps are kinematically defective ($N(\mathbf{J}^\top) \neq \mathbf{0}$) and are usually hyperstatic. According to

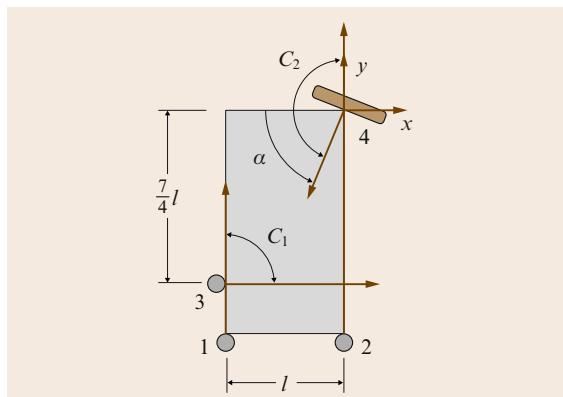

Fig. 28.17 Planar grasp with first-order form closure if $1.052 < \alpha < \frac{\pi}{2}$

Sect. 28.4.2, rigid-body modeling is not sufficient to capture the overall system behavior, because the generalized contact forces in $N(\mathbf{G}) \cap N(\mathbf{J}^\top)$ leave the dynamics indeterminate.

Many approaches have been used to overcome the rigid-body limitation in hyperstatic grasps such as those proposed in [28.12, 16, 17] where viscoelastic contact models have been used to solve the force indeterminacy. In [28.32], the authors found that a sufficient condition for hyperstaticity is $m > q + 6$, where m is the dimension of the contact force vector.

28.5.4 Example 4: Duality

Consider a frictionless disc constrained to translate in the plane (Fig. 28.16). In this problem $n_v = 2$, so the space of applied contact forces and object velocities is the plane \mathbb{R}^2 . In the top pair of pictures, a single (fixed) contact point imposes a half-space constraint on the instantaneous velocity and limits the force at a frictionless contact to the ray. Both the ray and the (dark gray) half space are defined by the contact normal pointing into the object. Notice that the ray and half space are dual cones. When two contacts are present, the (light gray) force cone becomes the nonnegative span of the two contact normals and the velocity cone is its dual. With the addition of the third contact, the grasp has form closure, as indicated by the degeneration of the velocity cone to the origin and the expansion of the force cone to become equal to the plane.

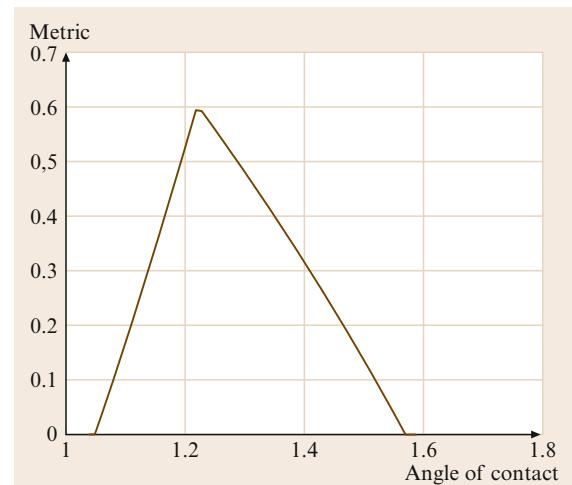

Fig. 28.18 Plot of closure metric versus angle of contact if $1.04 < \alpha < 1.59$

It is important to point out that the discussion of the dual cones applies to three-dimensional bodies after replacing the contact normals with the columns of \mathbf{G} .

28.5.5 Example 5: Form Closure

Form closure of a spatial object requires seven contacts, which is difficult to illustrate. Therefore, the only form closure example analyzed in this chapter is for the following planar problem.

The fundamental features of a planar grasp with four contacts are shown in Fig. 28.17. Notice that the normal at the fourth contact is well defined despite the contact occurring on the vertex of the object. The angle α of the finger is allowed to vary, and it can be shown that form

closure exists if α lies in the interval $1.0518 < \alpha < \frac{\pi}{2}$. Notice that a critical value of α occurs when the lower edge of \mathcal{C}_2 contains contact point 3 ($\alpha \approx 1.0518$) and contact point 2 ($\alpha = \frac{\pi}{2}$).

Choosing the frame for analysis with origin at the fourth contact point, the grasp matrix for this example is

$$\mathbf{G} = \begin{pmatrix} 0 & 0 & 1 & -\cos(\alpha) \\ 1 & 1 & 0 & -\sin(\alpha) \\ -l & 0 & \frac{7}{4}l & 0 \end{pmatrix}. \quad (28.79)$$

Form closure was tested for a range of angles as shown in the plot in Fig. 28.18, which indicates that the grasp farthest from losing form closure has $\alpha \approx 1.22$ radians, which is the configuration shown in the figure.

28.6 Conclusion and Further Reading

A great deal of understanding of grasping systems can be derived from the simple linear kinematic, dynamic, and contact models. The most widely used grasp classifications and closure properties can all be derived from these models under the rigid-body assumption. Linearizing these models leads to metrics and tests that can be computed efficiently using computational linear algebra and linear programming techniques. In-depth discussions of grasp kinematics and grasp classification can be found in [28.11, 16, 21, 32–36]. When making simplifying assumptions, one has to wonder what insights have been lost. For the interested reader, there are a host of papers that analyze grasping system under more sophisticated assumptions. In general, bodies are curved and compliant [28.13, 22, 31, 37–39]. Contact friction models are not quite as simple as the Coulomb approximation so widely adopted, and presented in this chapter; for example, if a contact has to resist a moment about its normal, its effective tangential friction coefficient is reduced [28.29]. In our analysis, the quadratic Coulomb friction cone was approximated by a polyhedral cone. The analysis problems are more difficult when using the quadratic cone, but they are quite tractable [28.30, 40]. In principle, a properly designed hand-object system could be controlled to maintain all contacts, but worldly realities can lead to unwanted slipping or twisting.

Other important research topics within the area of grasping are: grasp synthesis, force distribution, stability, and dexterous manipulation. Grasp synthesis is the problem of choosing the posture of the hand and contact point locations to optimize a grasp quality metric. Note that this is quite a different issue from *grasp*

acquisition, which refers to the act of achieving the chosen grasp. Grasp acquisition is an act of dexterous manipulation. One of the first studies of grasp synthesis for multifingered hands was undertaken by Jameson in 1985 [28.41] who designed a Levenberg–Marquardt algorithm to search the surface of an object for the locations of three points that would achieve force closure. Since this work, many other metrics and approaches to searching for high-quality grasps have been implemented (see, for example, [28.42–47]). A recent paper by Liu et al. provides an in-depth discussion of several quality metrics. They further demonstrate that, if one chooses finger contact locations by optimizing the metrics and if a force closure grasp exists, then the grasps obtained are force closed [28.48]. For grasping of several objects simultaneously, see [28.49].

The grasp force distribution problem is that of finding *good* joint actions and contact forces to balance a given external load applied to the object. This problem was studied in the context of walking machines first by McGhee and Orin [28.50] and later by several others [28.51, 52]. Kumar and Waldron applied similar techniques to force distribution problems in grasping [28.53]. Recent work by Han et al. and Buss et al. has solved the force distribution problem with nonlinear friction cone constraints by taking advantage of second-order cone programming and related techniques [28.30, 40, 54]. In power grasps, this problem is more involved because contact forces that cannot be applied may exist, as studied in [28.17, 19, 20, 55].

Grasp stability is too often equated to grasp closure, because all external forces can be balanced by the hand.

However, grasp closure is really equivalent to the existence of equilibrium, which is a necessary condition for stability, but not a sufficient condition. The common definition of stability outside of the field of robotic grasping requires that, when a system is deflected from an equilibrium point, the system returns to this point. This was the approach taken by *Hanafusa* and *Asada*, who studied grasp stability for a hand with three elastic fingers [28.56]. *Cutkosky* took the analysis to three dimensions and accounted for finger and object curvatures [28.37]. He showed that stability was dependent on the stiffnesses of the fingers and controller and on the curvatures of the bodies in contact.

Dexterous manipulation research first appeared in the literature in the 1970s. *Hanafusa* and *Asada* developed a plan to turn a nut onto a bolt [28.57]. Since then a progression of increasingly complex manipulation tasks have been studied at varying degrees of detail. *Mason* and many of his students studied pushing tasks in the horizontal plane, see for example [28.58–61]. Other notable planar work can be found in [28.62–66]. The planning and execution of dexterous manipulation tasks in three dimensions continues to be an open problem in robotics. However, for several interesting approaches and many useful insights, the following reading is recommended [28.67–72].

Cooperative Manipulators

Fabrizio Caccavale, Masaru Uchiyama

This chapter is devoted to cooperative manipulation of a common object by means of two or more robotic arms. The chapter opens with a historical overview of the research on cooperative manipulation, ranging from early 1970s to very recent years. Kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are presented in depth. As for the kinematics and statics, the chosen approach is based on the so-called symmetric formulation; fundamentals of dynamics and reduced-order models for closed kinematic chains are discussed as well. A few special topics, such as the definition of geometrically meaningful cooperative task space variables, the problem of load distribution, and the definition of manipulability ellipsoids, are included to give the reader a complete picture of modeling and evaluation methodologies for cooperative manipulators. Then, the chapter presents the main strategies for controlling both the motion of the cooperative system and the interaction forces between the manipulators and the grasped object; in detail, fundamentals of hybrid force/position control, proportional-derivative (PD)-type force/position schemes, feedback linearization techniques, and impedance control approaches are given. In the last section further reading on advanced topics

related to control of cooperative robots is suggested; in detail, advanced nonlinear control strategies are briefly discussed (i.e., intelligent control approaches, synchronization control, decentralized control); also, fundamental results on modeling and control of cooperative systems possessing some degree of flexibility are briefly outlined.

29.1 A Historical Overview

It was not long after the emergence of robotics technologies that multi-arm robot systems began to be investigated by robotics researchers. In the early 1970s, research on this topic had already started. This interest was mainly due to typical limitations in applications of single-arm robots. It has been recognized, in fact, that many tasks that are difficult or impossible to execute by a single robot become feasible when two

or more manipulators are employed in a cooperative way. Such tasks include, for instance, carrying heavy or large payloads, the assembly of multiple parts without using special fixtures, and handling of objects that are flexible or possess extra degrees of freedom. Research on this subject has been aimed at solving existing problems and opening up a new stream of applications in flexible manufacturing systems as well as in

poorly structured environments (e.g., outer space and undersea).

Examples of research work in the early days include that by *Fujii* and *Kurono* [29.1], *Nakano* et al. [29.2], and *Takase* et al. [29.3]. Already in those pieces of work important key issues in the control of multi-arm robots were investigated: master/slave control, force/compliance control, and task-space control. In [29.1] *Fujii* and *Kurono* proposed to adopt a compliance control concept for the coordination of multiple manipulators; they defined a task vector with respect to the object frame and controlled the compliance expressed in the same coordinate frame. An interesting feature of the work by *Fujii* and *Kurono* [29.1] and by *Takase* et al. [29.3] is that force/compliance control was implemented by exploiting back-drivability of the actuators, without using force/torque sensors. The importance of this technique in practical applications, however, was not recognized at that time, and more complex approaches using force/torque sensors lured people in robotics. *Nakano* et al. [29.2, 4] proposed a master/slave force control approach for the coordination of two arms carrying an object cooperatively and pointed out the necessity of force control for cooperative multiple robots.

In the 1980s, based on several fundamental theoretical results for single-arm robots, strong research on multi-arm robotic systems was renewed [29.5]. Definition of task vectors with respect to the object to be handled [29.6], dynamics and control of the closed kinematic chain formed by the multi-arm robot and the object [29.7, 8], and force control issues, such as hybrid position/force control [29.9–12], were explored. Through this research work, a strong theoretical background for the control of multi-arm robots has been formed, providing the basis for research on more advanced topics from the 1990s to today.

How to parameterize the constraint forces/moment on the object based on the dynamic model of the whole cooperative system has been recognized as a critical issue; in fact, this parametrization leads to the definition of task variables for the control and hence to an answer to one of the most frequently asked questions in the field of multi-arm robotics: how to control simultaneously the trajectory of the object, the mechanical stresses (internal forces/moment) acting on the object, load sharing among the arms, and even the external forces/moment on the object. Force decomposition may be a key to solving these problems and has been studied by *Uchiyama* and *Dauchez* [29.11, 12] and *Walker* et al. [29.13] as well as *Bonitz* and *Hsia* [29.14]. In detail, devising

a geometrically clear parametrization of the internal forces/moment acting on the object has been recognized as an important problem; *Williams* and *Khatib* have given a solution to this [29.15, 16]. Several cooperative control schemes based on the sought parameterizations have been designed, including control of motion and force [29.11, 12, 17–19] and impedance/compliance control [29.20–22]. Other approaches include adaptive control [29.23, 24], kinematic control [29.25], task-space regulation [29.26], joint-space control [29.27, 28], and coordinated control [29.29].

Also, the definition of user-oriented task-space variables for coordinated control [29.26] and the development of meaningful performance measures [29.30–33] have been fruitfully investigated in 1990s.

Load sharing among the arms is also an interesting issue on which many papers have been published [29.34–39]. Load sharing may be exploited both for optimal load distribution among arms and for robust holding of the object, when the object is held by the arms without being grasped rigidly. In both cases, anyhow, this becomes a problem of optimization and can be solved by either heuristic [29.40] or mathematical methods [29.41].

Other research efforts have been focused on cooperative handling of multibodied or even flexible objects [29.42–44]. Control of multi-flexible-arm robots has been investigated [29.45, 46], since the merits of flexible-arm robots can be exploited in cooperative systems [29.47], i.e., lightweight structure, intrinsic compliance and hence safety, etc.

Robust holding of an object in the presence of slippage of end-effectors on the object may be achieved as well, if the slippage is detected correctly [29.48].

A more recent control framework for cooperative systems is so-called synchronization control [29.49, 50]; in this class of approaches the control problem is formulated in terms of suitably defined errors accounting for the motion synchronization between the manipulators involved in the cooperative task. As for the nonlinear control of cooperative manipulation systems, efforts have been spent on intelligent control (see, e.g., [29.51] and [29.52], where fuzzy control is exploited to cope with unmodeled dynamics, parametric uncertainties, and disturbances) as well as on the investigation of control strategies in the presence of partial state feedback [29.53].

The problem of the implementation of cooperative control strategies on conventional industrial robots has attracted the increasing interest of the research community. In fact, the control units of industrial robots do

not present all the features needed to implement nonlinear torque control schemes, while the integration of force/torque sensing in standard industrial robot control units is often cumbersome and tends to be avoided in industry for many reasons: unreliability, cost, etc. Hence, the rebirth of the early methods, where force sensors were not used (*Fujii and Kurono* [29.1], *Inoue* [29.54]), has become attractive for industrial settings. Hybrid position/force control without using force/torque sensors has been successfully implemented [29.55]. Interesting results on the implementation of effective cooperative control strategies for industrial robots are presented, e.g., in [29.56], where a design approach that makes use of tool-based coordinate systems, trajectory generation, and distributed control of multiple robots is presented.

Another interesting aspect, related to the reliability and safety of cooperative manipulation systems, is investigated in [29.57], where the use of nonrigid grippers is considered to avoid large internal forces and, at the same time, to achieve safe manipulation of the object, even in the presence of failures and unpredicted contacts with the external environment.

Finally, it is worth mentioning the strict relationship between problems related to grasping of objects

by fingers/hands (widely described in Chap. 28) and those related to cooperative manipulation. In fact, in both cases, multiple manipulation structures grasp a commonly manipulated object. In multifingered hands only some motion components are transmitted through the contact point to the manipulated object (unilateral constraints), while cooperative manipulation via robotic arms is achieved by rigid (or near-rigid) grasp points and interaction takes place by transmitting all the motion components through the grasping points (bilateral constraints). While many common problems between the two fields can be tackled in a conceptually similar way (e.g., kinetostatic modeling, force control), many other are specific of each of the two application fields (e.g., form and force closure for multifingered hands). Interestingly, a common frame for both cooperative and multifingered manipulation has been proposed [29.25]; namely rolling/sliding of the grasp points on the object is taken into account by modeling the contacts via rotational/prismatic joints; then, the desired manipulator/finger joints trajectories are derived from the desired object motion by using numerical inverse kinematics algorithms.

29.2 Kinematics and Statics

Consider a system composed by M manipulators, each equipped with N_i joints ($i = 1, \dots, M$). Let \mathbf{p}_i denote the (3×1) vector of the position of the i -th end-effector coordinate frame, \mathcal{T}_i , with respect to a common base frame, \mathcal{T} ; let \mathbf{R}_i denote the (3×3) matrix which expresses the orientation of \mathcal{T}_i with respect to the base frame \mathcal{T} .

Both \mathbf{p}_i and \mathbf{R}_i can be expressed as a function of the $(N_i \times 1)$ vector of the joints variables of each manipulator \mathbf{q}_i through the direct kinematics equations

$$\begin{cases} \mathbf{p}_i = \mathbf{p}_i(\mathbf{q}_i), \\ \mathbf{R}_i = \mathbf{R}_i(\mathbf{q}_i). \end{cases} \quad (29.1)$$

Of course, the orientation of the end-effector frame may be expressed in terms of a minimal set of angles, i.e., a set of three Euler angles ϕ_i . In this case, direct kinematics can be expressed in terms of an operational space vector \mathbf{x}_i as follows

$$\mathbf{x}_i = \mathbf{f}_i(\mathbf{q}_i) = \begin{pmatrix} \mathbf{p}_i(\mathbf{q}_i) \\ \phi_i(\mathbf{q}_i) \end{pmatrix}. \quad (29.2)$$

The linear $\dot{\mathbf{p}}_i$ and angular ω_i velocity of the i -th end-effector can be collected in the (6×1) generalized velocities vector $\mathbf{v}_i = (\dot{\mathbf{p}}_i^\top \ \omega_i^\top)^\top$. Then, the differential direct kinematics can be expressed as

$$\mathbf{v}_i = \mathbf{J}_i(\mathbf{q}_i)\dot{\mathbf{q}}_i, \quad (29.3)$$

where the $(6 \times N_i)$ matrix \mathbf{J}_i is the so-called *geometric Jacobian* of the i -th manipulator (see Chap. 1). When the velocity is expressed as the derivative of the operational space vector, differential kinematics takes a formally similar form

$$\dot{\mathbf{x}}_i = \frac{\partial \mathbf{f}_i(\mathbf{q}_i)}{\partial \mathbf{q}_i} \dot{\mathbf{q}}_i = \mathbf{J}_{Ai}(\mathbf{q}_i)\dot{\mathbf{q}}_i, \quad (29.4)$$

where the $(6 \times N_i)$ matrix \mathbf{J}_{Ai} is the so-called *analytical Jacobian* of the i -th manipulator (see Chap. 1).

Let us consider the (6×1) vector of the generalized forces acting at the i -th end-effector

$$\mathbf{h}_i = \begin{pmatrix} \mathbf{f}_i \\ \mathbf{n}_i \end{pmatrix}, \quad (29.5)$$

where f_i and n_i denote the force and moment, respectively. By invoking the principle of virtual work, a relation dual to (29.3) can be derived

$$\tau_i = \mathbf{J}^\top(\mathbf{q}_i) \mathbf{h}_i , \quad (29.6)$$

where τ_i is the $(N_i \times 1)$ vector of the forces/torques acting at the joints of the i -th manipulator.

For the sake of simplicity, consider a system of two cooperative robots (Fig. 29.1) manipulating a common object. Let C be a fixed point of the object (e.g., the center of mass of the object), whose position in the base frame is given by the vector \mathbf{p}_C ; moreover, let \mathcal{T}_C be a coordinate frame attached to object with origin in C . The *virtual stick* [29.11, 12] is defined as the vector \mathbf{r}_i ($i = 1, 2$) which determines the position of \mathcal{T}_C with respect to \mathcal{T}_i ($i = 1, 2$); it is assumed that \mathbf{r}_i behaves as a rigid stick fixed to the i -th end-effector. Hence, each virtual stick, expressed in the frame \mathcal{T}_i (\mathcal{T}_C), is a constant vector if the commonly grasped object is rigid and tightly grasped by each manipulator. In this case, the direct kinematics of each manipulator can be expressed in terms of a virtual end-effector frame $\mathcal{T}_{S,i} = \mathcal{T}_C$, having the same orientation of \mathcal{T}_C and origin located in $\mathbf{p}_{S,i} = \mathbf{p}_i + \mathbf{r}_i = \mathbf{p}_C$. Hence, the position and orientation at the tip of each virtual stick are given by ($i = 1, 2$)

$$\mathbf{p}_{S,i} = \mathbf{p}_C , \quad \mathbf{R}_{S,i} = \mathbf{R}_C .$$

The set of Euler angles corresponding to $\mathbf{R}_{S,i}$ will be denoted by the (3×1) vector $\boldsymbol{\phi}_{S,i}$. Hereafter, it is assumed that the object grasped by the two manipulators can be considered rigid (or nearly rigid) and tightly (or nearly tightly) attached to each end-effector. Hence, the displacements between the above defined frames can be

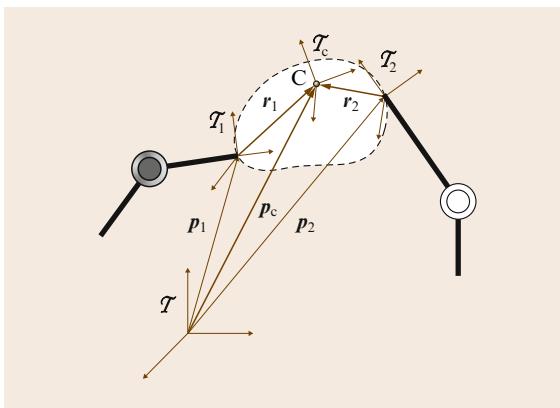

Fig. 29.1 Grasp geometry for a two-manipulator cooperative system manipulating a common object

considered null or negligible. Otherwise, if the manipulated object is subject to deformation (e.g., in the case of a flexible object) and/or the grasp is not tight (e.g., in the case of compliant grippers) the above defined coordinate frames, will be subject to nonnegligible displacements with respect to each other.

Let $\mathbf{h}_{S,i}$ denote the vector of generalized forces acting at the tip of the i -th virtual stick; it can be easily verified that the following equation holds

$$\mathbf{h}_{S,i} = \begin{pmatrix} \mathbf{I}_3 & \mathbf{O}_3 \\ -\mathbf{S}(\mathbf{r}_i) & \mathbf{I}_3 \end{pmatrix} \mathbf{h}_i = \mathbf{W}_i \mathbf{h}_i , \quad (29.7)$$

where \mathbf{O}_l and \mathbf{I}_l denote, respectively, the null matrix and the identity matrix of $(l \times l)$ dimensions, and $\mathbf{S}(\mathbf{r}_i)$ is the (3×3) skew-symmetric matrix operator performing the cross product. It is worth noticing that \mathbf{W}_i is always full rank.

By invoking the virtual works principle, a relation dual to (29.7) can easily be derived

$$\mathbf{v}_i = \begin{pmatrix} \mathbf{I}_3 & \mathbf{S}(\mathbf{r}_i) \\ \mathbf{O}_3 & \mathbf{I}_3 \end{pmatrix} \mathbf{v}_{S,i} = \mathbf{W}_i^\top \mathbf{v}_{S,i} , \quad (29.8)$$

where $\mathbf{v}_{S,i}$ is the generalized velocity vector of the virtual stick endpoint. When $\mathbf{r}_i = \mathbf{0}$, it is $\mathbf{W}_i = \mathbf{I}_6$; in other words, if the end-effector kinematics of each manipulator is referred to the corresponding virtual stick (or the object reduces to point), the forces and velocities at the two end-effectors coincide with their counterparts referred at the virtual sticks.

29.2.1 Symmetric Formulation

The kinetostatic formulation proposed by Uchiyama and Dauchez [29.12], i.e., the so-called *symmetric formulation*, is based on kinematic and static relationships between generalized forces/velocities acting at the object and their counterparts acting at the manipulators end-effectors (or at the virtual sticks endpoints).

Let us define first the *external forces* as the (6×1) vector of generalized forces given by

$$\mathbf{h}_E = \mathbf{h}_{S,1} + \mathbf{h}_{S,2} = \mathbf{W}_S \mathbf{h}_S , \quad (29.9)$$

with $\mathbf{W}_S = (\mathbf{I}_6 \ \mathbf{I}_6)$ and $\mathbf{h}_S = (\mathbf{h}_{S,1}^\top \ \mathbf{h}_{S,2}^\top)^\top$; in other words, \mathbf{h}_E represents the vector of generalized forces causing the object's motion. From (29.7) and (29.9) it follows that \mathbf{h}_E can be expressed in terms of end-effector forces as well

$$\mathbf{h}_E = \mathbf{W}_1 \mathbf{h}_1 + \mathbf{W}_2 \mathbf{h}_2 = \mathbf{W} \mathbf{h} , \quad (29.10)$$

with $\mathbf{W} = (\mathbf{W}_1 \ \mathbf{W}_2)$ and $\mathbf{h} = (\mathbf{h}_1^\top \ \mathbf{h}_2^\top)^\top$. It can be recognized that \mathbf{W}_S (\mathbf{W}) is a (6×12) matrix, having

a six-dimensional range space and a six-dimensional null space, describing the geometry of the grasp, and thus is usually termed the *grasp matrix*.

The inverse solution to (29.9) yields

$$\mathbf{h}_S = \mathbf{W}_S^\dagger \mathbf{h}_E + \mathbf{V}_S \mathbf{h}_I = \mathbf{U}_S \mathbf{h}_O , \quad (29.11)$$

where \mathbf{W}_S^\dagger denotes the Moore–Penrose pseudoinverse of \mathbf{W}_S

$$\mathbf{W}_S^\dagger = \frac{1}{2} \begin{pmatrix} \mathbf{I}_6 \\ \mathbf{I}_6 \end{pmatrix} . \quad (29.12)$$

\mathbf{V}_S is a matrix whose columns are a basis of the null space of \mathbf{W}_S , e.g.,

$$\mathbf{V}_S = \begin{pmatrix} -\mathbf{I}_6 \\ \mathbf{I}_6 \end{pmatrix} , \quad (29.13)$$

$\mathbf{h}_O = (\mathbf{h}_E^\top \mathbf{h}_I^\top)^\top$, and

$$\mathbf{U}_S = (\mathbf{W}_S^\dagger \mathbf{V}_S) . \quad (29.14)$$

The second term on the right-hand side of (29.11), i.e., $\mathbf{V}_S \mathbf{h}_I$, represents a vector of generalized forces, referred at the tip of the virtual sticks, which lies in the null space of \mathbf{W}_S ; thus, such forces do not contribute to external forces. Hence, the (6×1) vector \mathbf{h}_I is a generalized force which does not contribute to the object's motion. Therefore, it represents internal loading of the object (i.e., mechanical stresses) and is termed the *internal forces* vector [29.12]. A similar argument can be used for equation (29.10), whose inverse solution is

$$\mathbf{h} = \mathbf{W}^\dagger \mathbf{h}_E + \mathbf{V} \mathbf{h}_I = \mathbf{U} \mathbf{h}_O , \quad (29.15)$$

where

$$\mathbf{U} = (\mathbf{W}^\dagger \mathbf{V}) . \quad (29.16)$$

In [29.13] it has been shown that the first term on the right-hand side of (29.15) represents only contributions to external forces if the pseudoinverse of the grasp matrix is properly defined, i.e.,

$$\mathbf{W}^\dagger = \begin{pmatrix} \frac{1}{2} \mathbf{I}_3 & \mathbf{O}_3 \\ \frac{1}{2} \mathbf{S}(\mathbf{r}_1) & \frac{1}{2} \mathbf{I}_3 \\ \frac{1}{2} \mathbf{I}_3 & \mathbf{O}_3 \\ \frac{1}{2} \mathbf{S}(\mathbf{r}_2) & \frac{1}{2} \mathbf{I}_3 \end{pmatrix} . \quad (29.17)$$

As \mathbf{V}_S in (29.11), the columns of \mathbf{V} span the null space of \mathbf{W} , and can be chosen as [29.30]

$$\mathbf{V} = \begin{pmatrix} -\mathbf{I}_3 & \mathbf{O}_3 \\ -\mathbf{S}(\mathbf{r}_1) & -\mathbf{I}_3 \\ \mathbf{I}_3 & \mathbf{O}_3 \\ \mathbf{S}(\mathbf{r}_2) & \mathbf{I}_3 \end{pmatrix} . \quad (29.18)$$

A different parametrization of the inverse solutions to (29.9) and (29.10) can be expressed, respectively, as

$$\mathbf{h}_S = \mathbf{W}_S^\dagger \mathbf{h}_E + (\mathbf{I}_{12} - \mathbf{W}_S^\dagger \mathbf{W}_S) \mathbf{h}_S^* \quad (29.19)$$

and

$$\mathbf{h} = \mathbf{W}^\dagger \mathbf{h}_E + (\mathbf{I}_{12} - \mathbf{W}^\dagger \mathbf{W}) \mathbf{h}^* , \quad (29.20)$$

where \mathbf{h}_S^* (\mathbf{h}^*) is an arbitrary (12×1) vector of generalized forces acting at the tip of the i -th virtual stick (i -th end-effector) projected onto the null space of \mathbf{W}_S (\mathbf{W}) via $\mathbf{I}_{12} - \mathbf{W}_S^\dagger \mathbf{W}_S$ ($\mathbf{I}_{12} - \mathbf{W}^\dagger \mathbf{W}$).

By exploiting the principle of virtual work, the mappings between generalized velocities, dual to those derived above, can be established. In detail, the mapping dual to (29.11) is:

$$\mathbf{v}_O = \mathbf{U}_S^\top \mathbf{v}_S , \quad (29.21)$$

where $\mathbf{v}_S = (\mathbf{v}_{S,1}^\top \mathbf{v}_{S,2}^\top)^\top$, $\mathbf{v}_O = (\mathbf{v}_E^\top \mathbf{v}_I^\top)^\top$. The vector \mathbf{v}_E can be interpreted as the absolute velocity of the object, while \mathbf{v}_I represents the relative velocity between the two coordinate frames $\mathcal{T}_{S,1}$ and $\mathcal{T}_{S,2}$ attached to the tips of the virtual sticks [29.12]; this vector is null when the manipulated object is rigid and rigidly grasped. In a similar way, from (29.15), the following mapping can be devised

$$\mathbf{v}_O = \mathbf{U}^\top \mathbf{v} , \quad (29.22)$$

where $\mathbf{v} = (\mathbf{v}_1^\top \mathbf{v}_2^\top)^\top$.

Moreover, a set of position and orientation variables corresponding to \mathbf{v}_E and \mathbf{v}_I can be defined as follows [29.12, 25]

$$\mathbf{p}_E = \frac{1}{2} (\mathbf{p}_{S,1} + \mathbf{p}_{S,2}) , \quad \mathbf{p}_I = \mathbf{p}_{S,2} - \mathbf{p}_{S,1} , \quad (29.23)$$

$$\mathbf{R}_E = \mathbf{R}_1 \mathbf{R}^1 (k_{21}^1, \vartheta_{21}/2) , \quad \mathbf{R}_I^1 = \mathbf{R}_2^1 , \quad (29.24)$$

where $\mathbf{R}_2^1 = \mathbf{r}_1^\top \mathbf{R}_2$ is the matrix expressing the orientation of \mathcal{T}_2 with respect to the axes of \mathcal{T}_1 , while k_{21}^1 and ϑ_{21} are, respectively, the equivalent unit vector (expressed with respect to \mathcal{T}_1) and rotation angle that determine the mutual orientation expressed by \mathbf{R}_2^1 . Hence, \mathbf{R}_E expresses a rotation about k_{21}^1 by an angle which is half the angle needed to align \mathcal{T}_2 with \mathcal{T}_1 .

In turn, if the orientation variables are expressed in terms of Euler angles, a set of operational space variables can be defined as

$$\mathbf{x}_E = \begin{pmatrix} \mathbf{p}_E \\ \boldsymbol{\phi}_E \end{pmatrix} , \quad \mathbf{x}_I = \begin{pmatrix} \mathbf{p}_I \\ \boldsymbol{\phi}_I \end{pmatrix} , \quad (29.25)$$

where

$$\phi_E = \frac{1}{2}(\phi_{S,1} + \phi_{S,2}), \quad \phi_I = \phi_{S,2} - \phi_{S,1}. \quad (29.26)$$

It must be remarked, however, that the definitions in (29.26) keep a clear geometric meaning only if the orientation displacements between the virtual stick frames are small. In this case, as shown in [29.11, 12], the corresponding operational space velocities, \dot{x}_E and \dot{x}_I , correspond to v_E and v_I , respectively, with good approximation. Otherwise, if the orientation displacements become large, the variables defined in (29.26) do not represent any meaningful quantities, and other orientation representations have to be adopted, e.g., the unit quaternion (see Chap. 1 for a general introduction to quaternions and Sect. 29.3 for an application to cooperative robots kinematics).

Finally, by using (29.15) and (29.22), together with equations (29.3) and (29.6), the kinetostatic mappings between the force/velocities at the object and their counterparts in the joint space of the manipulators can be given

$$\tau = J_O^\top h_O, \quad (29.27)$$

$$v_O = J_O \dot{q}, \quad (29.28)$$

where $\tau = (\tau_1^\top \tau_2^\top)^\top$, $q = (q_1^\top q_2^\top)^\top$, and

$$J_O = U^\top J, \quad J = \begin{pmatrix} J_1 & O_6 \\ O_6 & J_2 \end{pmatrix}. \quad (29.29)$$

Formally similar mappings can be established in terms of operational space velocities \dot{x}_E and \dot{x}_I [29.11, 12] and the corresponding operational space forces/momenta.

29.2.2 Multifingered Manipulation

Hereafter some connections between the field of multi-arm cooperative manipulation, described in this chapter, and multifingered manipulation, described in Chap. 28, are briefly outlined, focusing on the kinetostatics of the two classes of manipulation systems.

Both in the case of multi-arm cooperative systems and of multifingered manipulation, two or more manipulation structures grasp a commonly manipulated object.

Cooperative manipulation via multiple robotic arms is achieved by rigidly grasping the object (e.g., via rigid

fixtures), and thus interaction takes place by exchanging both forces and moments at the grasp points. In other words, all the translational and rotational motion components are transmitted through the grasp points.

On the other side, when a multifingered hand manipulates an object, only some components of the motion are transmitted through the contact points. This is effectively modeled via properly defined constraint matrices, whose expression depends on the type of contact. In other words, constraint matrices act as filters selecting the components of the motion transmitted through each contact. In fact, as shown in Chap. 28, it is convenient to think of the object–finger contact point as twofold: a point on the tip of the finger and a point on the object. Hence, two generalized velocity vectors are defined for the i -th contact point (both expressed with respect to frame T_i): the velocity of the contact point on the hand, $v_{h,i}^i$, and the velocity of the contact point on the object $v_{o,i}^i$. The corresponding dual generalized force vectors are $h_{h,i}^i$ and $h_{o,i}^i$, respectively. A contact model is then defined via the $(m_i \times 6)$ constraint matrix H_i , selecting m_i velocity components transmitted through the contact ($v_{t,i}^i$), i.e.,

$$v_{t,i}^i = H_i v_{h,i}^i = H_i v_{o,i}^i. \quad (29.30)$$

The relation dual to (29.30) is

$$H_i^\top h_{t,i}^i = h_{h,i}^i = h_{o,i}^i, \quad (29.31)$$

where $h_{t,i}^i$ is the vector of the transmitted generalized forces. Hence, (29.10) can be rewritten as

$$h_E = W_1 \bar{R}_1 H_1^\top h_{t,1}^1 + W_2 \bar{R}_2 H_2^\top h_{t,2}^2, \quad (29.32)$$

where $\bar{R}_i = \text{diag}\{R_i, R_i\}$. Hence, a conceptually similar kinetostatic analysis can be developed, leading to the concept of external and internal forces (and related kinematic quantities) as well.

However, it must be remarked that, while in the case of cooperative manipulators, tightly grasping the object, internal stresses are usually undesirable effects (unless controlled squeezing of a deformable object has to be achieved), in multifingered hands suitably controlled internal forces are useful to guarantee a firm grasp even in the presence of external loading applied to the object (see, e.g., the problem of form and force closure discussed in Chap. 28).

29.3 Cooperative Task Space

The task-oriented formulation for the definition of the *cooperative task space* originally proposed in [29.25, 26] is here briefly reviewed. By starting from (29.23) and (29.24), this formulation defines directly the task variables in terms of the *absolute* and *relative* motion of the cooperative system, which can be directly computed from the position/orientation of the end-effector coordinate frames.

Let us define as *absolute coordinate frame*, \mathcal{T}_a , the frame whose position in the base frame is given by the position vector \mathbf{p}_a (*absolute position*)

$$\mathbf{p}_a = \frac{1}{2}(\mathbf{p}_1 + \mathbf{p}_2). \quad (29.33)$$

The orientation of \mathcal{T}_a with respect to the base frame (*absolute orientation*) is defined by means of the rotation matrix \mathbf{R}_a

$$\mathbf{R}_a = \mathbf{R}_1 \mathbf{R}^1 (\mathbf{k}_{21}^1, \vartheta_{21}/2). \quad (29.34)$$

Of course, the sole absolute variables cannot uniquely specify the cooperative motion, since 12 variables are required, e.g., for a two-arm system. Hence, in order to devise a complete description of the system's configuration, the position/orientation of each manipulator relative to the other manipulators in the system must be considered. In detail, for a two-arm system, the *relative position* between the manipulators is defined as

$$\mathbf{p}_r = \mathbf{p}_2 - \mathbf{p}_1, \quad (29.35)$$

while the *relative orientation* between the two end-effector frames is expressed via the following rotation matrix

$$\mathbf{R}_r^1 = \mathbf{R}_1^\top \mathbf{R}_2 = \mathbf{R}_2^1. \quad (29.36)$$

The variables \mathbf{p}_a , \mathbf{R}_a , \mathbf{p}_r , and \mathbf{R}_r^1 define the *cooperative task space*. Remarkably, \mathbf{R}_a and \mathbf{R}_r^1 coincide with \mathbf{R}_E and \mathbf{R}_E^1 , respectively.

It is worth pointing out a useful feature of the above defined cooperative task space formulation. In fact, it can be recognized that definitions (29.33–29.36) are not based on any special assumption on the nature of the manipulated object and/or the grasp. In other words, the cooperative task space variables can be effectively used to describe cooperative systems manipulating non-rigid objects and/or characterized by a nonrigid grasp. Also, the same task-space variables can be used to describe a pure motion coordination task, i.e., when the arms are required to perform a coordinated motion without physically interacting via a commonly manipulated

object. When the manipulators hold a rigid object (or a deformable object for which deformations are not commanded), then relative position and orientation are to be kept constant. Otherwise, if a relative motion between the end-effectors is allowed (or commanded), then \mathbf{p}_r^1 and \mathbf{R}_r^1 may vary according to the effective (commanded) relative motion.

As shown in [29.25, 26], absolute

$$\dot{\mathbf{p}}_a = \frac{1}{2}(\dot{\mathbf{p}}_1 + \dot{\mathbf{p}}_2), \quad \dot{\boldsymbol{\omega}}_a = \frac{1}{2}(\boldsymbol{\omega}_1 + \boldsymbol{\omega}_2), \quad (29.37)$$

and relative

$$\dot{\mathbf{p}}_r = (\dot{\mathbf{p}}_2 - \dot{\mathbf{p}}_1), \quad \dot{\boldsymbol{\omega}}_r = \boldsymbol{\omega}_2 - \boldsymbol{\omega}_1, \quad (29.38)$$

linear and angular velocities can be readily derived, as well as their dual variables (i.e., absolute/relative forces and moments)

$$\mathbf{f}_a = \mathbf{f}_1 + \mathbf{f}_2, \quad \mathbf{n}_a = \mathbf{n}_1 + \mathbf{n}_2, \quad (29.39)$$

$$\mathbf{f}_r = \frac{1}{2}(\mathbf{f}_2 - \mathbf{f}_1), \quad \mathbf{n}_r = \frac{1}{2}(\mathbf{n}_2 - \mathbf{n}_1). \quad (29.40)$$

Kinetostatic mappings, analogous to those derived in the previous section, can be established between linear/angular velocities (force/moment) and their counterparts defined at the end-effectors (or joints) level of each manipulator [29.25, 26].

Remarkably, the variables defined by the symmetric formulation and those used in the task-oriented formulation are related via simple mappings. In fact, forces (angular velocities, orientation variables) always coincide in the two formulations, while moments (linear velocities, position variables) coincide only when the object reduces to a point, or when the kinematics of each manipulator is referred to the tip of the corresponding virtual stick.

As shown in the following example, in the case of planar cooperative systems, the definition of the cooperative task-space variables is straightforward.

Example 29.1 (cooperative task-space variables for a planar two-arm system): For a planar two-arm system the i -th end-effector coordinates can be defined via the (3×1) vector

$$\mathbf{x}_i = \begin{pmatrix} \mathbf{p}_i \\ \varphi_i \end{pmatrix}, \quad i = 1, 2,$$

where \mathbf{p}_i is the (2×1) vector of the i -th end-effector position in the plane and φ_i is the angle describing its

orientation (i.e., the rotation of the end-effector frame about an axis orthogonal to the plane). Hence, the task-space variables can be readily defined as

$$\mathbf{x}_a = \frac{1}{2}(\mathbf{x}_1 + \mathbf{x}_2), \quad (29.41)$$

$$\mathbf{x}_r = \mathbf{x}_2 - \mathbf{x}_1, \quad (29.42)$$

since the orientation of each end-effector is simply represented by an angle.

In the spatial case, the definition of the orientation variables in terms of Euler angles, as in (29.34) and (29.36), is somewhat critical; in fact, since \mathcal{T}_1 and \mathcal{T}_2 do not coincide in general, orientation displacements are likely to be large and definitions analogous to (29.26) are not correct. Hence, geometrically meaningful orientation representations have to be adopted, e.g., the unit quaternion (see Chap. 1). In detail, by following

the approach in [29.26], the orientation variables can be defined as follows. Let

$$\mathcal{Q}_k^1 = \{\eta_k, \epsilon_k^1\} = \left\{ \cos \frac{\vartheta_{21}}{4}, k_{21}^1 \sin \frac{\vartheta_{21}}{4} \right\} \quad (29.43)$$

denote the unit quaternion extracted from $\mathbf{R}^1(k_{21}^1, \vartheta_{21}/2)$; let, also, $\mathcal{Q}_1 = \{\eta_1, \epsilon_1\}$ and $\mathcal{Q}_2 = \{\eta_2, \epsilon_2\}$ denote the unit quaternions extracted from \mathbf{R}_1 and \mathbf{R}_2 , respectively. Then, the absolute orientation can be expressed in terms of quaternion product as follows

$$\mathcal{Q}_a = \{\eta_a, \epsilon_a\} = \mathcal{Q}_1 * \mathcal{Q}_k^1, \quad (29.44)$$

while the relative orientation can be expressed as the quaternion product

$$\mathcal{Q}_r^1 = \{\eta_r, \epsilon_r^1\} = \mathcal{Q}_1^{-1} * \mathcal{Q}_2, \quad (29.45)$$

where $\mathcal{Q}_1^{-1} = \{\eta_1, -\epsilon_1\}$ (i.e., the conjugate of \mathcal{Q}_1) represents the unit quaternion extracted from \mathbf{R}_1^\top .

29.4 Dynamics and Load Distribution

The equations of motion of the i -th manipulator in a cooperative manipulation system are given by

$$\mathbf{M}_i(\mathbf{q}_i)\ddot{\mathbf{q}}_i + \mathbf{c}_i(\mathbf{q}_i, \dot{\mathbf{q}}_i) = \boldsymbol{\tau}_i - \mathbf{J}_i^\top(\mathbf{q}_i)\mathbf{h}_i, \quad (29.46)$$

where $\mathbf{M}_i(\mathbf{q}_i)$ is the symmetric positive-definite inertia matrix and $\mathbf{c}_i(\mathbf{q}_i, \dot{\mathbf{q}}_i)$ is the vector of the forces/torques due to the centrifugal, Coriolis, gravity, and friction effects. The model can be expressed in compact form as

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) = \boldsymbol{\tau} - \mathbf{J}^\top(\mathbf{q})\mathbf{h}, \quad (29.47)$$

where the matrices are block-diagonal (e.g., $\mathbf{M} = \text{blockdiag}\{\mathbf{M}_1, \mathbf{M}_2\}$) and the vectors are stacked (e.g., $\mathbf{q} = (\mathbf{q}_1^\top \mathbf{q}_2^\top)^\top$).

The object's motion is described by the classical Newton–Euler equations of rigid body

$$\mathbf{M}_E(\mathbf{R}_E)\ddot{\mathbf{v}}_E + \mathbf{c}_E(\mathbf{R}_E, \omega_E)\dot{\mathbf{v}}_E = \mathbf{h}_E = \mathbf{W}\mathbf{h}, \quad (29.48)$$

where \mathbf{M}_E is the inertia matrix of the object and \mathbf{c}_E collects the nonlinear components of the inertial forces/momenta (i.e., gravity, centrifugal and Coriolis forces/momenta).

The above equations must be completed by imposing the closed-chain constraints arising from the kinematic coupling between the two manipulators through the commonly manipulated rigid object. The constraints can

be expressed by imposing a null internal velocity vector in the mapping (29.21)

$$\mathbf{v}_I = \mathbf{V}_S^\top \mathbf{v}_S = \mathbf{v}_{S,1} - \mathbf{v}_{S,2} = \mathbf{0}, \quad (29.49)$$

which can be expressed, by using (29.8) and (29.22), in terms of end-effector velocities (where the notation $\mathbf{W}_i^{-\top}$ stands for $(\mathbf{W}_i^\top)^{-1}$)

$$\mathbf{V}^\top \mathbf{v} = \mathbf{W}_1^{-\top} \mathbf{v}_1 - \mathbf{W}_2^{-\top} \mathbf{v}_2 = \mathbf{0}, \quad (29.50)$$

and, finally, in terms of joint velocities

$$\mathbf{V}^\top \mathbf{J}(\mathbf{q})\dot{\mathbf{q}} = \mathbf{W}_1^{-\top} \mathbf{J}_1(\mathbf{q}_1)\dot{\mathbf{q}}_1 - \mathbf{W}_2^{-\top} \mathbf{J}_2(\mathbf{q}_2)\dot{\mathbf{q}}_2 = \mathbf{0}. \quad (29.51)$$

Equations (29.47), (29.48), and (29.51) represent a constrained dynamical model of the cooperative system in the joint space; $N_1 + N_2$ generalized coordinates (i.e., \mathbf{q}_1 and \mathbf{q}_2) are related to each other by the six algebraic closed-chain constraints (29.51). This implies that the total number of degrees of freedom is $N_1 + N_2 - 6$ and the model has the form of a set of differential-algebraic equations.

29.4.1 Reduced-Order Models

The above derived dynamic model incorporates a set of closed-chain constraints, which reduces the number of independent generalized coordinates to $N_1 + N_2 - 6$.

Hence, it is expected that, by eliminating six equations via the constraints (29.51), a reduced-order model can be obtained. Early work on reduced-order modeling of closed chains can be, e.g., found in [29.58]. Later, in [29.59, 60], this problem has been tackled by first deriving, from (29.47), (29.48), and (29.51), a joint space model of the whole closed chain in the form

$$\mathbf{M}_C(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}_C(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{D}_C(\mathbf{q})\boldsymbol{\tau}, \quad (29.52)$$

where \mathbf{M}_C , \mathbf{D}_C , and \mathbf{c}_C depend on the dynamics of the manipulators and the object, as well as on the geometry of the grasp. The above model can be integrated, once the joint torques vector $\boldsymbol{\tau}$ is specified over an assigned time interval, to solve for the joint variables \mathbf{q} (*forward dynamics*). However, the model cannot be used to find $\boldsymbol{\tau}$ from assigned \mathbf{q} , $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$ (*inverse dynamics*), since the $((N_1 + N_2) \times (N_1 + N_2))$ matrix \mathbf{D}_C is not full rank [29.60], and thus the inverse dynamics problem turns out to be underspecified.

In order to find a reduced-order model, composed by $N_1 + N_2 - 6$ equations, a $((N_1 + N_2 - 6) \times 1)$ pseudovelocity vector has to be considered:

$$\mathbf{v} = \mathbf{B}(\mathbf{q})\dot{\mathbf{q}}, \quad (29.53)$$

where the $((N_1 + N_2 - 6) \times (N_1 + N_2))$ matrix $\mathbf{B}(\mathbf{q})$ is selected so that $(\mathbf{A}^\top(\mathbf{q}) \mathbf{B}^\top(\mathbf{q}))^\top$ is nonsingular and

$$\mathbf{A}(\mathbf{q}) = \mathbf{W}_2^\top \mathbf{V}^\top(\mathbf{q}).$$

Then, the reduced-order model can be written in terms of the variables \mathbf{q} , \mathbf{v} , and $\dot{\mathbf{v}}$ as

$$\boldsymbol{\Sigma}^\top(\mathbf{q})\mathbf{M}_C(\mathbf{q})\boldsymbol{\Sigma}(\mathbf{q})\dot{\mathbf{v}} + \boldsymbol{\Sigma}^\top(\mathbf{q})\mathbf{c}_R(\mathbf{q}, \mathbf{v}) = \boldsymbol{\Sigma}^\top(\mathbf{q})\boldsymbol{\tau}, \quad (29.54)$$

where $\boldsymbol{\Sigma}$ is an $((N_1 + N_2) \times (N_1 + N_2 - 6))$ matrix such that

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{B} \end{pmatrix}^{-1} = (\boldsymbol{\Pi} \boldsymbol{\Sigma}),$$

and \mathbf{c}_R depends on \mathbf{c}_C , $\boldsymbol{\Sigma}$, and $\boldsymbol{\Pi}$ [29.60]. The reduced-order model can be used for computing the forward dynamics; in this case, however, the problem of expressing a reduced set of *pseudocoordinates* related to \mathbf{v} in the numerical integration has to be considered. Since $\boldsymbol{\Sigma}^\top$ is nonsquare, the inverse dynamics problem still admits infinitely many solutions in terms of $\boldsymbol{\tau}$. However, this does not prevent the application model (29.54) to cooperative manipulators control (see, e.g., the decoupled control architecture proposed in [29.59, 60]).

29.4.2 Load Distribution

The problem of load sharing in multi-arm robotic systems is that of distributing the load among the arms composing the system (e.g., a strong arm may share the load more than a weak one). This is possible because a multi-arm system has redundant actuators; in fact, if a robotic arm is equipped with the number of actuators strictly needed for supporting the load, no optimization of load distribution is possible. In this section, this problem is presented according to the results in [29.35–41].

We can introduce a load-sharing matrix in the framework adopted for presenting the kinematics of the cooperative manipulators. By replacing the Moore–Penrose inverse in equation (29.11) with a suitably defined generalized inverse, \mathbf{W}_S^- , the following expression can be devised for the generalized forces at the tip of the virtual sticks

$$\mathbf{h}_S = \mathbf{W}_S^- \mathbf{h}_E + \mathbf{V}_S \mathbf{h}'_I, \quad (29.55)$$

where

$$\mathbf{W}_S^- = \begin{pmatrix} \mathbf{L} \\ \mathbf{I}_6 - \mathbf{L} \end{pmatrix}^\top, \quad (29.56)$$

and the matrix \mathbf{L} is the so-called load sharing matrix. It can be easily proved that the nondiagonal elements of \mathbf{L} only yield a \mathbf{h}_S vector in the null space of \mathbf{W}_S , that is, the space of internal forces/momenta. Therefore, without losing generality, let us choose \mathbf{L} such that

$$\mathbf{L} = \text{diag}\{\lambda\}, \quad (29.57)$$

where the vector $\lambda = (\lambda_1, \dots, \lambda_6)^\top$ collects a set of constants λ_i representing the load-sharing coefficients.

The problem is that of properly tuning the load-sharing coefficients to ensure correct cooperative manipulation of the object by the arms. In order to answer this question, it must be noticed that, by combining equations (29.11) and (29.55), the following relation can be obtained

$$\mathbf{h}_I = \mathbf{V}_S^\dagger (\mathbf{W}_S^- - \mathbf{W}_S^\dagger) \mathbf{h}_E + \mathbf{h}'_I, \quad (29.58)$$

which, bearing in mind that only \mathbf{h}_E and \mathbf{h}_S are really existing forces/momenta, indicates that

- \mathbf{h}_I , \mathbf{h}'_I , and λ_i can be thought of as *artificial* parameters, introduced for better understanding of the manipulation process;
- \mathbf{h}'_I and λ_i are not independent; the concept of internal forces/momenta and the concept of load sharing are mathematically mixed with each other.

Therefore, tuning the load-sharing coefficients or choosing suitable internal forces/moments is strictly equivalent from the mathematical (and, also, from the performance) point of view. Only one variable among \mathbf{h}_I , \mathbf{h}'_I , and λ is independent; hence, any of those redundant parameters, to be optimized for load sharing, can be exploited. This is more generally stated in [29.38, 39]. In [29.41], internal forces/moments \mathbf{h}_I are tuned, both for the sake of simplicity and for consistency with the adopted control laws.

A very relevant problem related to load sharing is that of robust holding, i.e., the problem of determining forces/moments applied to object by the arms, \mathbf{h}_S , required to keep the grasp even in the presence of disturbing external forces/moments. This problem can be solved by tuning the internal forces/moments (or the load-sharing coefficients, of course) and is addressed, e.g., in [29.40], where conditions to keep the grasp are expressed via end-effector forces/moments. Namely, by replacing \mathbf{h}_S in (29.55) into the equations expressing the grasp conditions, a set of linear inequalities for both \mathbf{h}'_I and λ are obtained:

$$\mathbf{A}_L \mathbf{h}'_I + \mathbf{B}_L \lambda < \mathbf{c}_L , \quad (29.59)$$

where \mathbf{A}_L and \mathbf{B}_L are 6×6 matrices and \mathbf{c}_L is a (6×1) vector. In [29.40], a solution λ for the inequality is obtained heuristically. The above inequality can be transformed into another inequality expressed with respect to

\mathbf{h}_I , of course; however, λ is fitter to such heuristic algorithm because it can be understood intuitively. The same problem may be solved mathematically, by introducing an objective function to be optimized; in this way, the problem is recast in the framework of mathematical programming. To this purpose, let us choose a quadratic cost function of \mathbf{h}_I to be minimized

$$f = \mathbf{h}_I^\top \mathbf{Q} \mathbf{h}_I , \quad (29.60)$$

where \mathbf{Q} is a (6×6) positive-definite matrix. The above cost function can be seen as a (pseudo)energy to be dissipated by the joint actuators: i.e., the arms dissipate electrical energy in the actuators to yield the internal forces/moments \mathbf{h}_I . A solution to the quadratic programming problem (29.60) can be found, e.g., in [29.41].

For further insights on the problem of robust holding in the framework of multifingered manipulation, the reader is referred to Chap. 28.

Interestingly, in [29.36] the problem of load distribution is formulated in such a way to take into account manipulators dynamics at the joint level. This approach allows the expression of the load-sharing problem directly in terms of joints actuators torques; at this level, different subtask performance indexes can be used, in a similar way as was done to solve the inverse kinematics of redundant manipulators, to achieve load distribution solutions.

29.5 Task-Space Analysis

As for single-arm robotic systems, a major issue in cooperative manipulation is that of task-space performance evaluation via the definition of suitable manipulability ellipsoids. These concepts have been extended to multi-arm robotic systems in [29.30]. Namely, by exploiting the kinetostatic formulation in Sect. 29.3, velocity and force manipulability ellipsoids are defined by regarding the whole cooperative system as a mechanical transformer from the joint space to the cooperative task space. Since the construction of force/velocity ellipsoids involves nonhomogeneous quantities (i.e., forces and moments, linear and angular velocities), special attention must be paid to the definition of such concepts [29.14, 61, 62]. Also, as for the ellipsoids involving internal forces, a major issue is that of physically meaningful parametrization of the internal forces (see, e.g., the work in [29.15, 16]).

In detail, by following the approach in [29.30], the *external force manipulability ellipsoid* can be defined by

the following scalar equation

$$\mathbf{h}_E^\top (\mathbf{J}_E \mathbf{J}_E^\top) \mathbf{h}_E = 1 , \quad (29.61)$$

where $\mathbf{J}_E = \mathbf{W}^{\dagger\top} \mathbf{J}$. The *external velocity manipulability ellipsoid* is defined dually by the following scalar equation

$$\mathbf{v}_E^\top (\mathbf{J}_E \mathbf{J}_E^\top)^{-1} \mathbf{v}_E = 1 . \quad (29.62)$$

In the case of dual-arm systems the *internal force manipulability ellipsoid* can be defined as

$$\mathbf{h}_I^\top (\mathbf{J}_I \mathbf{J}_I^\top) \mathbf{h}_I = 1 , \quad (29.63)$$

where $\mathbf{J}_I = \mathbf{V}^\top \mathbf{J}$. Also, the *internal velocity ellipsoid* can be defined, via kinetostatic duality, as

$$\mathbf{v}_I^\top (\mathbf{J}_I \mathbf{J}_I^\top)^{-1} \mathbf{v}_I = 1 . \quad (29.64)$$

The internal force/velocity ellipsoids can be defined in the case of cooperative systems composed of more than

two manipulators by considering one pair of interacting end-effectors at a time [29.30].

The manipulability ellipsoids can be seen as performance measures aimed at determining the arms' attitude to cooperate in a given system's configuration. Also, as for the single-arm systems, the manipulability ellipsoids can be used to determine optimal postures for redundant multi-arm systems.

Besides the above described approach, two other main approaches have been proposed to analyze

the manipulability of cooperative multi-arm systems: the task-oriented manipulability measure [29.31] and polytopes [29.32]. Moreover, in [29.33] a systematic approach to perform dynamic analysis of multi-arm systems is presented. Namely, the concept of dynamic manipulability ellipsoid is extended to multi-arm systems, and indexes of the system's capability of generating object accelerations along assigned task-space directions are devised.

29.6 Control

When a cooperative multi-arm system is employed for the manipulation of a common object, it is important to control both the absolute motion of the held object and the internal stresses applied to it. Hence, most of the control approaches to cooperative robotic systems can be classified as force/motion control schemes, in that they decompose the control action in a motion control loop, aimed at tracking of the desired object motion, and a force control loop, aimed at controlling the internal loading of the object.

Early approaches to the control of cooperative systems are based on the *master/slave* concept [29.2]. Namely, the cooperative system is decomposed into:

- a master arm, which is in charge of imposing the absolute motion of the object; hence, the master arm is position controlled so as to achieve accurate and robust tracking of position/orientation reference trajectories, in the face of external disturbances (e.g., forces due to the interaction with the other co-operating arms); in other words, the master arm is controlled so as to have a *stiff* behavior;
- the slave arms, which are force controlled so as to achieve a *compliant* behavior with respect to the interaction forces; hence, it is expected that the slave arms are capable of following (as smoothly as possible) the motion imposed by the master arm.

A natural evolution of the above approach is the so-called *leader-follower* [29.58], where the follower arms reference motion is computed via closed-chain constraints.

However, such approaches suffered from implementation issues, mainly due to the fact that the compliance of the slave arms has to be very large, so as to follow the motion imposed by the master arm smoothly. Also, a difficulty arises when the roles of master and slave have to be assigned to the arms for a given coopera-

tive task, since the master/slave modes may need to be dynamically changed during the task execution.

Hence, a more natural non-master/slave approach has been pursued later, where the cooperative system is seen as a whole. Namely, the reference motion of the object is used to determine the motion of all the arms in the system and the interaction forces acting at each end-effector are fed back so as to be directly controlled. To this aim, the mappings between the forces and velocities at the end-effector of each manipulator and their counterparts at the manipulated object are to be considered in the design of the control laws.

29.6.1 Hybrid Control

In [29.11, 12] a non-master/slave approach has been proposed, based on the well-known scheme proposed by Raibert and Craig for the robot/environment interaction control of single-arm systems (see Chap. 7). The operational space vector for the hybrid position/force control is defined via the following variables

$$\mathbf{x}_O = \begin{pmatrix} \mathbf{x}_E \\ \mathbf{x}_I \end{pmatrix}, \quad (29.65)$$

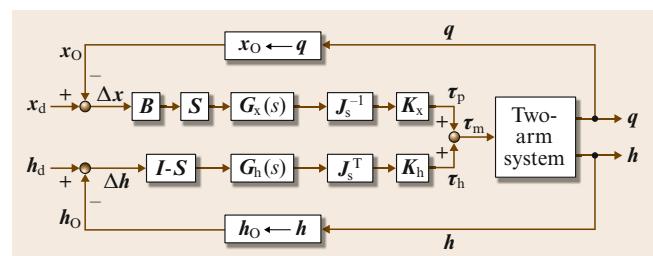

Fig. 29.2 A hybrid position/force control scheme

where \mathbf{x}_E , \mathbf{x}_I are the operational space vectors, defined by specifying the orientation via a minimal set of orientation angles (e.g., Euler angles). The generalized forces vector to be considered is

$$\mathbf{h}_O = \begin{pmatrix} \mathbf{h}_E \\ \mathbf{h}_I \end{pmatrix}. \quad (29.66)$$

The organization of the control scheme is shown diagrammatically in Fig. 29.2. The suffixes d and m represent the desired value and the control command, respectively. The command vector τ_m to the actuators of the two arms is given by two contributions:

$$\tau_m = \tau_p + \tau_h. \quad (29.67)$$

The first term, τ_p , is the command vector for the position control and is given by

$$\tau_p = \mathbf{K}_x \mathbf{J}_s^{-1} \mathbf{G}_x(s) \mathbf{S} \mathbf{B} (\mathbf{x}_{O,d} - \mathbf{x}_O), \quad (29.68)$$

while τ_h is the command vector for the force control

$$\tau_h = \mathbf{K}_h \mathbf{J}_s^\top \mathbf{G}_h(s) (\mathbf{I} - \mathbf{S}) (\mathbf{h}_{O,d} - \mathbf{h}_O). \quad (29.69)$$

The matrix \mathbf{B} transforms the errors on the orientation angles into equivalent rotation vectors. The matrix \mathbf{J}_s is the Jacobian matrix that transforms the joint velocity $\dot{\mathbf{q}}$ into the task-space velocity \mathbf{v}_O . The matrix operators $\mathbf{G}_x(s)$ and $\mathbf{G}_h(s)$ represent position and force control laws, respectively. The gain matrices \mathbf{K}_x and \mathbf{K}_h are assumed to be diagonal; their diagonal elements convert velocity and force commands into actuator commands, respectively. The matrix \mathbf{S} selects the position-controlled variables; it is diagonal and its diagonal entries take the values of 1 or 0; namely, the i -th workspace coordinate is position controlled if the i -th diagonal element of \mathbf{S} is 1, while it is force controlled if it is 0. Finally, \mathbf{I} is the identity matrix having the same dimensions as \mathbf{S} , while \mathbf{q} and \mathbf{h} are the vectors of measured joint variables and measured end-effector generalized forces, respectively.

29.6.2 PD Force/Motion Control

In [29.17] a Lyapunov-based approach is pursued to devise force/position PD-type control laws. Namely, the joints torques inputs to each arm are computed as the combination of two contributions:

$$\tau_m = \tau_p + \tau_h, \quad (29.70)$$

where τ_p is a PD-type term (eventually including a feedback/feedforward model-based compensation term), taking care of position control, while τ_h is in charge of internal forces/moment control.

Namely, the PD and model-based terms can be computed at the joint level

$$\tau_p = \mathbf{K}_p \mathbf{e}_q - \mathbf{K}_d \dot{\mathbf{q}} + \mathbf{g} + \mathbf{J}^\top \mathbf{W}^\dagger \mathbf{g}_E, \quad (29.71)$$

where $\mathbf{e}_q = \mathbf{q}_d - \mathbf{q}$, \mathbf{q}_d is the vector of desired joint variables, \mathbf{K}_p and \mathbf{K}_d are positive-definite matrix gains, \mathbf{g} is the vector of the gravitational forces/torques acting at the manipulators joints, \mathbf{g}_E is the vector of gravity forces/moment at the manipulated object.

Since the cooperative task is usually assigned in terms of absolute and relative motion, the equivalent end-effector desired trajectories are to be computed by using the closed-chain constraints, as in the following example.

Example 29.2 (computation of desired trajectories for a planar two-arm system): For the planar two-arm system, the desired trajectories defining the cooperative task are assigned by specifying the absolute, $\mathbf{x}_{a,d}(t)$, and relative, $\mathbf{x}_{r,d}(t)$, desired motion. Then, the corresponding end-effectors desired trajectories can be computed as

$$\mathbf{x}_{1,d}(t) = \mathbf{x}_{a,d}(t) - \frac{1}{2} \mathbf{x}_{r,d}(t), \quad (29.72)$$

$$\mathbf{x}_{2,d}(t) = \mathbf{x}_{a,d}(t) + \frac{1}{2} \mathbf{x}_{r,d}(t), \quad (29.73)$$

where (29.41) and (29.42) have been exploited.

In the spatial case (29.72, 29.73) do not hold, since the absolute and relative orientation must be expressed in terms of geometrically meaningful quantities, e.g., via (29.44, 29.45). However, the same approach may be pursued at the expense of a slightly more complex expressions of the above formulas [29.26].

Once, the desired position/orientation for each end-effector has been obtained, the inverse kinematics of each arm has to be computed to provide the desired joint trajectories, \mathbf{q}_d , to the control loop; to this aim, e.g., numerical inverse kinematics algorithms may be employed (see Chaps. 1 and 11).

Also, a PD-type control law can be expressed in terms of end-effector variables, i.e.,

$$\tau_p = \mathbf{J}^\top (\mathbf{K}_p \mathbf{e} - \mathbf{K}_v \mathbf{v}) - \mathbf{K}_d \dot{\mathbf{q}} + \mathbf{g} + \mathbf{J}^\top \mathbf{W}^\dagger \mathbf{g}_E, \quad (29.74)$$

where \mathbf{e} is the tracking error computed in terms of end-effector position/orientation variables, \mathbf{v} is the vector

collecting the end-effector velocities, and \mathbf{K}_p , \mathbf{K}_v , and \mathbf{K}_d are positive-definite matrix gains.

Finally, the same concept may be exploited to design a PD control law directly in the object space

$$\boldsymbol{\tau}_p = \mathbf{J}^\top \mathbf{W}^\dagger (\mathbf{K}_p \mathbf{e}_E - \mathbf{K}_v \mathbf{v}_E) - \mathbf{K}_d \dot{\mathbf{q}} + \mathbf{g} + \mathbf{J}^\top \mathbf{W}^\dagger \mathbf{g}_E, \quad (29.75)$$

where \mathbf{e}_E is the tracking error computed in terms of object absolute position/orientation variables, \mathbf{v}_E is the object's generalized velocity vector, and \mathbf{K}_p , \mathbf{K}_v , and \mathbf{K}_d are positive-definite matrix gains.

The internal force control term can instead be designed as follows

$$\boldsymbol{\tau}_h = \mathbf{J}^\top \mathbf{V} \mathbf{h}_{I,c}, \quad (29.76)$$

where

$$\mathbf{h}_{I,c} = \mathbf{h}_{I,d} + \mathbf{G}_h(s)(\mathbf{h}_{I,d} - \mathbf{h}_I), \quad (29.77)$$

$\mathbf{G}_h(s)$ is a matrix operator representing a strictly proper linear filter, such that $\mathbf{I} - \mathbf{G}_h(s)$ has zeros only in the left half plane, and $\mathbf{h}_{I,d}$ is the vector of desired internal forces; the internal force vector can be computed from the vector of measured end-effector forces as $\mathbf{h}_I = \mathbf{V}^\dagger \mathbf{h}$. A particularly simple choice, ensuring a null error at steady state, is given by

$$\mathbf{G}_h(s) = \frac{1}{s} \mathbf{K}_h,$$

where \mathbf{K}_h is a positive-definite matrix. Remarkably, when an infinitely rigid object/grasp is considered, preprocessing of the force error via a strictly proper filter is needed to ensure closed-loop stability [29.17]; e.g., if a simple proportional feedback is adopted (i.e., $\mathbf{G}_h(s) = \mathbf{K}_h$), the closed loop will be unstable in the presence of an arbitrary small time delay, unless a small (namely, smaller than 1) force gain is adopted. In practice, the closed kinematic chain will be characterized by some elasticity (e.g., due to grippers, end-effector force/torques sensors, joints); in this case, the product between the control gain \mathbf{K}_h and the stiffness of the flexible components has to be chosen sufficiently small to ensure stability.

An interesting extension of the above approach has been given in [29.26, 28], where kinetostatic filtering of the control action is performed so as to filter all the components of the control input which contribute to internal stresses at the object. Namely, the control law (29.71) can be modified by weighting the proportional term ($\mathbf{K}_p \mathbf{e}_q$) via the filtering matrix

$$\boldsymbol{\phi} = \mathbf{J}^\top (\mathbf{W}^\dagger \mathbf{W} + \mathbf{V} \boldsymbol{\Sigma} \mathbf{V}^\dagger) \mathbf{J}^{-\top},$$

where the (6×6) diagonal matrix $\boldsymbol{\Sigma} = \text{diag}\{\sigma_i\}$ weights the components of $\mathbf{J}^{-\top} \mathbf{K}_p \mathbf{e}_q$ in each direction of the subspace of the internal forces via the constant values $0 \leq \sigma_i \leq 1$. In detail, if $\boldsymbol{\Sigma} = \mathbf{O}_6$ then all these components are completely canceled from the control action, while the choice $\boldsymbol{\Sigma} = \mathbf{I}_6$ leads to the control law (29.71) without kinetostatic filtering. In a similar way, the control laws (29.74) and (29.75) can be modified so as to introduce proper kinetostatic filtering of $\mathbf{K}_p \mathbf{e}$ and $\mathbf{K}_p \mathbf{e}_E$, respectively.

29.6.3 Feedback Linearization Approaches

A further improvement of the PD-plus-gravity compensation control approach has been achieved by introducing a full model compensation, so as to achieve feedback/feedforward linearization of the closed-loop system. The feedback linearization approach formulated at the operational space level is the base for the so-called *augmented object* approach [29.63, 64]. In this approach the system is modeled in the operational space as a whole, by suitably expressing its inertial properties via a single augmented inertia matrix \mathbf{M}_O . Hence, the dynamics of the cooperative system in the operational space can be written as

$$\mathbf{M}_O(\mathbf{x}_E) \ddot{\mathbf{x}}_E + \mathbf{c}_O(\mathbf{x}_E, \dot{\mathbf{x}}_E) = \mathbf{h}_E. \quad (29.78)$$

In (29.78), \mathbf{M}_O and \mathbf{c}_O are the operational space terms modeling, respectively, the inertial properties of the whole system (manipulators and object) and the Coriolis, centrifugal, friction, and gravity terms.

In the framework of feedback linearization (formulated in the operational), the problem of controlling the internal forces can be solved, e.g., by resorting to the *virtual linkage* model [29.16] or according to the scheme proposed in [29.29], i.e.,

$$\begin{aligned} \boldsymbol{\tau} = & \mathbf{J}^\top \mathbf{W}^\dagger [\mathbf{M}_O(\ddot{\mathbf{x}}_{E,d} + \mathbf{K}_v \dot{\mathbf{e}}_E + \mathbf{K}_p \mathbf{e}_E) + \mathbf{c}_O] \\ & + \mathbf{J}^\top \mathbf{V} (\mathbf{h}_{I,d} + \mathbf{K}_h \int (\mathbf{h}_{I,d} - \mathbf{h}_I)). \end{aligned} \quad (29.79)$$

The above control law yields a linear and decoupled closed-loop dynamics

$$\begin{aligned} \ddot{\mathbf{e}}_E + \mathbf{K}_v \dot{\mathbf{e}}_E + \mathbf{K}_p \mathbf{e}_E &= \mathbf{0} \\ \tilde{\mathbf{h}}_I + \mathbf{K}_h \int \tilde{\mathbf{h}}_I dt &= \mathbf{0}, \end{aligned} \quad (29.80)$$

where $\tilde{\mathbf{h}}_I = \mathbf{h}_{I,d} - \mathbf{h}_I$. Hence, the closed-loop dynamics guarantees asymptotically vanishing motion and force errors.

29.6.4 Impedance Control

An alternative control approach can be pursued based on the well-known impedance concept (see Chap. 7). In fact, when a manipulation system interacts with an external environment and/or other manipulators, large values of the contact forces and moments can be avoided by enforcing a compliant behavior, with suitable dynamic features, of the robotic system. Impedance control schemes have been proposed in the case of cooperative manipulation to control object/environment interaction forces [29.21] or internal forces [29.22]. More recently, an impedance scheme for the control of both external forces and internal forces has been proposed [29.65].

In detail, the impedance scheme in [29.21] enforces the following mechanical impedance behavior between the object displacements and the forces acting on object due to interaction with the environment:

$$\mathbf{M}_E \ddot{\mathbf{a}}_E + \mathbf{D}_E \tilde{\mathbf{v}}_E + \mathbf{K}_E \mathbf{e}_E = \mathbf{h}_{\text{env}}, \quad (29.81)$$

where:

- \mathbf{e}_E represents the vector of the object's displacements between the desired and actual pose,
- $\tilde{\mathbf{v}}_E$ is the difference between the object's desired and actual generalized velocities,
- $\ddot{\mathbf{a}}_E$ is the difference between the object's desired and actual generalized accelerations,

and \mathbf{h}_{env} is the generalized force acting on object due to the interaction with the environment. The impedance dynamics is characterized in terms of given positive-definite mass (\mathbf{M}_E), damping (\mathbf{D}_E), and stiffness (\mathbf{K}_E) matrices to be properly chosen so as to achieve the desired compliant behavior of the object.

As for the pose displacements used in (29.81), special attention has to be paid to the orientation variables.

Example 29.3 (external impedance for a planar two-arm system): For the planar two-arm system the quantities in (29.81) can be defined in a straightforward way. Namely,

$$\mathbf{e}_E = \mathbf{x}_{E,d} - \mathbf{x}_E, \quad (29.82)$$

$$\tilde{\mathbf{v}}_E = \dot{\mathbf{x}}_{E,d} - \dot{\mathbf{x}}_E, \quad (29.83)$$

$$\ddot{\mathbf{a}}_E = \ddot{\mathbf{x}}_{E,d} - \ddot{\mathbf{x}}_E, \quad (29.84)$$

where \mathbf{x}_E is the (3×1) vector collecting the object's position and the orientation, while $\mathbf{x}_{E,d}$ represents its desired counterpart. Hence, \mathbf{M}_E , \mathbf{D}_E , and \mathbf{K}_E are (3×3) matrices.

In the spatial case, orientation displacements cannot be defined as in (29.82), and geometrically meaningful

orientation representations (i. e., rotation matrices and/or angle/axis representations) or in terms of operational space variables (i. e., differences between operational space vectors) have to be adopted [29.65].

The impedance scheme in [29.22], enforces a mechanical impedance behavior between the i -th end-effector displacements and the internal forces, i. e.,

$$\mathbf{M}_{I,i} \ddot{\mathbf{a}}_i + \mathbf{D}_{I,i} \tilde{\mathbf{v}}_i + \mathbf{K}_{I,i} \mathbf{e}_i = \mathbf{h}_{I,i}, \quad (29.85)$$

where

- \mathbf{e}_i is the vector expressing the displacement of the i -th end-effector between the desired and actual pose,
- $\tilde{\mathbf{v}}_i$ is the vector expressing the difference between the desired and actual velocities of the i -th end-effector,
- $\ddot{\mathbf{a}}_i$ is the vector expressing the difference between the desired and actual accelerations of the i -th end-effector,

and $\mathbf{h}_{I,i}$ is the contribution of the i -th end-effector to the internal force, i. e., the i -th component of the vector $\mathbf{VV}^\dagger \mathbf{h}$. Again, the impedance dynamics is characterized in terms of given positive-definite mass ($\mathbf{M}_{I,i}$), damping ($\mathbf{D}_{I,i}$), and stiffness ($\mathbf{K}_{I,i}$) matrices, to be properly chosen so as to achieve a suitable compliant behavior of the end-effectors with respect to internal forces.

Example 29.4 (Internal impedance for a planar two-arm system): For the planar two-arm system the quantities in (29.85) can be defined in a straightforward way as well

$$\mathbf{e}_i = \mathbf{x}_{i,d} - \mathbf{x}_i, \quad (29.86)$$

$$\tilde{\mathbf{v}}_i = \dot{\mathbf{x}}_{i,d} - \dot{\mathbf{x}}_i, \quad (29.87)$$

$$\ddot{\mathbf{a}}_i = \ddot{\mathbf{x}}_{i,d} - \ddot{\mathbf{x}}_i, \quad (29.88)$$

where \mathbf{x}_i is the (3×1) vector collecting the position in the plane and the orientation angle of the i -th end-effector, while $\mathbf{x}_{i,d}$ represents its desired counterpart. Again, $\mathbf{M}_{I,i}$, $\mathbf{D}_{I,i}$, and $\mathbf{K}_{I,i}$ are (3×3) matrices.

As for the spatial case, orientation displacements in (29.85) cannot be defined as in (29.86), and geometrically meaningful orientation representations (i. e., rotation matrices and/or angle/axis representations) or in terms of operational space variables (i. e., differences between operational space vectors) have to be adopted [29.65].

The above two approaches have been combined in [29.65], where two control loops are designed to enforce an impedance behavior both at the object level (external forces) and at the end-effector level (internal forces).

29.7 Conclusions and Further Reading

In this chapter, the fundamentals of cooperative manipulation have been presented. A historical overview of the research on cooperative manipulation has been provided. The kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are considered. Special topics, such as the definition of a cooperative task space and the problem of load distribution, have also been touched on. Then, the main control approaches for cooperative systems have been discussed. A few advanced topics related to control of cooperative robots, i. e., advanced nonlinear control as well as the modeling and control of cooperative systems including flexible elements, will be briefly outlined in the following.

Some of the first attempts to cope with uncertainties and disturbances in cooperative robots control focused on adaptive strategies [29.23, 24], in which the unknown parameters are estimated online, based on a suitable linear-in-the-parameters model of the uncertainties. In detail, the approach in [29.23] is aimed at controlling the object motion, the interaction force due to the contact object/environment, and the internal forces; the adaptive control law estimates the unknown model parameters, both of the manipulators and of the object, on the basis of suitable error equations. In [29.24], the adaptive control concept is used to design a decentralized scheme, i. e., a centralized coordinator is not used, for redundant cooperative manipulators.

A recently developed control framework for cooperative systems is the so-called synchronization control [29.49, 50]; in this approach the control problem is formulated in terms of suitably defined errors accounting for motion synchronization between the manipulators involved in the cooperative task. Namely, the key idea in [29.49] is to ensure tracking of the desired trajectory assigned to each manipulator, while synchronizing its motion with other manipulators motion. In [29.50], the problem of synchronizing the motion of multiple manipulators systems is solved by using only position measurements; the synchronization controller consists of a feedback control law and a set of nonlinear observers, and synchronization is ensured by suitably defining the coupling errors between the manipulators' motions.

Recently, research efforts have been spent on intelligent control [29.51, 52]. Namely, in [29.51], a semi-decentralized adaptive fuzzy control scheme, with \mathcal{H}_∞ performance in motion and internal force

tracking, is proposed; the controller of each robot consists of two parts: a model-based adaptive controller and an adaptive fuzzy logic controller; the model-based adaptive controller handles the nominal dynamics, including a purely parametric uncertainties model, while the fuzzy logic controller is aimed at counteracting the effect of unstructured uncertainties and external disturbances. In [29.52], a decentralized adaptive fuzzy control scheme is proposed, where the control law makes use of a multi-input multi-output fuzzy logic engine and a systematic online adaptation mechanism.

Finally it is worth mentioning the efforts invested in the investigation of control strategies using partial state feedback, i. e., only joints position and end-effector forces are fed back to the controller. A recent contribution was provided by the work in [29.53], in which a decentralized control algorithm that achieves asymptotic tracking of desired positions and forces by using a nonlinear observer for velocities was proposed.

Flexibility in a cooperative system may arise, e.g., due to the use of nonrigid grippers to grasp the manipulated object. In fact, the adoption of compliant grippers allows large internal forces to be avoided and, at the same time, achieves safe manipulation of the object, even in the presence of failures and unpredicted contacts with the external environment. In detail, the work in [29.57] develops a non-model-based decentralized control scheme. Namely, a proportional–derivative (PD) position feedback control scheme with gravity compensation, is designed; the PD scheme is capable of regulating the position/orientation of the manipulated object and, simultaneously, achieves damping of the vibrations induced by the compliant grippers; also, a hybrid scheme is adopted to control internal forces along the directions in which the compliance of grippers is too low to ensure limited internal stresses at the manipulated object.

Other research efforts have been focused on handling multibodied objects, or even flexible objects [29.42–44]. Those objects are difficult to handle and, therefore, assembly of those objects in manufacturing industry is not automated. Also, cooperative control of multi-flexible-arm robots has been investigated [29.45, 46]. Once the modeling and control problem is solved (see Chap. 13), the flexible-arm robot is a robot with many merits [29.47]: it is lightweight, compliant, and hence

safe, etc. Combining control methods for flexible-arm robots, such as vibration suppression, with the co-operative control methods presented in this chapter

is straightforward [29.45]. Automated object-retrieval operation with a two-flexible-arm robot has been demonstrated in [29.46].

Haptics

30. Haptics

Blake Hannaford, Allison M. Okamura

The word *haptics*, believed to be derived from the Greek word *haptethai*, means *related to the sense of touch*. In the psychology and neuroscience literature, haptics is the study of human touch sensing, specifically via *kinesthetic* (force/position) and *cutaneous* (tactile) receptors, associated with perception and manipulation. In the robotics and virtual reality literature, haptics is broadly defined as real and simulated touch interactions between robots, humans, and real, remote, or simulated environments, in various combinations. This chapter focuses on the use of specialized robotic devices and their corresponding control, known as *haptic interfaces*, that allow human operators to experience the sense of touch in remote (teleoperated) or simulated (virtual) environments.

Haptic technology is intimately connected with robotics through its reliance on dexterous mechatronic devices and draws heavily on the theoretical foundations of manipulator design, actuation, sensing, and control. In this chapter, we begin with motivation for haptic interface design and use, including the basic design of a haptic interface, information about human haptics, and examples of haptic interface applications. Next, we review concepts in the mechatronic design of kinesthetic haptic interfaces, including sensors, actuators, and mechanisms. We then examine the control aspect of kinesthetic haptic interfaces, particularly the rendering of virtual environments and stable and accurate display of forces. We next review tactile displays, which vary widely in their design due to the many types of tactile information that can be presented to a human operator. Finally, we provide resources for further study of haptics.

write a note without the sense of touch. These simple tasks become extremely difficult to perform without adequate haptic feedback. To improve human operator

30.1 Overview

Haptics is the science and technology of experiencing and creating touch sensations in human operators. Imagine trying to button a coat, shake someone's hand, or

performance in simulated and teleoperated environments, haptic interfaces seek to generate a compelling sensation that the operator is directly touching a real environment.

Haptic interfaces attempt to replicate or enhance the touch experience of manipulating or perceiving a real environment through mechatronic devices and computer control. They consist of a haptic device (a manipulandum with sensors and actuators) and a control computer with software relating human operator inputs to haptic

information display. While the low-level design of haptic interfaces varies widely depending on the application, their operation generally follows the *haptic loop* shown in Fig. 30.1. First, the haptic device *senses* an operator input, which may be position (and its derivatives), force, muscle activity, etc. Second, the sensed input is applied to a virtual or teleoperated environment. For a virtual environment, the effect of the operator's input on virtual objects and the subsequent response to be displayed to the operator are computed based on models and a *haptic rendering* algorithm. In teleoperation, a manipulator that is remote in space, scale, or power attempts to track the operator's input. When the manipulator interacts with its real environment, haptic information to be relayed to the operators is recorded or estimated. Finally, *actuators* on the haptic device are used to physically convey touch sensations to the human operator. Based on the haptic feedback, whether through unconscious or conscious human control, or simply system dynamics, the operator input is modified. This begins another cycle of the haptic loop.

Despite the simplicity of the concept of haptic display, there exist many challenges to developing compelling haptic interfaces. Many of these are addressed through fundamental robotics theory and an understanding of human haptic capabilities. In general, haptic interface performance specifications are based on human sensing and motor control characteristics. One major challenge in artificially generating haptic sensations is that the human operator's motion should be unrestricted when there is no contact with a virtual or remote object. Haptic devices must allow the human operator to make desired motions, thus requiring back-drivability and sufficient degrees of freedom of motion. A variety of robotic designs are used in haptic devices, including exoskeletons, actuated grippers, parallel and serial manipulators, small-workspace *mouse*-like devices, and large-workspace devices that capture whole arm, and even whole body, movement. Another challenge is that humans integrate kinesthetic (force/position) and cutaneous (tactile) information with motion and control cues to form haptic perceptions. Haptic devices would ideally include both force and tactile displays, although this has been rarely done due to size and weight limitations of actuators. Because of the human's sensitivity to high-frequency information, for many haptic interfaces and applications, this loop must repeat at a high frequency, typically 1 kHz. Not only does a high update rate provide realistic (nondiscretized) touch sensations to the human operator, it also typically helps to maintain system stability. Controls analysis for haptic devices must consider

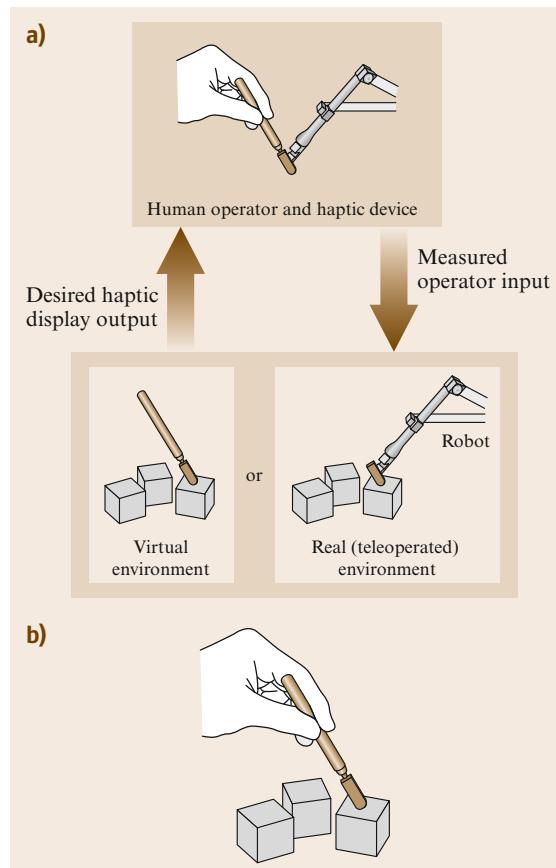

Fig. 30.1 (a) The *haptic loop* of a generic haptic interface. A haptic device senses human operator input, such as position or force, and the system applies this input to a virtual or teleoperated environment. The response of the environment to be relayed to the human operator is computed through models, haptic rendering, sensing, and/or estimation. Finally, actuators on the haptic device display corresponding touch sensations to the human operator. **(b)** The ideal result is that the human operator feels that he or she is interacting directly with a real environment

both the continuous nature of the physical dynamics and the discrete nature of the computer control.

Before we examine the various components of haptic interfaces in detail, it is useful to motivate their design through a review of human haptics and applications of haptics. The remainder of this section is devoted to those topics.

30.1.1 Human Haptics

Anatomy and Physiology

Two functions of the human nervous system play a primary role in haptics: kinesthesia (the internal sensing of forces and displacements inside muscles, tendons, and joints), and tactile sensing (the sensation of deformations of the skin). Haptics incorporates both, and is associated with an activity such as manipulation or exploration. Most of this chapter will address systems meant to interact primarily with the kinesthetic modality. Devices specifically aimed at tactile perception are described in Sect. 30.5. Even if tactile stimuli are not explicitly generated by a haptic device, tactile receptors are still stimulated, and are known to respond to frequencies as high as 10 000 Hz [30.2] and displacements as small as 2–4 μm [30.3–5].

Kinesthesia is mediated by muscle spindles, which transduce stretch of muscles, and Golgi tendon organs, which transduce joint rotation, especially at the extremes of motion. In principle, these and similar receptors could be stimulated directly to produce haptic sensations. For example, a vibration applied to a muscle tendon creates a strong sensation of muscle lengthening and corresponding joint motion in humans [30.6, 7]. Research in peripheral nerve stimulation for prosthesis control has demonstrated that electrodes implanted within individual fascicles of peripheral nerve stumps in amputees can be stimulated to produce sensations of touch or movement referred to the amputee's phantom hand [30.8].

Psychophysics

At the next level up from physiology and anatomy, psychophysics [30.1], the science of the physical capabilities of the senses, has been a rich source of design data for haptic device development. Its chief contribution has been methodologies that haptics researchers have applied to answer questions about what capabilities are needed in haptic devices. These sensory capabilities could then be translated into design requirements. Some of the chief psychophysical methods that have been fruitfully applied to haptics include threshold mea-

surement by the method of limits and adaptive up-down methods. However, perception at threshold is not 100% reliable. Perception accuracy tends to depend on the strength of the stimulus, and the tradeoff between hit rate and false alarms depends strongly on the probability that a stimulus will be present in a given time interval (P_{stim}).

A more general notion is the receiver operating curve (Fig. 30.2, borrowed by psychophysics from radar theory), which plots the probability of a subject response given the existence of a stimulus, versus the probability of response given no stimulus. The curve is generated by measuring both probabilities at several different values of P_{stim} . The ideal response is the point (0,1): 100% response for stimuli and 0% response for nonstimuli. Human response is near this point for stimuli much above threshold, but declines to a rounded curve and eventually the 45° line as response below threshold becomes equal to chance.

Another relevant concept from psychophysics is the just noticeable difference (JND), commonly expressed as a percentage. This is the magnitude of a relative change in a stimulus, such as a force or displacement applied to the finger that is just perceivable by subjects. For example, Jones [30.9] has measured JNDs of 6%

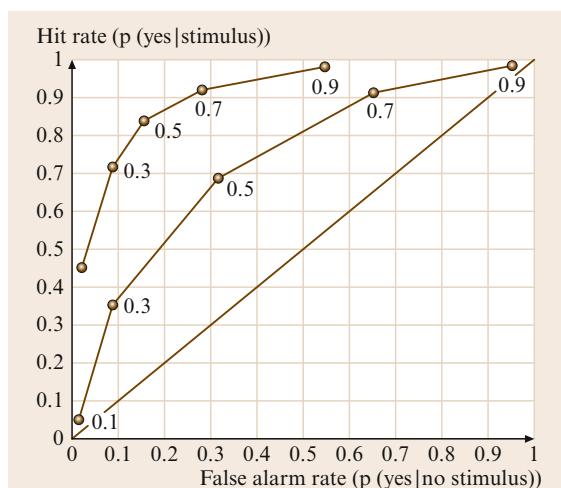

Fig. 30.2 Receiver operating curve (ROC). The ROC encodes the tradeoffs made by a subject between risk of false alarm and risk of missing a valid stimulus. Each point encodes a specific tradeoff between these two risks observed when stimuli are presented with a specified probability. ROCs for stronger signals tend towards the upper left hand corner. (after [30.1] with permission from Lawrence Erlbaum and Associates, Mahwah)

for force applied to the human finger over a range of 0.5–200 N.

Psychology: Exploratory Procedures

In influential research starting in the 1980s, *Lederman* and *Klatzky* defined stereotyped hand motions called *exploratory procedures* (EPs), which are characteristic of human haptic exploration [30.10–12]. They placed objects into the hands of blindfolded subjects, and videotaped their hand motions. Their initial experiments [30.10] showed that the EPs used by subjects could be predicted based on the object property (texture, mass, temperature, etc.) that the subjects needed to discriminate. They also showed that the EPs chosen by subjects were the ones best able to discriminate that property. Furthermore, when asked to answer specific questions about objects (*Is this eating utensil further a fork?*), subjects used a two-stage sequence in which a more general lifting EP preceded more specific EPs [30.12].

Lederman and Klatzky's eight EPs (Fig. 30.3) and the property for which they are optimal are:

1. lateral motion (texture)
2. pressure (hardness)
3. static contact (temperature)
4. unsupported holding (weight)
5. enclosure (global shape, volume)
6. contour following (exact shape, volume)
7. part motion test (part motion)
8. function testing (specific function)

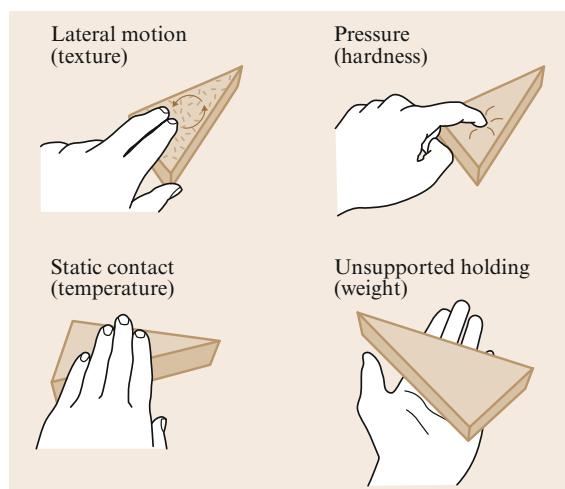

Fig. 30.3 Four of the eight human exploratory procedures (EPs) (after *Lederman* and *Klatzky* [30.10])

Each of these EPs is a bimanual task involving contact with interior surfaces of the hand, motion of the wrist, various degrees of freedom of the, and tactile and temperature sensors in the skin (e.g., EPs 1 and 3), and kinesthetic sensors in the arm (EP 4). A haptic device capable of supporting all of these EPs is far beyond today's state of the art. However, the significance of these results for the design of haptic interface is great, since they allow us to derive device requirements from EPs.

30.1.2 Application Examples

The most common haptic device encountered by the general population is a vibration display device that provides haptic feedback while an operator plays a video game. For example, when the operator drives off the virtual road or bumps into a virtual wall, the hand controller shakes to imply driving over a rough surface or displays an impulse to represent the shock of hitting a hard surface. We examine two more pragmatic examples, medical simulators and computer-aided design systems, in detail below. In addition, we review several commercially available haptic devices. Although haptic interfaces are not yet in widespread commercial use outside of entertainment, they are being integrated into numerous applications where the potential benefits are clear enough to justify the adoption of new technologies. A variety of novel and creative applications are being developed regularly in numerous fields, including

- assistive technology
- automotive
- design
- education
- entertainment
- human-computer interaction
- manufacturing/assembly
- medical simulation
- micro/nanotechnology
- molecular biology
- prosthetics
- rehabilitation
- scientific visualization
- space
- surgical robotics

Medical Simulations

A major example driving much of today's haptic virtual environment research is simulation for training of

hands-on medical procedures. Medical invasive therapeutic and diagnostic procedures, ranging from drawing blood samples to surgery, are potentially dangerous and painful for the patient and require the student to learn hands-on skills mediated by haptic information pathways [30.13]. Simulators both with and without haptic feedback aim to replace supervised learning directly on human patients or on animals. Simulators have proven highly effective in developing minimally invasive surgery skills [30.14], especially when haptic feedback is provided in early training [30.15]. Expected benefits of training with haptic simulators include

- reduced risk to patients both during and immediately after training
- increased ability to simulate unusual conditions or medical emergencies
- ability to collect physical data during the training process and provide specific and directed feedback to the student
- increased training time per unit of instructor effort

Approaches for simulator designs, specific medical applications, and training evaluation methods have also been widely studied in the last two decades, e.g., [30.16, 17]. However, the costs of this technology are still high. In addition, it is not always clear which improvements in simulator technology, such as haptic device performance or accuracy of soft-tissue modeling, lead to improved clinical performance and, ultimately, patient outcomes.

Computer-Aided Design

The Boeing Company [30.18] has studied the use of haptic interfaces for solving advanced problems in computer-aided design (**CAD**). One such problem is verification of the ability to efficiently maintain a complex system such as an aircraft. In the past, mechanics could verify the procedures (such as change-out of parts) on a physical prototype. However, this analysis is difficult or impossible to perform visually on an advanced **CAD** system. The VoxMap Pointshell system (Fig. 30.4) was developed to allow test extraction of parts with a haptic interface. Force sensations from the haptic interface reproduce for the operator the physical constraints of the part bumping into elements of the complex workplace. If the operator can remove the part in the haptic interface, it is verified that this part can be maintained without undue disassembly of the aircraft. This capability has been proved useful in actual design activities.

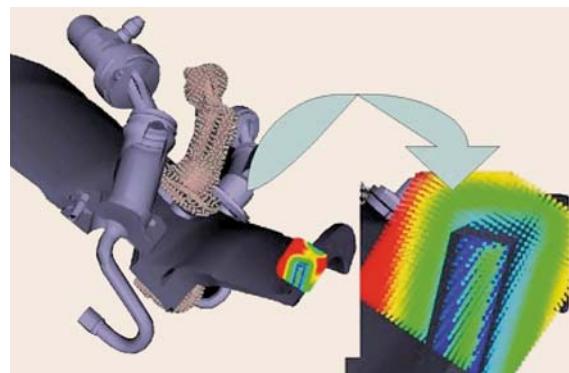

Fig. 30.4 Boeing computer-aided design (**CAD**) application for assembly and maintenance verification of complex aircraft systems. Boeing researchers developed the Voxmap/Pointshell software for haptically rendering very complex models in six degrees of freedom at high rates. (Courtesy of Bill McNeely, Boeing Phantom Works)

Commercially Available Haptic Devices and Systems

There are a wide variety of haptic devices available for purchase, ranging from high-fidelity research devices to inexpensive entertainment systems. Some researchers also build their own haptic devices in order to implement novel designs, meet particular application constraints, or save costs. At the time of this writing, the bulk of commercially available haptic devices are designed by two companies: SensAble Technologies [30.19] and Immersion Corporation [30.20]. SensAble has developed the Phantom line of stylus-type haptic devices

Fig. 30.5 The Phantom Omni device from SensAble Technologies. This low-cost device senses motion in six degrees of freedom from the stylus and can apply forces in the x , y , and z directions to the stylus tip. (Courtesy SensAble Technologies, Inc., Woburn)

(Fig. 30.5). The Phantom Premium [30.21] has been the most widely used haptic device in research to date. The high price of haptic devices (compared to visual displays) restricts the development of some commercial applications. The Phantom Omni, which is an order of magnitude less expensive than the Phantom Premium, has also gained popularity among haptics and robotics researchers. In 2007, Novint Technologies [30.22] released the Novint Falcon, an inexpensive three-degree-of-freedom haptic device that is in turn an order of magnitude less expensive than the Phantom Omni. This device is aimed more toward entertainment applications.

Immersion has aimed at the mass market and consumer segments with a wide variety of haptics-based products, many of them involving a single degree of

freedom. For example, they have licensed technology to makers of various video games, as well as mobile phone manufacturers, in the form of vibratory feedback in handheld devices and haptic-enabled steering wheels for driving games. Immersion also has a medical division selling medical simulators with haptic feedback.

Software for haptic rendering has also become widely available, through both commercial sources and research groups. Most companies that sell haptic devices also provide a standard development kit (**SDK**) with haptic rendering capability. In addition, not-for-profit open-source projects such as Chai3D (www.chai3d.org) aim to make rendering algorithms from different groups publicly available, shortening application development time and allowing direct comparison of algorithms for benchmarking purposes.

30.2 Haptic Device Design

There are two broad classes of haptic devices: *admittance* and *impedance* devices. Admittance devices sense the force applied by the operator and constrain the operator's position to match the appropriate deflection of a simulated object or surface in a virtual world. In contrast, an impedance haptic device senses the position of the operator, and then applies a force vector to the operator according to computed behavior of the simulated object or surface.

Robots of the impedance type are back-drivable, have low friction and inertia, and have force-source actuators. A commonly used impedance haptic device in robotics-related research is the Phantom Premium [30.21, 23]. Robots of the admittance type, such as typical industrial robots, are non-back-drivable and have velocity-source actuators. The velocity is controlled with a high-bandwidth low-level controller, and is assumed to be independent of applied external forces. Some commercially available haptic devices, such as the Haptic-Master [30.24], do operate under admittance control. While such closed-loop force control has been used for haptic display, more commonly designers have opted for mechanisms specially designed for open-loop force control to achieve simultaneously low cost and high bandwidth.

The choice of admittance or impedance architecture has many profound implications in the design of the software and hardware system. For a variety of reasons, including cost, the majority of haptic devices implemented today are of the impedance type. Because the preponderance of systems today are impedance de-

vices and limitations on space, we limit our subsequent discussion to that class.

30.2.1 Mechanisms

Creating high-fidelity haptic sensations in the operator requires attention to mechanism design (Chap. 4). The requirements for impedance haptic devices are similar to those for designing manipulators suitable for force control (Chap. 8). Desirable mechanism attributes for open-loop force control include low inertia, high stiffness, and good kinematic conditioning throughout a workspace designed to effectively match the appropriate human limb, primarily the finger or arm. The weight of the mechanism should be minimized, as it is perceived by the operator as weight and inertia of the virtual or teleoperated environment. Kinematic singularities (Chaps. 1, 4, and 12) are detrimental to haptic interfaces because they create directions in space in which the end-point cannot be moved by the human operator and thus impose disturbances on the illusion of haptic contact with virtual objects. High transmission ratios must be avoided as they introduce significant amounts of friction. This constraint requires haptic interfaces to make high demands on actuator performance.

Measures of Mechanism Performance

The ideal haptic device can move freely in any direction and is free of singular configurations as well as the *bad* effects of operating in their neighborhood. Traditionally, kinematic performance has been derived from

the mechanism's Jacobian matrix, $J(p, q)$, using some of the following well-known measures:

- manipulability [30.25]: the product of the singular values of $J(p, q)$
- mechanism isotropy [30.26]: the ratio of smallest to the largest singular value of $J(p, q)$
- minimum force output [30.25, 27, 28]: maximizing the force output in the *worst* direction

Dynamics can also be introduced into the cost function using measures such as dynamic manipulability [30.29]. This is still an active area of research and there is no consensus yet on which dexterity measure is most appropriate for haptic devices.

Kinematic and Dynamic Optimization

This aspect of design requires synthesis of mechanisms that match the workspace of the (most often) human finger or arm while simultaneously avoiding kinematic singularities.

A haptic device workspace is defined to match that of the targeted human limb. This can be assisted by the use of anthropometric data [30.30]. The performance goals, such as low inertia and avoidance of kinematic singularities, must be formalized into a quantitative performance measure which can be computed for any candidate design. Such a measure must account for

- uniformity of kinematic conditioning throughout the target workspace
- favoring designs with lower inertia
- guaranteeing that the target workspace is reachable

The measures of mechanism performance defined above operate at a single point in space and thus must be integrated over the entire workspace to derive a figure of merit for a proposed haptic device design. For example, if S is the set of all joint angles Θ , such that the end effector is inside the target workspace, one such measure is

$$M = \min_S W(\Theta), \quad (30.1)$$

where $W(\Theta)$ is a measure of design performance. The performance measure should include a link length penalty such as

$$M = \min_S \frac{W(\Theta)}{l^3}, \quad (30.2)$$

in order to avoid solutions which have excessive size, compliance, and mass of long links. We could search a large family of mechanism designs to maximize M .

For example, if a design has five free parameters (typically link lengths and offsets), and we study ten possible values for each parameter, 10^5 designs must be evaluated.

Available computing power has grown much faster than the complexity of realizable mechanisms on the human scale (as measured by their degrees of freedom). Thus, brute-force search of design spaces is often sufficient, and sophisticated optimization techniques are not necessary.

Grounded Versus Ungrounded Devices

Most current devices that provide kinesthetic feedback are physically grounded, that is, forces felt by the operator are with respect to the operator's *ground*, such as the floor or desktop. Ungrounded haptic feedback devices are more mobile and can operate over larger workspaces compared to grounded devices, which enables them to be used in large-scale virtual environments. A number of ungrounded kinesthetic feedback devices have been developed, for example [30.31–33]. Comparisons have been made between the performance of ungrounded and grounded haptic displays [30.34]. Some ungrounded devices provide tactile rather than kinesthetic sensations, and these are described in Sect. 30.5.

30.2.2 Sensing

Haptic devices require sensors to measure the state of the device. This state may be modified by the operator's applied position/force, the haptic control law, and/or device and environment dynamics. The operator's input is sensed in the form of an applied position or an applied force. Sensing requirements for haptics are similar to those of other robotic devices (Chap. 20) so only haptics-specific sensing issues are discussed here.

Encoders

Rotary optical quadrature encoders are typically used as position sensors on the joints of haptic devices. They are often integrated with rotary motors, which serve as actuators. The underlying sensing mechanism for encoders is described in Sect. 20.1. The required resolution of an encoder for a haptic device depends on the ratio between the angular distance of a single encoder tick to the end-point motion in Cartesian space. The resolution of the selected position encoder has effects beyond simple spatial resolution of the endpoint, including the maximum stiffness that can be rendered (Sect. 30.4) without unstable or nonpassive behavior [30.35].

Many haptic applications, such as the rendering of virtual environments with damping (in which force is proportional to velocity), require velocity measurement. Velocity is typically obtained by numerical differentiation of the position signal obtained by an encoder. An algorithm for velocity estimation must be selected which is free of noise but minimizes phase lag at the frequencies of interest [30.36]. Thus, an alternative method is to use specialized hardware that measures the time between encoder ticks in order to compute the velocity [30.37].

Force Sensors

Force sensors are used in haptic devices as the operator input to an admittance-controlled device, or as a mechanism for canceling device friction and other undesirable dynamic properties in an impedance-controlled device. Force sensors are described in Sect. 20.4. When a force sensor such as a strain gauge or load cell measures the operator's applied force, care must be taken to thermally isolate the sensor, since thermal gradients in the sensor caused by body heat can affect force readings.

30.2.3 Actuation and Transmission

Haptic devices are differentiated from traditional computer input devices by actuators that are controlled to provide appropriate haptic sensations to the human operator. The performance of the haptic device depends heavily on the actuator properties and the mechanical transmission between the actuator and the haptic interaction point (**HIP**).

Requirements for Haptics

The primary requirements for actuators and mechanical transmission in impedance-type haptic devices are: low inertia, low friction, low torque ripple, back-driveability, and low backlash. In addition, if the design is such that the actuator itself moves as the user's position changes, a higher power-to-weight ratio is desired. Although closed-loop force control has been used for haptic display in impedance devices, most often the mechanism is designed to have sufficiently low friction and inertia so that open-loop force control is accurate enough.

One common mechanical transmission for haptic devices is the capstan drive (Fig. 30.6), which consists of smooth cables wrapped around pulleys of differing diameter to provide a gear ratio. A no-slip, high-friction contact between the cable and the pulleys is maintained through several wraps of the cable. The capstan drive minimizes friction forces felt by human operator be-

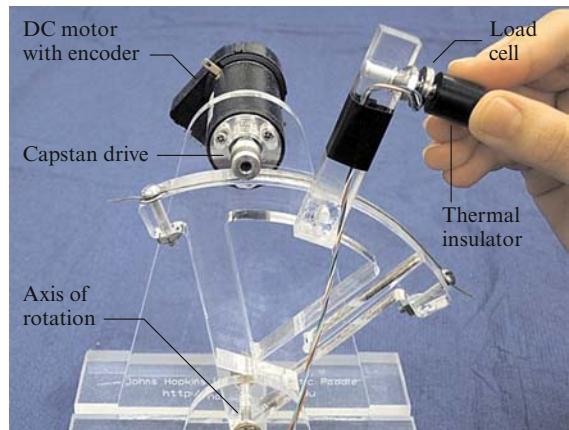

Fig. 30.6 This version of the Haptic Paddle [30.38] includes an encoder for position sensing, a single-axis load cell for force sensing, and a brushed motor with capstan transmission for actuation

cause it prevents translational forces on motor and joint axes.

Current amplifiers are typically used to create a direct relationship between the voltage output by the computer via a digital-to-analog (D/A) converter and the torque output by the motor. The effect of actuator and amplifier dynamics and D/A resolution on system stability is typically negligible in comparison to position sensor resolution and sampling rate for most haptic devices. Actuator or amplifier saturation can produce undesirable behavior, particularly in multi-degree-of-freedom haptic devices where a single saturated motor torque may change the apparent geometry of virtual objects. The force vector, and thus the corresponding actuator torques, must be scaled appropriately if any actuator is saturated.

30.2.4 An Example Device

As an illustrative example, we will provide detailed design information for a simple one-degree-of-freedom haptic device known as the Haptic Paddle [30.38]. This section is meant to provide a concrete description of the types of components that are used in kinesthetic haptic devices, and the device can also be constructed following the instructions provided by John Hopkins University [30.39]. Many widely available haptic devices share the common working principles of this device and differ chiefly in kinematic details arising from a greater number of degrees of freedom.

The haptic paddle shown in Fig. 30.6 is equipped with two sensors: a position encoder and a force sensor. A 500-counts-per-turn Hewlett-Packard HEDS 5540 encoder that is mounted directly on the motor. The quadrature process yields 2000 counts per revolution; the capstan transmission gear ratio and lever arm result in a position resolution of 2.24×10^{-5} m at the HIP. A PCI-Quad04 board from Measurement Computing is used to interface with the encoder. An Entran ± 10 N load cell (model ELFS-T3E-10N) is used to measure the applied operator force. A Delrin cap thermally insulates the load cell. In this device, the load cell can be used to minimize the effect of friction through a control law that attempts to zero the applied operator force when the HIP is not in contact with a virtual object. The signal from the load cell is passed through an instrumentation amplifier (Burr-Brown INA103) with a gain of 5 before it is read by the 16-bit A/D (PCI-DAS6402 configured for a range of ± 1.25 V).

30.3 Haptic Rendering

Haptic rendering (in impedance systems) is the process of computing the force required by contacts with virtual objects based on measurements of the operator's motion. This section describes haptic rendering for virtual environments. Haptic feedback for teleoperators is described in Chap. 31.

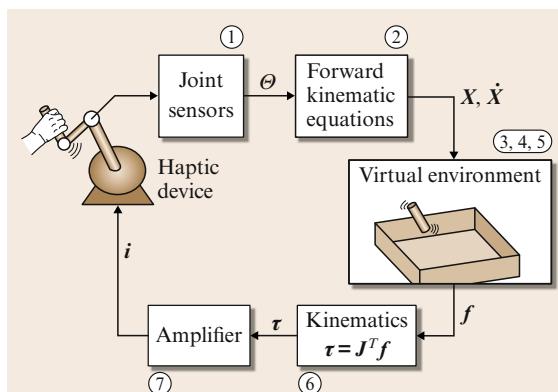

Fig. 30.7 Schematic diagram of the haptic rendering cycle for an impedance haptic display system. Virtual object moves in the virtual environment according to operator's displacement of the haptic device. Joint displacements (Θ) sensed in the device (1) are processed through kinematics (2), collision detection (3), surface point determination (4), force calculation (5), kinematics (6), and actuation (7)

The actuator is a brushed Maxon DC motor (model 118754m RE-25) with an aluminum pulley attached to the shaft. Like many commercial haptic devices, a cable is wrapped several times around the motor pulley and attached at each end of the large partial pulley. A PCI-DAS6402 data-acquisition card from Measurement Computing, is used to output voltages to the motor amplifier. The 16-bit D/A is configured for ± 10 V. The output of the D/A is passed through a current amplifier that gives a current through the motor that is proportional to the D/A voltage; the current amplifier is built around a National Semiconductor LM675 power operational amplifier. This gives direct control of applied torque on the motor. The resulting system has a force felt at the driving point that is proportional to the output voltage (1.65 N/V) during static operation. When the system is moving, the force applied to the operator may differ due to human and device dynamics.

An important property of haptic systems is that their timing constraints are quite severe. To illustrate this point, tap a pencil on the table top. You hear a sound which is an audio representation of the contact dynamics between pencil tip and table top. Tactile receptors in the human fingers are known to respond up to 10 kHz [30.2]. To realistically render this type of contact between hard surfaces would require response well into the audio range of frequencies (up to 20 kHz) and thus sampling times of around 25 μ s. Even with specialized designs, haptic devices do not have this bandwidth, and such high fidelity is not usually a goal of haptic rendering. Achieving stability in any type of hard contact requires very high sampling rates. In practice, most haptic simulation systems are implemented with at least 1000 Hz sampling rate. This can be reduced to the low hundreds of Hertz if the virtual environment is limited to soft materials.

Basic Haptic Rendering

The computational process of haptic rendering can be formulated into the following seven sequential steps for each cycle (Fig. 30.7). The rendering cycle must typically be completed in under 1 ms for stability and realism:

1. Sensing (Sect. 30.2.2)
2. Kinematics
3. Collision detection

4. Determining surface point
5. Force calculation
6. Kinematics
7. Actuation (Sect. 30.2.3)

Kinematics

The position and velocity measurements acquired by sensors are typically in joint space. These must be converted through the forward kinematics model and the Jacobian matrix (Chap. 1) to the Cartesian position and velocity of the operator's hand or fingertip. In some applications the operator is virtually holding a tool or object whose shape is represented in the virtual environment but whose position and orientation are determined by the operator. In others, the operator's fingertip or hand is represented by a point which makes only point contact with objects in the virtual environment (VE). We refer to a virtual handheld object as a virtual tool and, following [30.40], we refer to the single end-point as the haptic interaction point (**HIP**).

Collision Detection

For the point contact case, the collision detection software must determine if the position of the **HIP** at the current instant of time represents contact with a virtual object. In practice this usually means to determine if the **HIP** is penetrating or inside the object surface. The object surface is represented by a geometric model such as polygons or splines.

Although there is an extensive literature on collision detection in computer graphics, there are unique

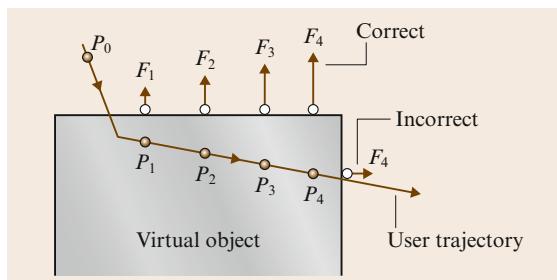

Fig. 30.8 Illustration of subtle aspects of haptic rendering of contact force. The operator fingertip trajectory enters object surface moving down and to right. Haptic interaction points (**HIP**) are shown at times 1–4 (solid circles, P_0 – P_4). Intermediate haptic interaction points (**IHIP**) are shown when the **HIP** is inside the object (open circles). At position P_4 , the algorithm must not render force based on the closest surface point or the operator will be ejected from the side of the object (feeling unnatural force tangential to the top surface)

aspects of the collision detection problem for haptics. In particular, speed of computation is paramount and worst-case speed, as opposed to average speed, is what counts. Solutions that evaluate in constant time are preferred. Section 30.3.1 addresses collision detection and haptic rendering for complex environments.

If the **HIP** is found to be outside all objects, then a force of zero is returned.

Determining Surface Point

Once it is determined that the **HIP** is inside a surface, the force to be displayed to the operator must be computed. Many researchers have used the idea of a virtual spring connecting the **HIP** to the nearest point on the surface as a model of interpenetration and force generation [30.40–42]. Basdogan and Srinivasan named this point the intermediate haptic interaction point (**IHIP**). However all of these authors realized that the closest surface point is not always the most faithful model of contact. For example, as the **HIP** moves laterally below the top surface of a cube (Fig. 30.8), eventually it becomes close enough to the edge that the closest surface point becomes the side of the cube. In this situation, the algorithm needs *memory* to keep the **IHIP** on the top surface and generate an upward force at all times or the operator is suddenly ejected out the side of the cube.

Force Calculation

Force is commonly computed by using the spring model (Hooke's Law)

$$f = kx, \quad (30.3)$$

where x is the vector from the **HIP** to the **IHIP**, and $k > 0$. When k is sufficiently large, the object surface will feel like a wall perpendicular to x . This *virtual wall*, or impedance surface, is a fundamental building block of most haptic virtual environments. Because the virtual wall is only displayed if a collision between the **HIP** and virtual object is detected, the wall is a unilateral constraint, governed by a nonlinear switching condition. As will be described in the following section, haptic virtual environments with complex geometries are often formed using a polygonal mesh in which each polygon is essentially a virtual wall. A virtual surface may also be allowed to deform globally, while the local interaction with the operator is governed by a virtual wall. *Virtual fixtures*, which are often constructed from virtual walls, can be overlaid on haptic feedback teleoperators to assist the operator during a teleoperated task (Chap. 31).

The pure stiffness model described above can be augmented to provide other effects, particularly through

the use of the *virtual coupling* described in Sect. 30.3.2. Damping can be added perpendicular or parallel to the surface. In addition, Coulomb or other nonlinear friction may be displayed parallel to the surface. To provide a more realistic display of hard surfaces, vibrations can also be displayed open loop at the moment of collision between the **HIP** and the surface, as is described in Sect. 30.5.

Kinematics

The computed force in Cartesian space must then be transformed into torques in the actuator space. Typically the calculation is

$$\boldsymbol{\tau} = \mathbf{J}^\top \mathbf{f} \quad (30.4)$$

where $\boldsymbol{\tau}$ is the torque command to the actuators, \mathbf{f} is the desired force vector, and \mathbf{J}^\top is the transpose of the haptic device Jacobian matrix (Chap. 1). If the haptic device has no dynamics and the actuators are perfect, the exact desired force is displayed to the operator. However, real device dynamics, time delays, and other nonidealities result in applied operator forces that differ from the desired forces.

30.3.1 Rendering Complex Environments

Today's computer power is sufficient that a variety of relatively simple algorithms can effectively render haptics for simple virtual environments, say consisting of a handful of simple geometric primitives such as spheres, cubes, and planes. However, the challenge is to scale these algorithms to complex environments such as those we are used to seeing in computer graphic renderings consisting of 10^5 – 10^7 polygons. A variety of approaches have been tried in the literature for efficient rendering of complex scenes. Zilles and Salisbury [30.41] found planar constraints due to the nearby surface polygons and solved for the closest IHIP point using Lagrange multipliers. Ruspini et al. [30.43] added force shading and friction models. Ho et al. [30.40] used a hierarchy of bounding spheres to determine the initial contact (collision) point, but thereafter searched neighboring surfaces, edges, and vertices (referred to as geometric primitives) of the current contacted triangle to find the closest point for the IHIP. Gregory et al. [30.44] imposed a discretization of three-dimensional (3-D) space onto the hierarchy to speed up the detection of initial contact with the surface. Johnson et al. [30.45] performed haptic rendering on moving models based on local extrema in distance between the model controlled by the haptic device and the rest of the scene. Lin and

Otraduy [30.46, 47] used level-of-detail representations of the objects for performing multiresolution collision detection, with the goal of satisfying real-time constraints while maximizing the accuracy of the computed proximity information.

Alternative algorithms and efficiencies can be derived by not representing the object surface as polygons. Thompson and Cohen [30.48] derived the mathematics for computing the interpenetration depth for surfaces directly from non-uniform rational B-spline (**NURBS**) models. McNeely et al. [30.18] took the extreme approach of voxelizing space at the millimeter scale. Each voxel contained a precomputed normal vector, stiffness properties, etc. 1000 Hz rendering was achieved with very complex **CAD** models containing millions of polygons (in the graphical equivalent representation), but large amounts of memory and precomputation are required. The performance of this algorithm is sufficiently high that it can be used to render hundreds of contact points simultaneously. This allows the operator to *hold* an arbitrarily shaped tool or object. The tool/object is populated by points surrounding its surface and the resultant force and moment on the tool is the sum of interaction forces computed on all of the surface points.

For surgical simulation, researchers have focused on the modeling and haptic rendering of the interaction between surgical instruments and organs. Researchers have attempted to model virtual tissue behavior in a wide variety of ways, which can be broadly classified as

1. linear elasticity based,
2. nonlinear (hyperelastic) elasticity-based finite-element (**FE**) methods
3. other techniques that are not based on **FE** methods or continuum mechanics

While most conventional linear and nonlinear **FE** algorithms cannot be run in real time, methods such as preprocessing can allow them to run at haptic rates [30.49]. Many researchers rely on data acquired from real tissues to model organ deformation and fracture accurately. Major challenges in this field include the modeling of connective tissue supporting the organ, friction between instruments and tissues, and topological changes occurring during invasive surgical procedures.

30.3.2 Virtual Coupling

So far we have rendered forces by computing the length and direction of a virtual spring and applying Hooke's Law (30.3). This spring is a special case of a *virtual coupling* [30.42] between the **HIP** and the IHIP. The vir-

tual coupling is an abstraction of the interpenetration model of force rendering. Instead of viewing the objects as compliant, we assume them to be rigid but connect them to the operator through a virtual spring. This imposes an effective maximum stiffness (that of the virtual coupling).

Problems with stable contact rendering (Sect. 30.4) often require more sophisticated virtual couplings than

a simple spring. For example, damping can be added, generalizing the force rendering model of (30.3) to

$$f = kx + b\dot{x}. \quad (30.5)$$

The parameters k and b can be empirically tuned for stable and high-performance operation. More-formal design methods for the virtual coupling are covered in Sect. 30.4.

30.4 Control and Stability of Haptic Interfaces

Introduction to the Problem

The haptic rendering system depicted in Fig. 30.7 is a closed-loop dynamical system. It is a challenge to render realistic contact forces yet retain the stable behavior of human-environment contact in the natural world. Instability in haptic interfaces manifests itself as buzzing, bouncing, or even wildly divergent behavior. The worst case for impedance devices is during attempted contact with stiff objects. Empirically, instability is frequently encountered when developing haptic interfaces with stiff virtual objects, but this instability can be eliminated by reducing the stiffness of the virtual object or by the operator making a firmer grasp on the haptic device.

Problem Description in Classical Control Terms

Although linear theory is of very limited use in applications, it can be applied to a basic analysis of the factors affecting instability [30.50]. Such a highly simplified model of an impedance device is shown in Fig. 30.9. $G_1(s)$ and $G_2(s)$ represent dynamics of the haptic device for both operator position sensing and force display respectively. Assume that the virtual environment and human operator/user (HO) can each be represented by a linear impedance such as

$$Z_{VE} = \frac{F_{VE}(s)}{X_{VE}(s)}, \quad (30.6)$$

$$Z_{HO} = \frac{F_{HO}(s)}{X_{HO}(s)}. \quad (30.7)$$

Then the loop gain of the closed-loop system from the human operator and back again is

$$G_l(s) = G_1(s)G_2(s)\frac{Z_{VE}(s)}{Z_{HO}(s)}. \quad (30.8)$$

Stability in the classical sense is assessed by applying the magnitude and phase criteria of Nyquist to $G_l(s)$. Increasing Z_{VE} (corresponding to stiffer or heavier virtual

objects) increases the magnitude of $G_l(s)$ and thus destabilizes the system while a firmer grasp by the human operator, which increases the magnitude of Z_{HO} , has a stabilizing effect. Similar arguments apply to phase shifts that might be present in any part of the system.

Limitations of Linear Theory

Although the model of Fig. 30.9 illustrates some qualitative features of haptic interface stability, linear continuous time theory is of little use in designing methods to stabilize the loop. Interesting virtual environments are nonlinear. Furthermore, they can rarely be linearized because applications often simulate discontinuous contact, for example, between a stylus in free space and a hard surface. A second feature is digital implementation, which introduces sampling and quantization—both of which have significant effects.

Sampling

Colgate et al. [30.42] incorporated consideration of discrete time sampling behavior in the stability analysis. They considered the problem of implementing a virtual wall of stiffness

$$H(z) = K + B \frac{z - 1}{Tz}, \quad (30.9)$$

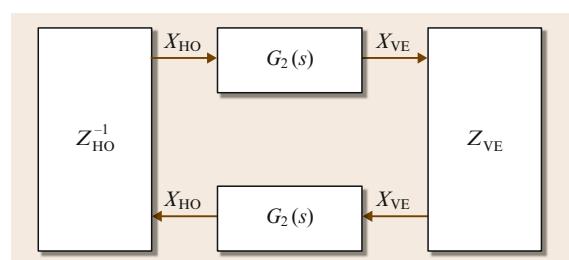

Fig. 30.9 Highly simplified linear model of haptic rendering to highlight some stability issues

where K is the virtual wall stiffness, B is the virtual wall damping coefficient, z is the z -transform variable, and T is the sampling time. They further modeled the haptic device (HD) in continuous time as

$$Z_{\text{HD}}(s) = \frac{1}{ms + b}, \quad (30.10)$$

where m and b are the mass and damping of the haptic device, respectively. They derived the following condition for passivity of the device

$$b > \frac{KT}{2} + |B|, \quad (30.11)$$

showing a significant stabilizing effect of high sampling rates and also of high mechanical damping in the haptic device.

Quantization

Additional factors include delays due to numerical integration schemes and quantization. These contributing factors to instability have been termed *energy leaks* by *Gillespie and Cutkosky* [30.51].

Passivity

Interesting virtual environments are always nonlinear and the dynamic properties of a human operator are important. These factors make it difficult to analyze haptic

systems in terms of known parameters and linear control theory. One fruitful approach is to use the idea of passivity to guarantee stable operation. Passivity is a sufficient condition for stability, and is reviewed more completely in Chap. 31 on telerobotics. There are many similarities between the control of haptic interfaces and bilateral teleoperation.

The major problem with using passivity for design of haptic interaction systems is that it is overly conservative, as shown in [30.35]. In many cases, performance can be poor if a fixed damping value is used to guarantee passivity under all operating conditions. *Adams and Hannaford* derived a method of virtual coupling design from two-port network theory which applied to all causality combinations and was less conservative than passivity based design [30.52]. They were able to derive optimal virtual coupling parameters using a dynamic model of the haptic device and by satisfying Lewellyn's *absolute stability criterion*, an inequality composed of terms in the two-port description of the combined haptic interface and virtual coupling system. *Miller et al.* derived another design procedure which extended the analysis to nonlinear environments and extracted a damping parameter to guarantee stable operation [30.53–55].

30.5 Tactile Display

Tactile displays are used to convey force, contact, and shape information to the skin. They purposely stimulate cutaneous receptors, with little effect on kinesthetic sensation. This is in contrast to the kinesthetic displays described earlier in this chapter, which focus on force display but also inherently provide cutaneous sensations through physical contact with a tool or thimble. Tactile displays are usually developed for a specific purpose, such as display of contact events, contact location, slip/shear, texture, and local shape. This is logical in some respects—as different types of cutaneous receptors, each with its own frequency response, receptive field, spatial distribution, and sensed parameter (e.g. local skin curvature, skin stretch, and vibration)—are associated with the different exploratory procedures described in Sect. 30.1.1.

In contrast to kinesthetic displays, the design and prototyping of tactile displays to render realistic contact information for virtual reality or teleoperation have proven very challenging. Accurate recreation of the local shape and pressure distribution at each fingertip requires a dense array of actuators. Devices specifi-

cally aimed at tactile perception are an active area of research, but most have not reached the stage of applications or commercial distribution, with the notable exception of Braille displays for the blind. In this section, we describe the various types of tactile displays, their design considerations, rendering algorithms, and applications.

30.5.1 Vibration Feedback

Vibration feedback is a popular method of providing tactile feedback. It can be used as a stand-alone method for haptic feedback or as an addition to a kinesthetic display. Vibrating elements, such as piezoelectric materials and small voice-coil motors, are lighter than the actuators used in kinesthetic devices, and can often be added to kinesthetic devices with little impact on existing mechanisms. In addition, high-bandwidth kinesthetic displays can be programmed to display open-loop vibrations through their normal actuators. The sensitivity for human vibration sensing ranges from DC to over 1 kHz, with peak sensitivity around 250 Hz.

We first consider the use of vibrations to convey impact or contact events—a technique that straddles kinesthetic and tactile feedback. When humans touch an environment, fast-acting sensors embedded in the skin record the minute vibrations occurring from this interaction. As described in Sect. 30.3, conventional approaches to haptic display usually consist of designing a virtual model with simple geometry, then using a first-order stiffness control law to emulate a surface. However, such first-order models often lack the realism of higher-order effects such as impact. With common haptic rendering algorithms, surfaces feel squishy or unrealistically smooth. One solution to improving the realism of such environments is to add higher-order effects such as textures and contact vibrations. These effects can use a library of surface models based on ad hoc analytical descriptions [30.56], which are sometimes tuned using qualitative operator feedback, physical measurements (reality-based models created from empirical data) [30.57, 58], or a combination of the two [30.59]. At the instant collision is detected between the HIP and a surface of the virtual object, the appropriate waveform is called out of the library, scaled according to the context of the motion (such as velocity or acceleration), and played open loop through an actuator. That actuator may be the same one simultaneously displaying lower-frequency force information, as shown in

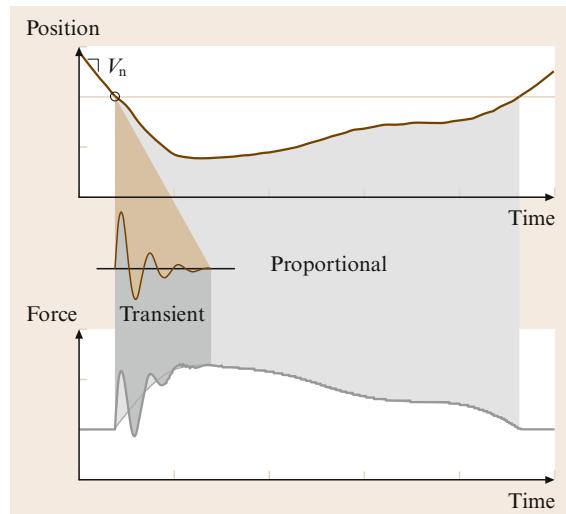

Fig. 30.10 Event-triggered open-loop force signals superimpose on traditional penetration-based feedback forces, providing vibration feedback that improves the realism of hard surfaces in virtual environments (after [30.60] with permission)

Fig. 30.10, or it might be a separate transducer. Kuchenbecker et al. [30.60] considered the dynamics of the haptic device to display the most accurate vibration waveforms possible, and compared a number of different vibration waveform generation techniques meant to convey impact superimposed on force feedback in virtual environments. Most of the vibration feedback methods performed similarly in terms of realism, and they were also significantly more realistic than conventional force feedback alone.

Vibration feedback can also be used to provide information about patterned textures, roughness, and other phenomena that have clear vibratory signals. This type of vibration feedback is often termed *vibrotactile* feedback. In teleoperated environments, Kontarinis and Howe [30.61] showed that damaged ball bearings could be identified through vibration feedback, and Dennerlein et al. [30.62] demonstrated that vibration feedback improved performance over no haptic feedback, for a telemanipulation task inspired by undersea field robotics. In these teleoperator systems, vibration-sensitive sensors such as accelerometers and piezoelectric sensors are used to pick up and, in most cases, directly provide the vibration signals as inputs to a vibrotactile actuator. In virtual environments, Okamura et al. [30.63] displayed vibrations modeled based on textures and puncture of a membrane. Similar to the event-based haptics above, the vibration waveforms were modeled based on earlier experiments and played open loop during interaction with the virtual environment.

Finally, vibration feedback has been used as a method of sensory substitution, to convey direction, attention, or other information, e.g., [30.64–66]. In this case, the strength and clarity of the signal, not realism, is the goal. Vibration frequencies near the peak human sensitivity are most effective, and there exist commercially available vibrotactile actuators (or *tactors*) suitable for such applications, e.g., Engineering Acoustic, Inc.'s C2 Tactor [30.67]. Elements within an array of tactors can be selectively turned on and off to evoke the sensory saltation phenomenon, in which a pattern of brief pulses on a series of tactors is perceived not as successive taps at different locations, but as a single tap that is traveling or hopping over the skin.

30.5.2 Contact Location, Slip, and Shear Display

In early work related to robotic dexterous manipulation, it was found that knowledge of the contact point

between a robot hand and a grasped object is essential for manipulation. Without this knowledge, the robot will easily drop the object due to rapid accumulation of grasp errors. While many robotics researchers and some companies have developed tactile array sensors capable of measuring contact location, pressure distribution, and local object geometry (Chap. 19), practical methods for display of this information to the human operator of a virtual or teleoperated environment have proven much more difficult. We begin our discussion of contact display by considering contact location, slip, and shear display, which have the common goal of displaying the motion of a single area of contact relative to the skin (almost invariably on a finger). Arrays of pins that rise and fall to create a pressure distribution on the skin have been the most popular method to date for displaying contact information, but we will address those designs in the following section on local shape, since their primary advantage is the display of spatially distributed information. Instead, we will focus here on tactile devices that are designed to specifically address the problem of contact location and motion.

As an example of contact location display, *Provancher et al.* [30.68] developed a system that renders the location of the contact centroid moving on the user's fingertip. The tactile element is a free-rolling cylinder that is normally suspended away from the fingertip, but comes into contact with the skin when the operator pushes on a virtual object. The motion of the cylinder over the skin is controlled by sheathed push-pull wires. This allows the actuators to be placed remotely, creating a lightweight, thimble-sized package that can be unobtrusively mounted on a kinesthetic haptic device. An experiment demonstrated that human operators performed similarly during real manipulation and virtual manipulation (using the tactile display) in an object curvature discrimination task. In addition, operators were able to use the device to distinguish between manipulations of rolling and anchored but rotating virtual objects.

Humans use slip and incipient slip widely during manipulation tasks [30.69]. To reproduce these sensations for experiments to characterize human slip sensation, researchers have created stand-alone one-degree-of-freedom slip displays [30.70–72]. *Webster et al.* [30.72] created a two-degree-of-freedom tactile slip display, which uses an actuated rotating ball positioned under the user's fingertip. The lightweight, modular tactile display can be attached to a multi-degree-of-freedom kinesthetic interface and used to display virtual environments with slip. Experimental results demonstrate that operators

complete a virtual manipulation task with lower applied forces using combined slip and force feedback in comparison with conventional force feedback alone. Skin stretch can also be integrated with a slip display to provide information about pre-slip conditions. For example, *Tsagarakis et al.* [30.73] developed a lightweight device that uses a V configuration of miniature motors to provide sensations of relative lateral motion (direction and velocity) onto the operator's fingertips. Generation of two-dimensional slip/stretch is achieved by coordinating the rotational speed and direction of the two motors.

A novel device that uses slip and friction to display compelling tactile sensations is the TPaD (tactile pattern display) [30.74]. Ultrasonic frequency, low amplitude vibrations of a flat plate create a film of air between the plate and a human finger touching the plate, thereby reducing friction. The 33 kHz vibration of the plate cannot be perceived by the human. The amount of friction reduction varies with vibration amplitude, allowing indirect control of shear forces on the finger during active exploration. Finger position and velocity feedback enables haptic rendering of spatial texture sensations.

30.5.3 Local Shape

Most tactile devices for local shape display consist of an array of individual pin elements that move normal to the surface. Often, a layer of elastic material is used to cover the pins so that the operator contacts a smooth surface rather than the pins directly. Other systems use individual elements that move laterally, and some substitute electrodes for moving parts to form an array of electrocutaneous elements. A number of researchers have used psychophysical and perceptual experimental results to define design parameters such as number of pins, spacing, and amplitude of pin-based tactile displays. A commonly used metric is the two-point discrimination test, which defines the minimum distance between two contact points on the skin at which they are perceived as two, rather than one point. This discrimination limit varies widely for skin on different parts of the body, with the fingertips having one of the smallest (usually cited as less than 1 mm, although this depends on the shape and size of the contacts) [30.75, 76]. *Moy et al.* [30.77] quantified several perceptual capabilities of the human tactile system based on predicted subsurface strain and psychophysical experiments that measured amplitude resolution, the effects of shear stress, and the effects of viscoelasticity (creep and relaxation) on tactile perception for static touch. They found that 10%

amplitude resolution is sufficient for a teletaction system with a 2 mm elastic layer and 2 mm tacter spacing. A different type of experiment examines the kind of tactile information relevant to a particular application. For example, *Peine* and *Howe* [30.78] found that sensed deformation of the fingerpad, and not changes in pressure distribution, were responsible for localizing lumps in a soft material, such as a tumor in tissue.

We will now highlight a few distinctive designs of array-type tactile displays. A number of actuator technologies have been applied to create tactile arrays, including piezoelectric, shape-memory alloy (**SMA**), electromagnetic, pneumatic, electrorheological, micro-electromechanical system (**MEMS**), and electro-tactile. Further reading on tactile display design and actuation is available in review papers, including [30.80–85].

We will first consider two ends of the spectrum in complexity/cost of the pin-based approach. *Killebrew* et al. [30.86] developed a 400-pin, 1 cm^2 tactile stimulator to present arbitrary spatiotemporal stimuli to the skin for neuroscience experiments. Each pin is under independent computer control and can present over 1200 stimuli per minute. While not practical for most haptic

applications due to the size and weight of the actuation unit, it is the highest-resolution tactile display built to date and can be used to evaluate potential designs for lower-resolution displays. *Wagner* et al. [30.79] created a 36-pin, 1 cm^2 tactile shape display that uses commercially available radio-controlled (**RC**) servomotors. The display can represent maximum frequencies of 7.5–25 Hz, pending on the amount of pin deflection, and is shown in Fig. 30.11. *Howe* et al. [30.87, 88] have also explored the use of shape-memory alloys for pin actuation, for the application of remote palpation.

In contrast to pins that move normal to the surface, recent tactile array designs have incorporated pins that move laterally. First introduced by *Hayward* and *Cruz-Hernandez* [30.89], the most recent compact, lightweight, modular design [30.90] uses a 6×10 piezo bimorph actuator array with a spatial resolution of $1.8\text{ mm} \times 1.2\text{ mm}$. The force of the individual actuators provides sufficient skin pad motion/stretch to excite mechanoreceptors [30.91]. A pilot test demonstrated that subjects could detect a virtual line randomly located on an otherwise smooth virtual surface, and the device has also been tested as a Braille display [30.92]. Another lateral stretch display and its evaluation is described in [30.93]. Other novel approaches to tactile display include sending small currents through the skin or tongue using an electrocutaneous array [30.94] and the application of air pressure to stimulate only superficial mechanoreceptors [30.95].

30.5.4 Temperature

Because the human body is typically warmer than objects in the environment, thermal perceptions are based on a combination of thermal conductivity, thermal capacity, and temperature. This allows us to infer not only temperature difference, but also material composition [30.96]. Most thermal display devices are based on thermoelectric coolers, also known as Peltier heat pumps. Thermoelectric coolers consist of a series of semiconductor junctions connected electrically in series and thermally in parallel. The thermoelectric cooler is designed to pump heat from one ceramic faceplate to the other, but if used in reverse, a temperature gradient across the device produces a proportional potential; as a measure of relative temperature change. The designs of haptic thermal displays mostly use off-the-shelf components, and their applications are typically straightforward, enabling identification of objects in a virtual or teleoperated environment by their temperature and thermal conductivity.

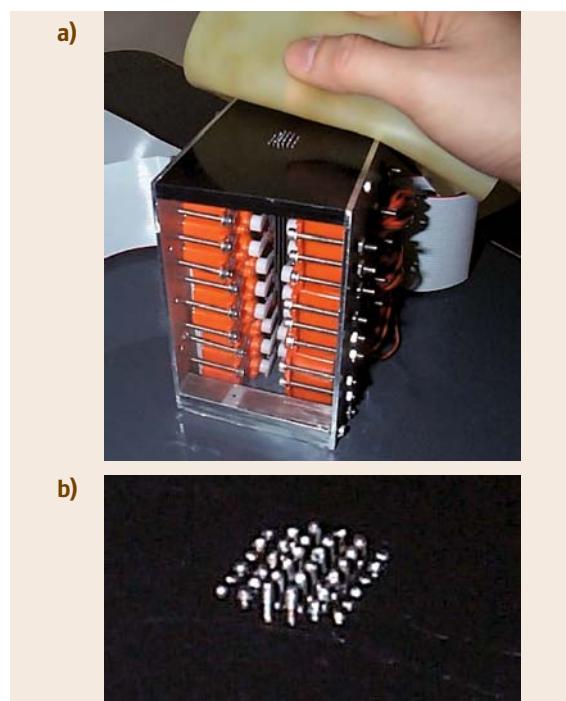

Fig. 30.11 (a) A low-cost 36-pin tactile display using **RC** servomotor actuation. (b) A closeup of the 6×6 display, showing a sine wave grating (after [30.79] with permission)

Ho and Jones [30.97] provide a review of haptic temperature display, as well as promising results suggesting that a thermal display is capable of facilitating object recognition when visual cues are limited. Although numerous systems have integrated thermal display with other types of haptic display, the Data Glove Input System designed by *Caldwell* et al. [30.98, 99] was one of the first to do so. Their haptic interface provides simultaneous force, tactile, and thermal feedback. The Peltier device used for thermal display contacts the dorsal surface of the index finger. Subjects achieved a 90%

success rate in identifying materials such as a cube of ice, a soldering iron, insulating foam, and a block of aluminum, based only on thermal cues. The study of human temperature perception is particularly interesting, including issues such as spatial summation and the psychological relevance of temperature display. For example, in prosthetic limbs, temperature display may be useful not only for practical reasons such as safety and material identification, but also for reasons of personal comfort, such as feeling the warmth of a loved one's hand.

30.6 Conclusions and Further Reading

Haptic technology, which attempts to provide compelling sensations to human operators in virtual and teleoperated environments, is a relatively new, but fast-growing and dynamic area of research. The field relies not only on fundamental foundations from robotics and control theory, but also on fields in the human sciences, particularly neuroscience and psychology. To date, commercial success of haptics has been in the areas of entertainment, medical simulation, and design, although novel devices and applications are regularly appearing.

There exist many books on the topic of haptic technology, most of them compendiums from workshops or conferences on the subject. One of the earliest books on haptics, by *Burdea* [30.100], provides a thorough review of applications and haptic devices up to 1996. A book specifically focused on haptic rendering, designed for potential use as a textbook, has been edited by *Ming Lin* and *Miguel Otaduy* [30.101]. In addition, we recommend the following useful articles: *Hayward* and *MacLean* [30.102, 103] describe the fundamentals of constructing experimental haptic devices of modest

complexity, the software components needed to drive them, and the interaction design concepts important to creating usable systems. *Hayward*, et al. [30.104] also provide a tutorial on haptic devices and interfaces. *Salisbury*, et al. [30.105] describe the basic principles of haptic rendering. *Hayward* [30.106] describes a number of tactile illusions that can inspire creative solutions for haptic interface design. *Robles-De-La-Torre* [30.107] underscores the importance of haptics with compelling examples of humans who have lost the sense of touch.

Finally, there exist two journals that are specific to the field of haptics: *Haptics-e* (www.haptics-e.org) and *IEEE Transactions on Haptics* (first issue expected 2008). Several conferences are specifically devoted to haptics: Eurohaptics and the Symposium on Haptic Interfaces for Virtual Environment and Teleoperator Systems are held separately in even years, and the on odd years become a single conference, World Haptics. The *IEEE* technical committee on haptics (www.worldhaptics.org) provides information about relevant publication forums.

31. Telerobotics

Telerobotics

Günter Niemeyer, Carsten Preusche, Gerd Hirzinger

In this chapter we present an overview of the field of telerobotics with a focus on control aspects. Motivated by an historical perspective and some challenging applications of this research area a classification of control architectures is given, including an introduction to the different strategies. An emphasis is taken on bilateral control and force feedback, which is a vital research field today. Finally we suggest some literature for a closer engagement with the topic of telerobotics.

31.1 Overview

Telerobotics is perhaps one of the earliest aspects of robotics. Literally meaning robotics at a distance, it is generally understood to refer to robotics with a human operator in control or human-in-the-loop. Any high-level, planning, or cognitive decisions are made by the human user, while the robot is responsible for their mechanical implementation. In essence, the *brain* is removed or distant from the *body*.

Herein the term *tele*, which is derived from the Greek and means distant, is generalized to imply a barrier between the user and the environment. This barrier is overcome by remote-controlling a robot at the environment, as indicated in Fig. 31.1. Besides distance, barriers may be imposed by hazardous environments or scaling to very large or small environments. All barriers have in common that the user cannot (or will not) physically reach the environment.

While the physical separation may be very small, with the human operator and the robot sometimes occupying the same room, telerobotic systems are often at

least conceptually split into two sites: the local site with the human operator and all elements necessary to support the system's connection with the user, which could be joysticks, monitors, keyboards, or other input/output devices, and the remote site, which contains the robot and supporting sensors and control elements.

To support this functionality, telerobotics integrates many areas of robotics. At the remote site, to operate the robot and execute the human's commands, the system may control the motion and/or forces of the robot. We refer to Chaps. 6 and 7 for detailed descriptions of these areas. Also, sensors are invaluable (Chap. 4), including force sensors (Chap. 19) and others (Part C). Meanwhile, at the local site information is often displayed haptically (Chap. 30).

A recent addition to telerobotics is the use of computer networks to transmit information between the two sites. This is the focus of Chap. 32 and opens up new possibilities in architectures. For example a single robot may be shared between multiple users or a single user may

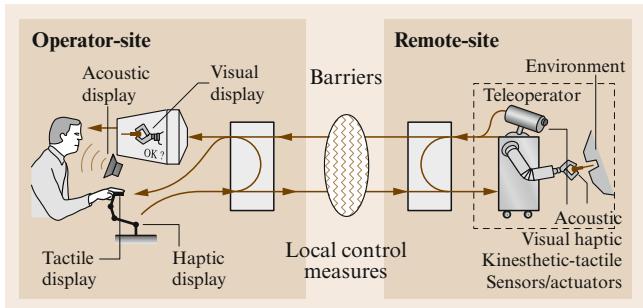

Fig. 31.1 Overview of a telerobotic system (from [31.1], adapted from [31.2])

control multiple robots. Web interfaces are simplifying this process, allowing access from anywhere on demand. In this chapter, we focus on point-to-point architectures with continual communications and operation.

We should also point out the relation between telerobotics and human exoskeletons, as described in Chap. 33. Exoskeletons are also controlled by a human operator, leaving all planning and high-level challenges to the user, and their control systems share many aspects with telerobotics. However, the two sites may be combined in an exoskeleton as the user directly touches and interacts with the robot. In this chapter, we will disallow any such connection.

The inclusion of the human operator makes telerobotics very attractive to handle unknown and unstructured environments. Applications are plentiful (Part F) and range from space robotics (Chap. 45) to dealing with hazardous environments (Chap. 48), from search and rescue situations (Chap. 50), to medical systems (Chap. 52) and rehabilitation (Chap. 53).

Before proceeding, we first define some basic terminology. Indeed many other terms are used nearly synonymously with telerobotics, in particular *teleoperation* and *telemansipulation*. Telerobotics is the most common, emphasizing a human's (remote) control of a robot. Teleoperation stresses the task-level operations, while telemansipulation highlights object-level manipulation.

Within telerobotics, a spectrum of control architectures has been used. *Direct control* or *manual control* falls at one extreme, indicating that the user is controlling the motion of the robot directly and without any automated help. At the other extreme, *supervisory control* implies that user's commands and feedback occur at a very high level and the robot requires substantial intelligence and/or autonomy. Between the two extrema

lie a variety of *shared control* architectures, where some degree of autonomy or automated help is available to assist the user.

In practice, many systems involve at least some level of direct control and include a joystick or similar device in the user interface, to accept the user's commands. As an instrumented mechanical device, this joystick can itself be viewed as a robot. The local and remote robots are called master and slave, respectively, while the system is referred to as a *master-slave system*. To provide direct control, the slave robot is programmed to follow the motions of the master robot, which is positioned by the user. It is not uncommon for the master robot (joystick) to be a kinematic replica of the slave, providing an intuitive interface.

Some master-slave systems provide force feedback, such that the master robot not only measures motions but also displays forces to the user. The user interface becomes fully bidirectional and such telerobotic systems are often called *bilateral*. The human–master interactions are a form of human–robot interaction (Chap. 57). The field of haptics (Chap. 30) also discusses bidirectional user interfaces, involving both motion and force, though more commonly to interface the user with virtual instead of remote environments. We should note that both motion and force may become the input or output to/from the user, depending on the system architecture.

Finally, *telepresence* is often discussed as an ultimate goal of master–slave systems and telerobotics in general. It promises to the user not only the ability to manipulate the remote environment, but also to perceive the environment as if encountered directly. The human operator is provided with enough feedback and sensations to feel present in the remote site. This combines the haptic modality with other modalities serving the human senses of vision, hearing or even smell and taste. We focus our descriptions on the haptic channel, which is created by the robotic hardware and its control systems. The master–slave system becomes the medium through which the user interacts with the remote environment and ideally they are fooled into forgetting about the medium itself. If this is achieved, we say that the master–slave system is transparent.

The chapter first examines telerobotic hardware and systems, before discussing various control architectures to operate these systems. A specific focus is placed on bilateral master–slave systems, which make the operator feel most connected to the remote environment and also present the largest stability and control problems.

31.2 Telerobotic Systems and Applications

Like mobile, industrial, and most areas of robotics, telerobotic systems are designed specifically with their tasks and requirements in mind. As such, many unique systems have evolved, of which we present an overview for different applications. We begin with a short historical perspective, then describe different applications with various robot designs and user interfaces.

31.2.1 Historical Perspective

Teleoperation enjoys a rich history and dates back to nuclear research by Raymond C. Goertz in the 1940s and 1950s. In particular, he created systems for humans to handle radioactive material from behind shielded walls. The first systems were electrical, controlled by an array of on-off switches to activate various motors and move various axes [31.3]. Without any feel, these manipulators were *slow and somewhat awkward to operate*, leading *Goertz* to build pairs of mechanically linked master-slave robots [31.3, 4]. Connected by gears, linkages, and cables these systems allowed the operator to use natural hand motions and transmitted forces and vibrations through the connecting structure, yet they limited the distance between the operator and environment and required the use of kinematically identical devices, see Fig. 31.2. *Goertz* quickly recognized the value of electrically coupled manipulators and laid the foundations of modern telerobotics and bilateral force-reflecting positional servos [31.5].

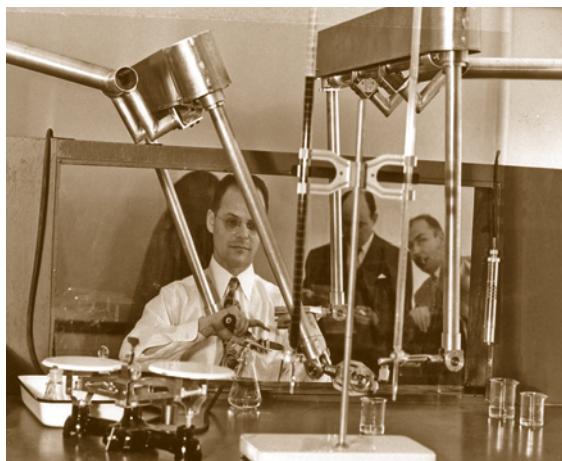

Fig. 31.2 Raymond C. Goertz used electrical and mechanical teleoperators in the early 1950s to handle radioactive material. (Courtesy Argonne National Labs)

At the beginning of the 1960s the effects of time delay on teleoperation started to become a topic of research [31.6, 7]. To cope with this problem the concept of supervisory control was introduced [31.2] and inspired the next years of development. In the late 1980s and early 1990s theoretical control came into play with Lyapunov-based analysis and network theory [31.8–13]. Using these new methods bilateral control of telerobotic systems became the vital research area it is today see Sect. 31.4. The growth of the Internet and its use as a communication medium fueled further this trend, adding the challenges of nondeterministic time delay.

On the hardware side, the Central Research Laboratory model M2 of 1982 was the first telerobotic system which realized force feedback while separating master and slave electronics. It was developed together with the Oak Ridge National Laboratory and was used for some time for a wide range of demonstration tasks including military, space or nuclear applications. The National Aeronautics and Space Administration (NASA) tested

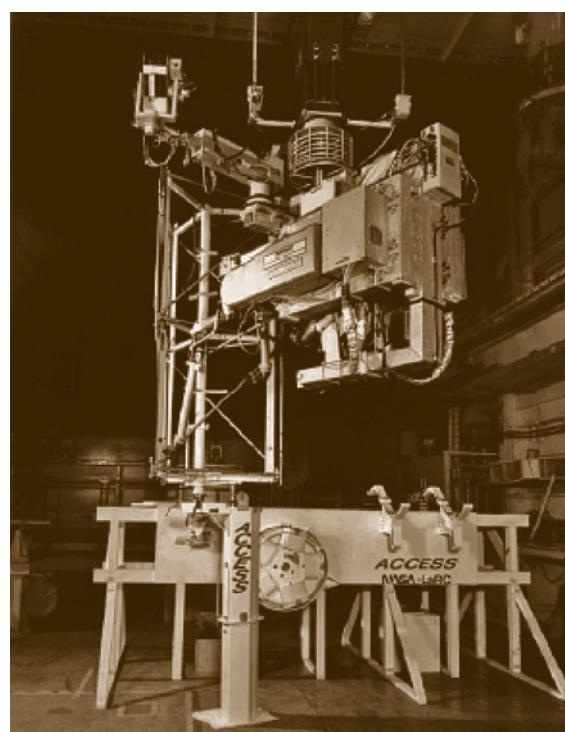

Fig. 31.3 The telerobotic system CRL Model M2 is used to verify the assembly of space truss structures (1982). (Courtesy of the Oak Ridge National Laboratory)

the M2 system to simulate the ACCESS space truss assembly with excellent results (Fig. 31.3). The advanced servomanipulator (ASM) was developed from the M2 to improve the remote maintainability of manipulators and intended as a foundation for telerobotic systems [31.14].

Also driven by the nuclear application, bilateral servomanipulators for teleoperation were developed in France in the Commission de Energie Atomique (CEA) by *Vertut* and his colleagues [31.15]. With the MA 23 they demonstrated telerobotic operation including computer-assisted functionalities to improve the operator's performance [31.16]. The assistance included software jigs and fixtures or virtual walls and restrictions [31.17], see also Sect. 31.3.2.

For space applications a dual-arm force reflecting telerobotic system was developed by *Bejczy* et al. at the Jet Propulsion Laboratory (JPL) [31.18]. In this approach for the first time kinematically and dynamically different master and slave systems were used, requiring control in Cartesian space coordinates. Figure 31.4 shows the master control station with its two back-drivable hand controllers. This system was used for simulating teleoperation in space.

In the 1980s and 1990s, as nuclear power activities began to decline, interest shifted to other areas such as space, medicine or undersea. Efforts were accelerated by the availability of increasing computer power as well as the introduction of novel hand controllers, e.g., the PHANTOM device [31.19], popularized by haptic applications in virtual reality (see Chap. 30).

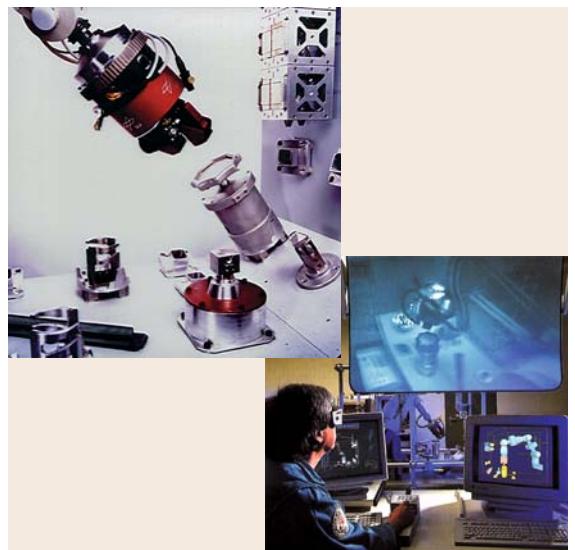

Fig. 31.5 ROTEX, the first remotely controlled robot in space (1993). Telerobot in space and ground operator station. (Courtesy of the German Aerospace Center, DLR)

In 1993 the first telerobotic system was flown in space with the German Spacelab Mission D2 on board the Space Shuttle Columbia. The robot technology experiment (ROTEX) demonstrated remote control of a space robot by means of local sensory feedback, predictive displays, and teleoperation [31.20]. In this experiment the round trip delay was 6–7 s, such that it was not feasible to include force feedback into the control loop.

With the first transatlantic telesurgery demonstration in 2001, Computer Motion demonstrated the feasibility of telerobotic systems even in the delicate field of surgery [31.21]. A surgeon in New York (USA) used a ZEUS system to perform a laparoscopic cholecystectomy on a patient located in Strasbourg (France), as depicted in Fig. 31.6. The system did not include force feedback, so the surgeon had to rely on visual feedback only.

In this perspective we gave only reference to the systems, that are seen to be milestones within the history of telerobotics. Several different systems have been developed and added value to the research field, which could not be mentioned here.

31.2.2 Applications

Telerobotic systems have been motivated by issues of human safety in hazardous environments (e.g., nuclear

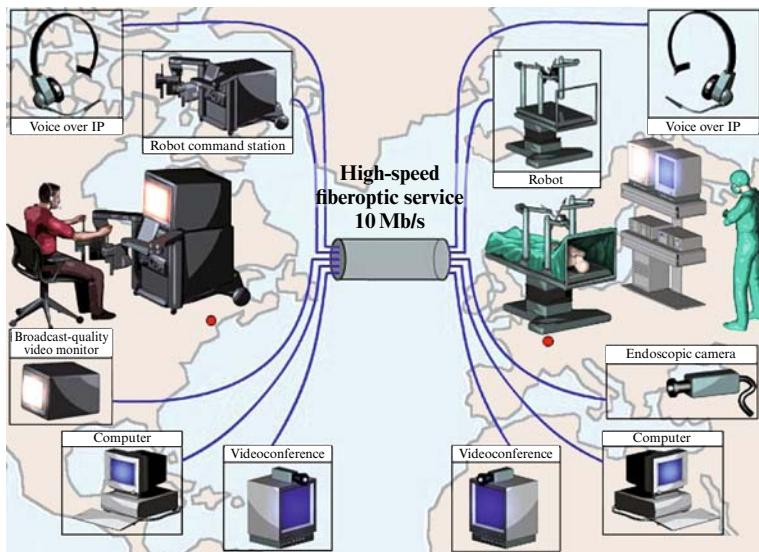

Fig. 31.6 Operation Lindberg. The first transcontinental telerobotic surgery (2001). (Courtesy M. Ghodoussi)

or chemical plants), the high cost of reaching remote environments (e.g., space), scale (e.g., power amplification or position scaling in micromanipulation or minimally invasive surgery), and many others. Not surprisingly, after their beginning in nuclear research, telerobotic systems have evolved to many fields of application. Nearly everywhere a robot is used, telerobotic systems can be found. The following are some of the more exciting uses.

In minimally invasive surgery telerobots allow procedures to be performed through small incisions, reducing the trauma to the patient compared to traditional surgery [31.22]. The da Vinci system, made by Intuitive Surgical Inc. [31.23] and shown in Fig. 31.7, is the only commercially available device at present. Other efforts,

however, include Computer Motion [31.24] and endoVia Medical [31.25] on the commercial side, as well as the University of Washington [31.26], Johns Hopkins University [31.27], the German Aerospace Center [31.28], and many others.

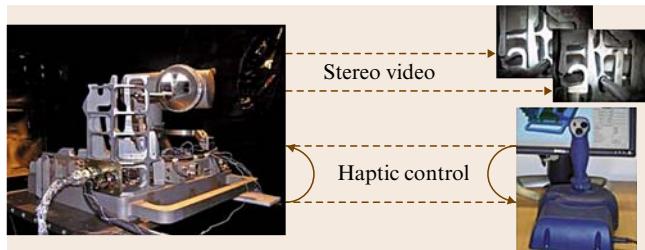

Fig. 31.9 ROKVISS, a telerobotic system providing stereo vision and haptic feedback to the ground operator. (Courtesy of the German Aerospace Center, DLR)

Protecting the operator from having to reach into a hazardous environment, telerobotic systems are widely used in nuclear or chemical industry. Some systems have been developed for the maintenance of high-voltage electrical power lines, which can be safely repaired without service interruption by a human operator using a telerobotic system. Disarming of explosives is another important task. Many systems like the telerob explosive ordnance disposal and observation robot (**tEOdor**) shown in Fig. 31.8 or PackBot, made by iRobot [31.29], are used by police and military to disarm mines and other explosives. Similar vehicles are remote controlled for search and rescue in disaster zones [31.30].

Space robotics is a classic application, in which distance is the dominating barrier, as discussed in Chap. 45. The **NASA** rovers on Mars are a famous example. Due to the time delay of several minutes, the rovers are commanded using supervisory control, in which the human operator is defining the goal of a movement and the rover achieves the goal by local autonomy using sensory feedback directly [31.31].

In orbital robotics the German technology experiment **ROKVISS** (robot component verification on ISS) is the most advanced telerobotic system [31.32]. Launched in 2004, it is installed outside the Russian module of the international space station. In this experiment advanced robot components of a slave system, including torque sensors and stereo video cameras, are validated in real space conditions. Due to a direct communication link between the space station and the operator station at **DLR** (German Aerospace Center), the time delay was reduced to about 20 ms allowing a bilateral control architecture with high-fidelity force feedback to the operator [31.33] (Fig. 31.9). This technology is leading toward robotic service satellites, called **Robonauts**, which can be remotely controlled from the ground to help real astronauts during extravehicular activity (**EVA**) or to perform repair and maintenance tasks [31.34].

31.3 Control Architectures

Compared to plain robotic systems, in which a robot executes a motion or other program without further consultation of a user or operator, telerobotic systems provide information to and require commands from the user. Their control architectures can be described by the style and level of this connection, as shown in Fig. 31.10. Organized in a spectrum, the three main categories are

- direct control
- shared control
- supervisory control

In practice, however, control architectures often include parts of all strategies.

Direct control implies no intelligence or autonomy in the system, so that all slave motion is directly controlled by the user via the master interface. If task execution is shared between direct control and local sensory feedback and autonomy, or if user feedback is augmented from virtual reality or other automatic aids, the architec-

ture is denoted as shared control. In supervisory control the user and slave are connected loosely with strong local autonomy, i.e., the operator is giving high-level commands, which are refined and executed by the tele-robot. The following explains the architectures in reverse order, followed by a detailed treatment of direct and bilateral control in Sect. 31.3.3, which introduces the basic ideas for Sect. 31.4.

31.3.1 Supervisory Control

Supervisory control, introduced by *Ferrell* and *Sheridan* in 1967 [31.2], is derived from the analog of supervising a human subordinate staff member. The supervisor gives high-level directives to and receives summary information from, in this case, the robot. *Sheridan* describes this approach in comparison with manual and automatic robot control [31.35]: “Human operators are intermittently programming and continually receiving information from a computer that itself closes an au-

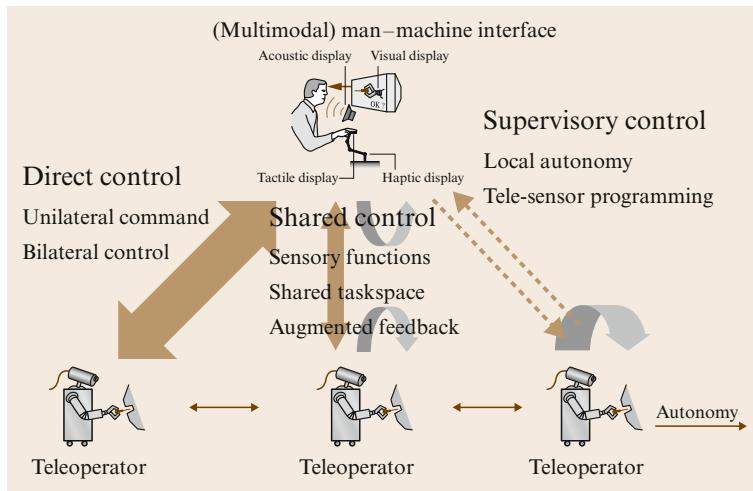

Fig. 31.10 Different concepts for telerobotic control architectures

tonomous control loop through artificial effectors and sensors.”

Today the autonomous control loops may be closed on the remote site, with only the state and model information being transmitted to the operator site. The operator supervises the telerobotic system and decides how to act and what to do. A special implementation of supervisory control is the telesensor programming approach, which is presented hereafter.

Telesensor Programming

The telesensor programming (**TSP**) approach is a shared autonomy concept that distributes intelligence between man and machine [31.36]. Presuming that sufficient information about the actual environment is available from the sensor systems, partial tasks can be executed independently on the machine level. Specifications and decisions on a high task planning level have to be done by human operators. Local sensory feedback loops are used by the robot system, while global task-level jobs have to be specified interactively by a human operator. This shared autonomy approach is the basis of the **TSP** paradigm, with which the robot can be teleprogrammed on a task directed level. The teaching of a robot system occurs not on the joint or cartesian manipulator level but on a higher language level, i. e., the operator plans activities at a level which can be performed by the robotic system independent of human intervention.

Figure 31.11 shows the structure of a **TSP** implementation, consisting of two control loops working in parallel. One loop controls the real (remote) system, which contains internal feedback for local autonomy. The other loop establishes a simulation environment

which is structurally equivalent to the real system, with a few exceptions.

Most importantly, any signal delay which may result from communication to the remote system, e.g., in space applications, is not duplicated in the simulation. This makes the simulation predictive with respect to the real system. A second exception is the display of internal variables in the simulation, which cannot be observed (measured) in the real system. This gives the operator or task planner more insight into what is happening or may happen in the system in response to commands. Communication between the two loops occurs via a common model data base which delivers a priori knowledge for execution on the remote system and a posteriori knowledge for model updating in the simulated world. For such a telerobotic control system unique tools are necessary to implement the required functionality. First a sophisticated simulation system has to be provided to emulate the real robot system. This includes the simulation of sensory perception within the real environment. Beyond this sensor simulation, the shared autonomy concept has to provide an efficient operator interface to setup task descriptions, to configure the task control parameters, to decide what kind of sensors and control algorithms should be used, and to debug an entire job execution phase.

In the field of telerobotics with large time delays, e.g., in space and undersea applications, this sensor-based task-directed programming approach [31.36] has advantages. Under direct visual feedback with a time delay of a few seconds, is not feasible for the human operator to handle the robot’s movements in a suitable way.

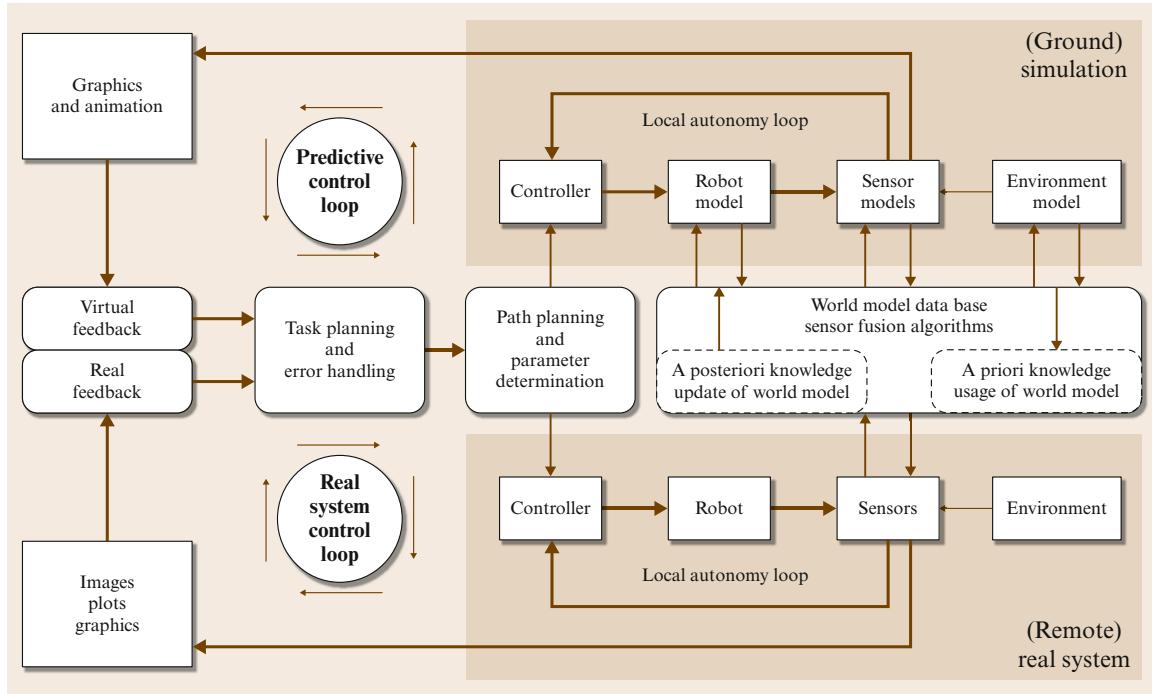

Fig. 31.11 The concept of telesensor programming as demonstrated during the ROTEX mission

Predictive simulation allows the operator to telemanipulate the remote system [31.37]. In addition, the use of force reflecting hand controllers to feed back force signals in shared and teleoperated control modes [31.38] or from the simulated predicted world can improve the operator's performance. Finally, an interactive supervisory user interface makes it possible to configure the environmental and control parameters.

The main feature of this telerobotic concept is to replace the time-delayed visual feedback with predictive stereo graphics including sensor simulation, providing a supervisory control technique that will allow a shift of more and more autonomy and intelligence to the robot system.

31.3.2 Shared Control

To enable telepresence in long-distance or risky applications (e.g., space or surgery) a sufficient *shared control* concept [31.39, 40] for the control of the teleoperator can be preferable to guarantee the safety of the teleoperator and/or task. Herein, shared control is based on local sensory feedback loops [31.41] at the teleoperator site (Fig. 31.11), by which gross commands were refined autonomously providing the teleoperator with a modest kind of sensory intelligence. The human operator originates gross path commands e.g. by using a kinesthetic feedback device, which are *fine-tuned* by the teleoperator.

In applications with large time delays the *shared autonomy* concept distributes intelligence between the operator and the teleoperator in the sense of a task-directed approach [31.42]. Control of the task is

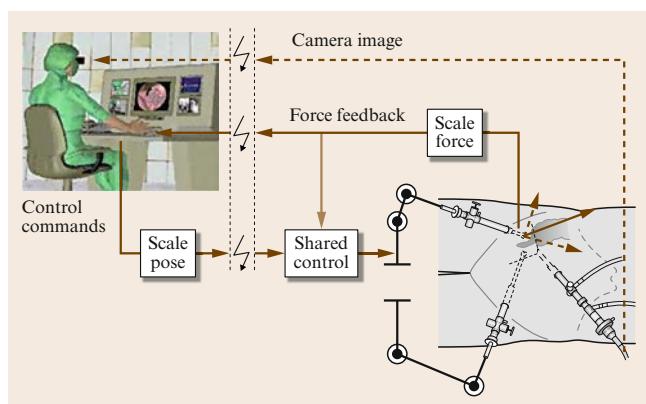

Fig. 31.12 An example for the shared control concept in telerobotic surgery

distributed between the human operator and the (autonomous) telerobot, such that each controls a subtask. An example can be seen in Fig. 31.12, where the autonomous part of the system controls and compensates the patient's movement, while the surgeon controls the operation itself on a virtual stabilized platform [31.43].

A special application of shared control is the use of *virtual fixtures* [31.44]. Virtual elements, such as virtual surfaces, guide tubes, or other appropriate objects, are superimposed into the visual and/or haptic scene for the user. These fixtures help the operator perform telerobotic or robot-assisted manipulation tasks by limiting movement into restricted regions and/or influencing movement along desired paths. Control is thus shared at the master site, taking advantage of preknowledge of the system or task to modify the user's commands and/or to combine them with autonomously generated signals.

Capitalizing on the accuracy of robotic systems, while sharing control with the operator, telerobotic systems with virtual fixtures can achieve safer and faster operation [31.45]. Abbott et al. describe the benefits by comparison to the common physical fixture of a ruler: "A straight line drawn by a human with the help of a ruler is drawn faster and straighter than a line drawn freehand. Similarly, a [master] robot can apply forces or positions to a human operator to help him or her draw a straight line." Based on the nature of the master robot and its controller, the virtual fixtures may indeed appear as impedance or admittance objects, i. e., providing corrective forces or positions to the user, respectively. In both cases, however, and in contrast to physical fixtures, the level and type of assistance can be programmed and varied.

31.3.3 Direct and Bilateral Teleoperation

To avoid difficulties in creating local autonomy, most telerobotic systems include some form of direct control: they allow the operator to specify the robot's motions. In the following we assume a master-slave system, i. e., the user is holding a joystick or master mechanism serving as an input device. We first describe unilateral operation, before focusing on bilateral control where the master also serves a display device.

Unilateral Acceleration or Rate Control

For underwater, airborne, or space applications, a slave robot may be a vehicle actuated by thrusters. Direct control thus requires the user to power the thrusters, which

in turn accelerate the vehicle. For other applications, the user may be required to command the rate or velocity of the vehicle or slave robot. In both scenarios, the input device is commonly a joystick, often spring centered, where the commands are proportional to the joystick displacement. For six-degree-of-freedom (DOF) applications, i. e., when the slave needs to be controlled in translation and orientation, a 6D-Space Mouse or alternatively often two joysticks are used for translation and orientation respectively.

Acceleration and rate control can require considerable effort for the operator to reach and hold a given target location. As expected, users can more accurately position a system under rate control than under acceleration control [31.46]. Indeed acceleration control necessitates users to regulate a second-order system versus a first-order system for rate control. Assuming the slave has local position feedback available, a control system is often incorporated locally, such that the user may specify position commands and is relieved from the dynamic control problem.

Position Control and Kinematic Coupling

Assuming that the slave is under position control, we next consider the kinematic coupling between master and slave, i. e., the mapping between master and slave positions. In particular, we must remember that the master mechanism moves in the master workspace, while the slave robot moves in the slave workspace. These two spaces are nearly always somewhat different.

Clutching and Offsets. Before even discussing how the two robots are coupled, we must understand that they are not always coupled, for example, before the system is turned on, master and slave robots may, for whatever reason, be placed in some initial position/configuration. We have three options of how to engage the system: (1) first autonomously move one or both robots so they come to the same position, (2) wait until someone (the user) externally moves one robot to match the location of the other, or (3) connect the two robots with some offset.

Once connected, most systems also allow a temporary disconnection between the two sites. The reason is twofold: to allow the user to rest without affecting the slave state and to allow a shift between the two robots. The latter is most important if the workspaces of both robots do not perfectly overlap. This is much like picking up your mouse off your mouse pad to reposition without moving the cursor.

In telerobotics the process is called *clutching* or sometimes also indexing. If clutching is allowed, or both robots are not constrained to start at the same location, the system must allow for offsets between the two robots.

Kinematically Similar Mechanisms. The simplest scenario involves a master and slave mechanism that are kinematically equivalent if not entirely identical. In this case, the two robots can be connected at a joint level. With \mathbf{q} denoting joint values and subscripts ‘m’ referring to the master, ‘s’ to the slave, ‘offset’ to a shared offset, and ‘d’ to a desired value, we can write

$$\begin{aligned}\mathbf{q}_{sd} &= \mathbf{q}_m + \mathbf{q}_{\text{offset}}, \\ \mathbf{q}_{md} &= \mathbf{q}_s - \mathbf{q}_{\text{offset}}.\end{aligned}\quad (31.1)$$

At the instance the two robots are to be connected or reconnected, the offset is computed as

$$\mathbf{q}_{\text{offset}} = \mathbf{q}_s - \mathbf{q}_m. \quad (31.2)$$

Most kinematically similar master–slave systems have the same workspace at both sites and do not allow clutching. By construction the offset is then always zero.

Depending on the controller architecture, the joint velocities may be similarly related, taking derivatives of (31.1). An offset in velocities is not necessary.

Kinematically Dissimilar Mechanisms. In many cases, the master and slave robots differ. Consider that the master is connected to the human user and thus should be designed accordingly. Meanwhile the slave works in some environment and may have a very different joint configuration and different number of joints. As a result, connecting the robots joint by joint may not be feasible or appropriate.

Instead kinematically dissimilar robots are connected at their tips. If \mathbf{x} is a robot’s tip position, we have

$$\begin{aligned}\mathbf{x}_{sd} &= \mathbf{x}_m + \mathbf{x}_{\text{offset}}, \\ \mathbf{x}_{md} &= \mathbf{x}_s - \mathbf{x}_{\text{offset}}.\end{aligned}\quad (31.3)$$

If orientations are also connected, with \mathbf{R} describing a rotation matrix, we have

$$\begin{aligned}\mathbf{R}_{sd} &= \mathbf{R}_m \mathbf{R}_{\text{offset}}, \\ \mathbf{R}_{md} &= \mathbf{R}_s \mathbf{R}_{\text{offset}}^{\top},\end{aligned}\quad (31.4)$$

where the orientational offset is defined as slave relative to master

$$\mathbf{R}_{\text{offset}} = \mathbf{R}_m^{\top} \mathbf{R}_s. \quad (31.5)$$

Again velocities and angular velocities may be connected if needed and do not require offsets.

Finally note that most telerobotic systems use a video camera at the remote site and a monitor at the local site. To make the connection appear natural, the slave position and orientation should be measured relative to the camera, while the master position and orientation should be measured relative to the user’s view.

Scaling and Workspace Mapping. Kinematically dissimilar master–slave robots are commonly also of different size. This means not only do they require clutching to fully map one workspace to another, but they often necessitate motion scaling. And so (31.3) becomes

$$\begin{aligned}\mathbf{x}_{sd} &= \mu \mathbf{x}_m + \mathbf{x}_{\text{offset}}, \\ \mathbf{x}_{md} &= \frac{(\mathbf{x}_s - \mathbf{x}_{\text{offset}})}{\mu}.\end{aligned}\quad (31.6)$$

The orientation, however, should not be scaled. The scale μ may be set to either map the two workspaces as best possible, or to provide the most comfort to the user.

If force feedback, introduced below, is provided, an equivalent force scale may be desired. This will prevent distortion of the remote environmental conditions, such as stiffness or damping, by the scaling.

Beyond linear scaling, several research efforts have created nonlinear or time-varying mappings, which deform the workspaces. These may effectively change the scale in the proximity of objects [31.47] or drift the offset to best utilize the master workspace [31.48].

Local Position Control. By construction we are now assuming that the slave follows a position command. This necessitates a local slave controller to regulate its position. In particular for kinematically dissimilar mechanisms, this will be a Cartesian tip position controller with appropriate inverse kinematics. For details we refer to Chap. 6.

If the slave robot has redundancies, these may be controlled either automatically to optimize some criterion or manually with additional user commands. We refer here to Chap. 11 for appropriate techniques.

31.4 Bilateral Control and Force Feedback

In pursuit of telepresence and to increase task performance, many master–slave systems incorporate force feedback. That is, the slave robot doubles as a sensor and the master functions as a display device, so that the system provides both forward and feedback pathways from the user to the environment and back. Figure 31.13 depicts the common architecture viewed as a chain of elements from the user to the environment.

The bilateral nature of this setup makes the control architecture particularly challenging: multiple feedback loops form and even without environment contact or user intervention, the two robots form an internal closed loop. The communications between the two sites often inserts delays into the system and this loop, so that stability of the system can be a challenging issue [31.49].

To present force information without stability problems, it is possible to use alternate displays, such as audio or tactile devices [31.50]. Meanwhile, the combination of vibrotactile methods with explicit force feedback can increase high-frequency sensations and provide benefits to the user [31.51]. Tactile shape sensing and display also extends the force information presented to the user [31.52].

In the following we discuss explicit force feedback. We first examine the basic architectures before discussing stability and some advanced techniques.

31.4.1 Position/Force Control

Two basic architectures couple the master and slave robots: position–position and position–force. We assume that the robot tips are to be connected by the equations of Sect. 31.3.3, giving the control laws for translation. Control of orientation or joint motions follows equivalent patterns.

Position–Position Architecture

In the simplest case, both robots are instructed to track each other. Both sites implement a tracking controller, often a proportional-derivative (PD) controller, to fulfill

these commands:

$$\begin{aligned} F_m &= -K_m(x_m - x_{md}) - B_m(\dot{x}_m - \dot{x}_{md}), \\ F_s &= -K_s(x_s - x_{sd}) - B_s(\dot{x}_s - \dot{x}_{sd}). \end{aligned} \quad (31.7)$$

If the position and velocity gains are the same ($K_m = K_s = K$, $B_m = B_s = B$), then the two forces are the same and the system effectively provides force feedback. This may also be interpreted as a spring and damper between the tips of each robot, as illustrated in Fig. 31.14. If the two robots are substantially different and require different position and velocity gains, the master–slave forces will be scaled and/or distorted.

Note we have assumed the slave is under impedance control and back-drivable. If the slave is admittance controlled, i. e., it accepts position commands directly, the second part of (31.7) is unnecessary.

Also note that by construction the user feels the slave’s controller forces, which include forces associated with the spring–damper and slave inertia in addition to environment forces. Indeed while moving without contact, the user will feel the inertial and other dynamic forces needed to move the slave. Furthermore, if the slave is not back-drivable, i. e., does not easily move under environment forces, the environment force may be entirely hidden from the user. Naturally this defeats the purpose of force feedback. In these cases, a local force control system may be used to render the slave back-drivable. Alternatively, a position–force architecture may be selected.

Position–Force Architecture

In the position–position architecture, the user is presented with the slave’s controller force. While this is very stable, it also means the user feels the friction and inertia in the slave robot, which the controller is actively driving to overcome. In many scenarios this is undesirable. To avoid the issue, position–force architectures place a force sensor at the tip of the slave robot and feedback the force from there. That is, the system is

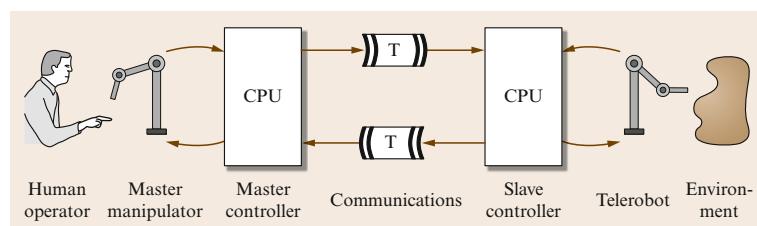

Fig. 31.13 A typical bilateral teleoperator can be viewed as a chain of elements reaching from user to environment

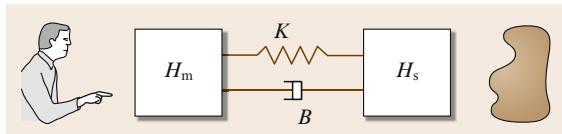

Fig. 31.14 A position–position architecture effectively creates a spring and damper between the two robots

controlled by

$$\begin{aligned} F_m &= F_{\text{sensor}}, \\ F_s &= -K_s(x_s - x_{sd}) - B_s(\dot{x}_s - \dot{x}_{sd}). \end{aligned} \quad (31.8)$$

This allows the user to only feel the external forces acting between the slave and the environment and presents a more clear sense of the environment. However, this architecture is less stable: the control loop passes from master motion to slave motion to environment forces back to master forces. There may be some lag in the slave's motion tracking not to mention any delay in communications. Meanwhile the loop gain can be very high: a small motion command can turn into a large force if the slave is pressing against a stiff environment. In combination, stability may be compromised in stiff contact and many systems exhibit contact instability in these cases.

31.4.2 Passivity and Stability

The two basic architectures presented in Sect. 31.4.1 clearly illustrate one of the basic tradeoffs and challenges in force feedback: stability and performance. Stability issues arise because any models of the system depend on the environment as well as the user. Both these elements are difficult to capture and, if we assume we want to explore unknown environments, impossible to predict. This issue makes a stability analysis very difficult. A common tool that avoids some of this issue is the concept of passivity. Although passivity provides only a sufficient (not a necessary) condition for stability, it incorporates the environmental uncertainty very well.

Passivity is an intuitive tool that examines the energy flows in a system and makes stability assertions if energy

is dissipated instead of generated. Three rules are of importance here. First, a system is passive if and only if it can not produce energy. That is the output energy from the system is limited by the initial and accumulated energy in the system. Second, two passive systems can be combined to form a new passive system. Third, the feedback connection of two passive systems is stable.

In the case of telerobotics, we generally assume that the slave robot will only interact with passive environments, that is, that the environments do not contain active motors or the like. Without the human operator, stability can therefore be assured if the system is also passive, without needing an explicit environment model.

On the master side the operator closes a loop and has to be considered in the stability analysis. In general, the master robot will be held by the user's hand and arm. A variety of models and parameters describe the human arm dynamics, mainly in the form of a mass–damper–spring system. In [31.53] we find a summary of model parameters used by different authors. For an impedance-controlled haptic interface, common to most systems, the worst-case scenario for stability is the situation when the operator is not holding the haptic device [31.54, 55]. Thus we may elect to ignore the human operator in the analysis, assuming the human force equals zero ($F_{\text{human}} = 0$). A system then found to be stable will also be stable if the operator is interacting with the device.

To apply passivity, we take the system originally depicted in Fig. 31.13 and describe it as two-port elements in Fig. 31.15. We choose a sign convention, such that the power at every boundary is positive if flowing to the right. For example, at the first boundary, the positive power flow is the product of master velocity times applied (human) force

$$P_{\text{left}} = \dot{x}_m^\top F_{\text{human}}. \quad (31.9)$$

Meanwhile at the last boundary, the positive power flow is the product of the slave velocity times the environment force (which ultimately opposes the human force)

$$P_{\text{right}} = \dot{x}_s^\top F_{\text{env}}. \quad (31.10)$$

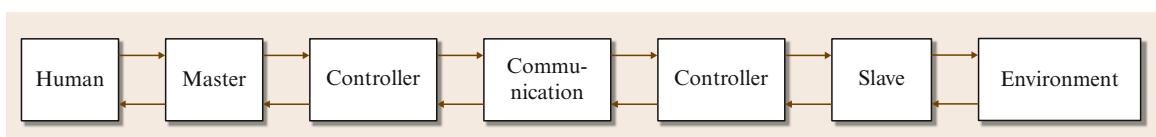

Fig. 31.15 A teleoperator can be analyzed as a chain of two-port elements connecting the one-port operator to the one-port environment

Therefore the entire telerobotic system is passive if

$$\begin{aligned} \int_0^t P_{\text{input}} dt &= \int_0^t (P_{\text{left}} - P_{\text{right}}) dt \\ &= \int_0^t (\dot{x}_m^\top F_{\text{human}} - \dot{x}_s^\top F_{\text{env}}) dt \\ &> -E_{\text{store}}(0). \end{aligned} \quad (31.11)$$

To simplify the analysis, we can examine the passivity of each two-port element and then deduce the overall passivity. The master and slave robots are mechanical elements and hence passive. The controllers of a position–position architecture mimic a spring and damper, which are also passive elements. So without delay, a position–position architecture is passive.

While powerful to handle uncertainty, passivity can be overly conservative. Many controllers are over-damped if every subsystem is passive. In contrast, the combination of an active and a passive subsystem may be passive and stable and show less dissipation. This is particularly true for the cascaded arrangement of two-port elements in the telerobotic system of Fig. 31.15. From network theory, the Llewellyn criterion specifies when a possibly active two-port connected with any passive one-port becomes passive. This two-port is then labeled unconditionally stable, as it will be stable in connection to any two passive one-ports. The Llewellyn criterion may hence be used as a more general stability test for telerobotic systems or components [31.56].

Passive controllers are also limited as they cannot hide the dynamics of the slave robot. In the above position–position architecture, the user will feel the forces associated with the slave inertia. In contrast the position–force architecture hides the slave inertia and friction from the user. As such, when the user inserts kinetic energy into the master without feeling any resistance, the system itself creates and injects the kinetic energy for the slave. This violates passivity and provides another insight as to why the architecture suffers from potential stability problems.

31.4.3 Transparency and Multichannel Feedback

Both basic architectures can be captured by the general teleoperator control system described by Lawrence [31.13], and later expanded by Hashtrudi-Zaad and Salcudean [31.56] and shown in Fig. 31.16.

Knowing that ideally a teleoperator would have the master motion track the slave motion, as well as have the operator's force match the environment's force, both velocity (from which position may be integrated or vice versa) and force may be measured at both sites, for example, in this way the slave can start moving as soon as the user applies a force to the master, even before the master itself has moved.

Following these concepts derived in [31.13], we can examine the relationships between velocity and force, in the form of impedances and admittances. Note we do this in a single degree of freedom, assuming that all degrees of freedom may be treated independently. The environment will exhibit some impedance $Z_e(s)$ that is not known in advance and relates the environment force to the slave's velocity

$$F_e(s) = Z_e(s)v_s(s). \quad (31.12)$$

If we describe the teleoperator in whole as a two-port with a hybrid matrix formulation

$$\begin{pmatrix} F_h(s) \\ v_m(s) \end{pmatrix} = \begin{pmatrix} H_{11}(s) & H_{12}(s) \\ H_{21}(s) & H_{22}(s) \end{pmatrix} \begin{pmatrix} v_s(s) \\ -F_e(s) \end{pmatrix} \quad (31.13)$$

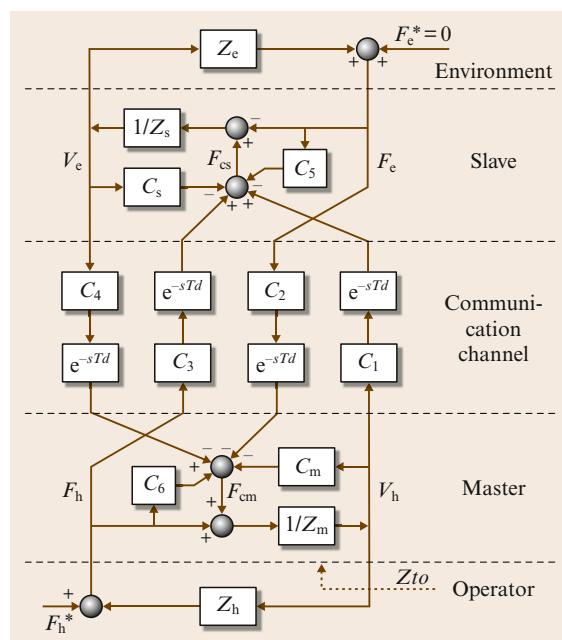

Fig. 31.16 In general, a controller will use both position and force information from both master and slave robot (after [31.56], adapted from [31.13])

then the user will perceive the impedance

$$Z_{\text{to}}(s) = \frac{\mathbf{F}_h(s)}{\mathbf{v}_m(s)} = (H_{11} - H_{12}Z_e)(H_{21} - H_{22}Z_e)^{-1}. \quad (31.14)$$

Transparency describes how close the user's perceived impedance comes to recreating the true environment impedance.

For a detailed treatment of passivity in telerobotics, impedance and admittance interpretations and designs, and transparency, we refer to some of the seminal works in [31.11–13, 56–59].

31.4.4 Time Delay and Scattering Theory

When delays occur in the communications between the local and remote site, even position–position architectures can suffer from serious instabilities [31.60, 61]. This can be traced to the communications block in Fig. 31.15, where the power entering the left side and exiting the right side do not add up. Rather energy may be generated inside the block, which feeds the instability [31.9].

Several approaches to operate under delay have been studied [31.62], in particular shared compliant control [31.63] and the addition of local force loops [31.64]. The use of the Internet for communication, adding variability to the delay, is also an area of interest [31.65, 66]. This further evokes issues of data reduction [31.67].

Here we note that natural wave phenomena are bilateral passive elements that tolerate delay. If the control system is described in the frequency domain and scattering matrices are used in place of impedance and admittance matrices, the system can tolerate delays [31.68]. Scattering matrices relate the sum of velocity and force to their difference, so that passivity becomes a condition on the system gain, which is unaffected by the delay. Alternatively, passivity may be explicitly observed and enforced to ensure stability [31.69–71].

31.4.5 Wave Variables

Building on the realization that delay communications can be active and that wave phenomena circumvent the

issue, wave variables provide an encoding scheme that is tolerant of delay [31.72]. Consider the power flowing through the system and separate the power moving forward and returning.

$$P = \dot{\mathbf{x}}^T \mathbf{F} = \frac{1}{2} \mathbf{u}^T \mathbf{u} - \frac{1}{2} \mathbf{v}^T \mathbf{v} = P_{\text{forward}} - P_{\text{return}}, \quad (31.15)$$

where the forward and returning power by construction have to be nonnegative. This leads to the definition of the wave variables

$$\begin{aligned} \mathbf{u} &= \frac{b\dot{\mathbf{x}} + \mathbf{F}}{\sqrt{2b}}, \\ \mathbf{v} &= \frac{b\dot{\mathbf{x}} - \mathbf{F}}{\sqrt{2b}}, \end{aligned} \quad (31.16)$$

where \mathbf{u} is the forward-moving and \mathbf{v} the returning wave.

If the normal signals are encoded into these wave variables, transmitted across the delay, and decomposed into regular variables, the system remains passive regardless of delay. In fact, in the wave domain, passivity corresponds to a wave gain of less than or equal to unity. No requirements are placed on phase and so lag does not destroy stability.

The wave impedance b relates velocity to force and provides a tuning knob to the operator. Large b values mean the system increases force feedback levels at the cost of feeling high inertial forces. Small values of b lower any unwanted sensations, making it easy to move quickly, but also lower the desirable environment forces. Ideally the operator would lower b when there is no risk of contact and raise b when contact is imminent.

Recent developments are incorporating both position–position and position–force architectures within the wave frame work, so the resulting system is stable with any environment, stable with any delay, yet maintains the feedback of high-frequency forces that help the operator identify happenings at the remote site [31.73]. To improve performance and assist the operator, predictors may also be incorporated [31.74].

31.5 Conclusions and Further Reading

Despite its age, telerobotics remains an exciting and vibrant area of robotics. In many ways, it forms a platform

which can utilize the advances in robotic technologies while simultaneously leveraging the proven skills and

capabilities of human users. Compare this, for example, with the development of the automobile and its relation to the driver. As cars are gradually becoming more sophisticated with added electronic stability control and navigation systems, they are becoming safer and more useful to their operators, not replacing them. Similarly telerobotics serves as a pathway for gradual progress and, as such, is perhaps best suited to fulfill robotics long-held promise of improving human life. It is seeing use in the challenging area of search and rescue. And with the recent developments and commercializations in telerobotic surgery systems, it is indeed impacting on the lives of tens of thousands of patients in a profound fashion and extending the reach of robotics into our world.

For further reading in the area of supervisory control, we refer to *Sheridan* [31.35]. Though published in 1992, it remains the most complete discussion on the topic. Unfortunately few other books are devoted to or even fully discuss telerobotics. In [31.75] many recent advances, including methods, experiments, applications, and developments, are collected. Beyond this, in the areas of bilateral and shared control, as well as to understand the various applications, we can only refer to the citations provided. Finally, in addition to the standard robotics journals, we note in particular *Presence: Teleoperators and Virtual Environments*, published by the MIT Press. Combined with virtual-reality applications, it focuses on technologies with a human operator.

Networked Telerobots

Dezhen Song, Ken Goldberg, Nak Young Chong

Telerobots, remotely controlled robots, are widely used to explore undersea terrains and outer space, to defuse bombs, and to clean up hazardous waste. Until 1994, telerobots were accessible only to trained and trusted experts through dedicated communication channels. This chapter describes networked telerobots, a new class of telerobots controllable over networks such as the Internet, that are accessible to the general public. This chapter will describe relevant network technology, the history of networked telerobots within the broader field of teleoperation, properties of networked telerobots, how to build a networked robot, example systems, and topics for future research.

32.1 Overview and Background

As illustrated in Fig. 32.1, the broader field of teleoperation, where the primary concerns are stability and time delay, is covered in Chap. 31. The field of networked robots, where autonomous robots and sensors communicate over local networks, is covered in Chap. 41. Networked telerobots, the subject of the present chapter, focuses on teleoperated robot systems that are accessible by the public via web browsers.

By 2006, several hundred networked telerobots have been developed and put online for public use. Many papers have been published describing these systems and a book on this subject by *Goldberg and Siegwart* is available [32.1]. Updated information about new research and an archive/survey of networked telerobots is available on the website of the IEEE technical committee on networked robots, which fosters research in both networked telerobots and networked robots (IEEE Technical Committee on Networked Robots <http://tab.ieee-ras.org/>).

Networked telerobots have the following properties

- The physical world is affected by a device that is locally controlled by a network *server*, which communicates with remote human users through web browsers such as Internet Explorer or Firefox, which are generally referred to as *clients*. As of 2006, the standard protocol for network browsers is the hypertext transfer protocol (HTTP), a stateless transmission protocol.
- Most networked telerobots are continuously accessible (online), 24 hours a day, 7 days a week.
- Since hundreds of millions of people now have access to the Internet, mechanisms are needed to handle client authentication and contention.
- Input and output for networked telerobots is usually achieved with the standard computer screen, mouse, and keyboard.
- Clients may be inexperienced or malicious, so online tutorials and safeguards are generally required.

32.2 A Brief History

Like many technologies, remotely controlled devices were first imagined in science fiction. In 1898, *Nicola Tesla* [32.2] demonstrated a radio-controlled boat in New York's Madison Square Garden. The first major experiments in teleoperation were motivated by the need to handle radioactive materials in the 1940s. *Gortz* demonstrated one of the first bilateral simulators in the 1950s at the Argonne National Laboratory [32.3]. Remotely operated mechanisms have been designed for use in inhospitable environments such as undersea [32.4] and space exploration [32.5]. At General Electric, *Mosher* [32.6] developed a two-arm teleoperator with video cameras. Prosthetic hands were also applied to teleoperation [32.7]. More recently, teleoperation has been considered for medical diagnosis [32.8], manufacturing [32.9], and micromanipulation [32.10]. See Chap. 31 and the book from *Sheridan* [32.11] for excellent reviews on teleoperation and telerobotics research.

The concept of hypertext (linked references) was proposed by Vannevar Bush in 1945 and was made possible by subsequent developments in computing and networking. In the early 1990s, Berners-Lee introduced the HTTP. A group of students led by Marc Andreessen developed an open-source version of the first graphical user interface, the *Mosaic* browser, and put it online in 1993. The first networked camera, or *webcam*, went online in November 1993 [32.12].

Approximately nine months later, the first networked telerobot went online. K. Goldberg and M. Mascha's Mercury Project combined an IBM industrial robot arm with a digital camera and used the robot's air nozzle to allow remote users to excavate for buried artifacts in a sandbox [32.13, 14]. Working independently, a team led by *K. Taylor* and *J. Trevelyan* at the University of Western Australia demonstrated a remotely controlled six-axis telerobot in September 1994 [32.15, 16]. These early projects pioneered a new field of networked telerobots. See [32.17–25] for other examples. An online archive of Networked Telerobots is at: <http://ford.ieor.berkeley.edu/ir/>.

Networked telerobots are a special case of *supervisory control* telerobots, as proposed by *Sheridan* and colleagues [32.11]. Under supervisory control, a local computer plays an active role in closing the feedback loop. Most networked robotics are type c supervisory control systems (see Fig. 32.2).

Although the majority of networked telerobotic systems consist of a single human operator and a single robot [32.26–33], *Chong* et al. [32.34] propose a useful taxonomy: single operator single robot (**SOSR**), single operator multiple robot (**SOMR**), multiple operator single robot (**MOSR**), and multiple operator multiple robot (**MOMR**).

The decade from 1995–2005 witnessed extensive development in networked telerobots. New systems, new experiments, and new applications now go well beyond the traditional fields such as defense, space, and nuclear material handling [32.11] that motivated teleoperation in early 1950s. As the Internet introduces universal access to every corner of life, the impact of networked robots becomes broader and deeper in modern society. Recent applications range from education, industry, commercial, health care, geology, and environmental monitoring, to entertainment and arts.

Networked telerobots provide a new medium for people to interact with a remote environment. A networked robot can provide more interactivity beyond that provided by a normal videoconferencing system. The physical robot not only represents the remote person but also transmits multimodal feedback to the person, which is often referred as *telepresence* in the literature [32.29]. *Paulos* and *Canny*'s personal roving presence (PProP) robot [32.35] and *Jouppi* and *Thomas*'s surrogate robot [32.29] are recent representative work.

Networked telerobots have great potential for education and training. In fact, one of the earliest networked telerobot systems [32.36] originated from the idea of a remote laboratory. Networked telerobots provide universal access to the general public, who may have little to no knowledge of robots, with opportunities to understand, learn, and operate robots, which were expensive scientific equipment limited to universities and large corporate laboratories before. Built on networked telerobots, online remote laboratories [32.37, 38] greatly improve distance learning by providing an interactive experience; for example, teleoperated telescopes help students to understand astronomy [32.39]. Teleoperated microscopes [32.40] help student to observe microorganisms. The Tele-Actor project [32.41] allows a group of students to remotely control a human tele-actor to visit environments that are normally not accessible to them such as cleanroom environments for a semiconductor manufactory facility and DNA analysis laboratories.

32.3 Communications and Networking

Below is a short review of relevant terminologies and technologies on networking. For details, see the texts by [32.42].

A communication network includes three elements: *links*, *routers/switchers*, and *hosts*. Links refer to the physical medium that carry bits from one place to another.

Examples of links include copper or fiber-optic cables and wireless (radio frequency or infrared) channels. Switches and routers are hubs that direct digital information between links. Hosts are communication end points such as browsers, computers, and robots.

Networks can be based in one physical area (local-area network, or **LAN**), or distributed over wide distances (wide-area network, or **WAN**). Access control is a fundamental problem in networking. Among a variety of methods, the *ethernet* protocol is the most popular. Ethernet provides a broadcast-capable multi-access **LAN**. It adopts a carrier-sense multiple-access (**CSMA**) strategy to address the multiple-access problem. Defined in the **IEEE 802.x** standard, **CSMA** allows each host to send information over the link at any time. Therefore, collisions may happen between two or more simultaneous transmission requests. Collisions can be detected either by directly sensing the voltage in the case of wired networks, which is referred to as collision detection (**CSMA/CD**), or by checking the time-out of

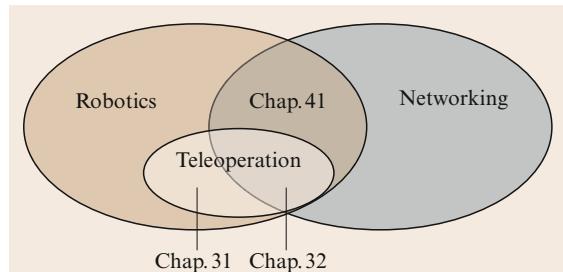

Fig. 32.1 Relationship between the subjects of networked telerobots (Chap. 32, the present chapter), teleoperation (Chap. 31), and networked robots (Chap. 41)

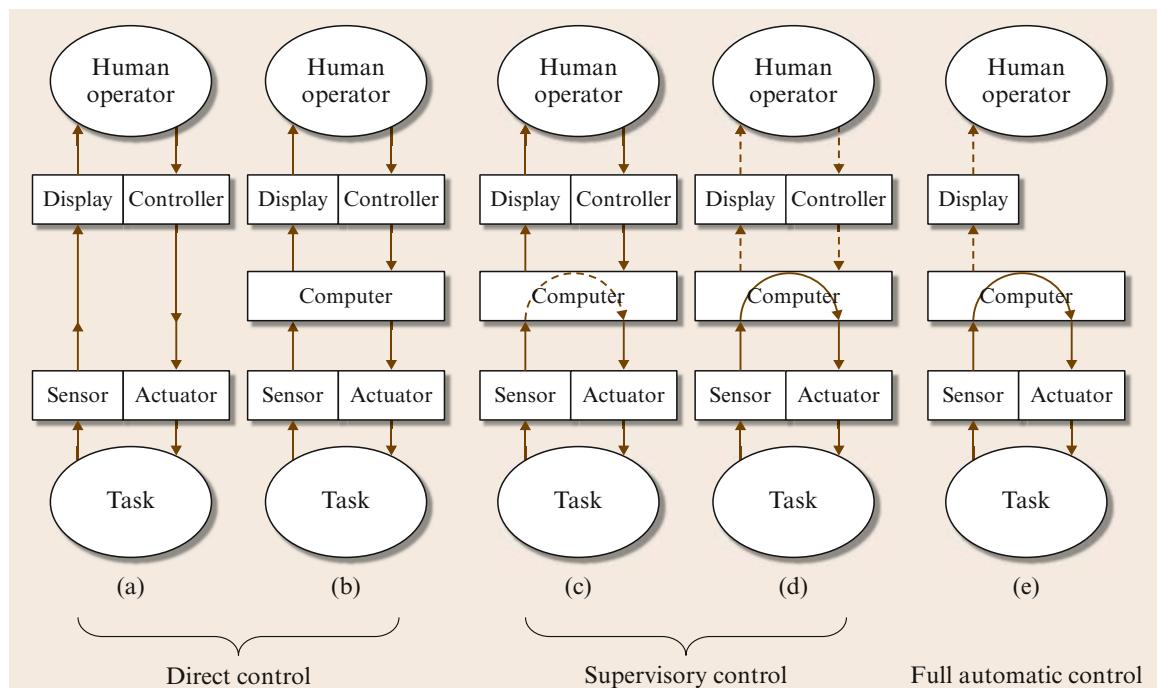

Fig. 32.2 A spectrum of teleoperation control modes adapted from *Sheridan's* text [32.11]. We label them (a–e), in order of increasing robot autonomy. At the *far left* would be a mechanical linkage where the human directly operates the robot from another room through sliding mechanical bars, and on the *far right* is the system where the human role is limited to observation/monitoring. In (c–e), the *dashed lines* indicated that communication may be intermittent

an anticipated acknowledgement in wireless networks, which is referred to as collision avoidance (**CSMA/CA**). If a collision is detected, both/all senders randomly back off a short period of time before retransmitting. **CSMA** has a number of important properties: (1) it is a completely decentralized approach, (2) it does not need clock synchronization over the entire network, and (3) it is very easy to implement. However, the disadvantages of **CSMA** are: (1) the efficiency of the network is not very high and (2) the transmission delay can change drastically.

As mentioned previously, **LANs** are interconnected with each other via routers/switchers. The information transmitted is in packet format. A packet is a string of bits and usually contains the source address, the destination address, content bits, and a checksum. Routers/switchers distribute packets according to their routing table. Routers/switchers have no memory of packets, which ensures scalability of the network. Packets are usually routed according to a first-in first-out (**FIFO**) rule, which is independent of the application. The packet formats and addresses are independent of the host technology, which ensures extensibility. This routing mechanism is referred to as packet switching in the networking literature. It is quite different from a traditional telephone network, which is referred to as circuit switching. A telephone network is designed to guarantee a dedicated circuit between a sender and a receiver once a phone call is established. The dedicated circuitry ensures communication quality. However, it requires a large number of circuits to ensure the quality of service (QoS), which leads to poor utilization of the overall network. A packet-switching network cannot guarantee dedicated bandwidth for each individual pair of transmissions, but it improves overall resource utilization. The Internet, which is the most popular communication media and the infrastructure of networked telerobots, is a packet-switching network.

32.3.1 The Internet

The creation of the Internet can be traced back to US Department of Defense's (**DoD**) APRA NET network in the 1960s. There are two features of the APRA NET network that enabled the successful evolution of the Internet. One feature is the ability for information (packets) to be rerouted around failures. Originally this was designed to ensure communication in the event of a nuclear war. Interestingly, this dynamic routing capability also allows the topology of the Internet to grow easily. The second important feature is the ability for heterogeneous net-

works to interconnect with one another. Heterogeneous networks, such as X.25, G.701, ethernet, can all connect to the Internet as long as they can implement the Internet protocol (**IP**). The **IP** is media, operating system (**OS**), and data rate independent. This flexible design allows a variety of applications and hosts to connect to the Internet as long as they can generate and understand **IP**.

Figure 32.3 illustrates a four-layer model of the protocols used in the Internet. On the top of the **IP**, we have two primary transport layer protocols: the transmission control protocol (**TCP**) and the user data protocol (**UDP**). **TCP** is an end-to-end transmission control protocol. It manages packet ordering, error control, rate control, and flow control based on packet round-trip time. **TCP** guarantees the arrival of each packet. However, excessive retransmission of **TCP** in a congested network may introduce undesirable time delays in a networked telerobotic system. **UDP** behaves differently; it is a broadcast-capable protocol and does not have a retransmission mechanism. Users must take care of error control and rate control themselves. **UDP** has a lot less overhead compared to **TCP**. **UDP** packets are transmitted at the sender's preset rate and the rate is changed based on the congestion of a network. **UDP** has great potential, but it is often blocked by firewalls because of a lack of a rate control mechanism. It is also worth mentioning that the widely accepted term **TCP/IP** refers to the family of protocols that build on **IP**, **TCP**, and **UDP**.

In the application layer of the Internet protocols, the **HTTP** is one of the most important protocols. **HTTP** is the protocol for the World Wide Web (**WWW**). It allows the sharing of multimedia information among

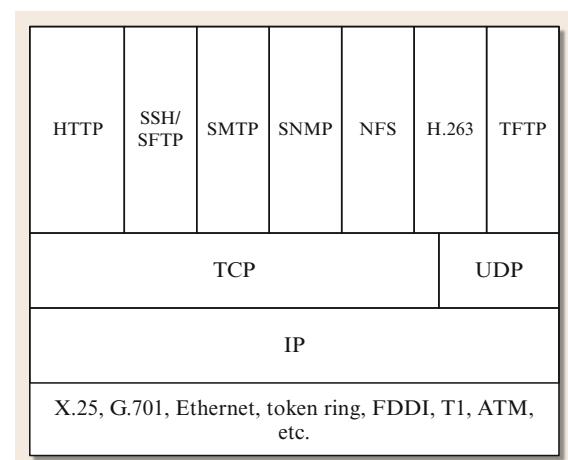

Fig. 32.3 A four-layer model of internet protocols (after [32.42])

Table 32.1 Last-mile Internet speed by wired connection type. If not specified, the downstream transmission and the upstream transmission share the same bandwidth

| Types | Bits per second |
|--------------------------------------------------------|-----------------------------------------------------------|
| Modem (V.92) | Up to 56 K |
| Integrated Services Digital Network (ISDN) BRI | 64–128 K |
| High Data Rate Digital Subscriber Line (HDSL) | 1.544 M duplex on two twisted-pair lines |
| Assymetric Digital Subscriber Line (ADSL) | 1.544–6.1 M downstream, 16–640 K upstream |
| Cable modem | 2–4 M downstream, 400–600 K upstream |
| Fiber to the home (FTTH) | 5–30 M downstream, 2–5 M upstream |
| Internet II/III node | ≥ 1 G (data are based on the service provided by Verizon) |

Table 32.2 Survey of wireless technologies in terms of bit rate and range

| Types | Bit rate (bps) | Band (Hz) | Range (m) |
|--------------------|----------------|-----------------|-----------|
| Zigbee (802.15.4) | 20–250 K | 868–915 M/2.4 G | 50 |
| 3G cellphone | 400 K–1.15 M | ≤ 3.5 G | 15 000 |
| Bluetooth | 732 K | 2.4 G | 100 |
| MWBA (802.20) | 1 M | ≤ 3.5 G | 15 000 |
| WiFi (802.11a,b,g) | 11–54 M | 2.4 G or 5.8 G | 100 |
| WiMax (802.16) | 70 M | 2–11, 10–66 G | 50 000 |

heterogeneous hosts and OSs including text, image, audio, and video. The protocol has significantly contributed to the boom of the Internet. It also changes the traditional client/server (C/S) communication architecture to a browser/server (B/S) architecture. A typical configuration of the B/S architecture consists of a web server and clients with web browsers. The web server projects the contents in hypertext markup language (**HTML**) format or its variants, which is transmitted over the Internet using HTTP. User inputs can be acquired using the common gateway interface (**CGI**) or other variants. The B/S architecture is the most accessible because no specialized software is needed at the client end.

32.3.2 Wired Communication Links

Even during peak usage, the network backbones of the Internet often run at less than 30% of their overall capacity. The average backbone utilization is around 15–20%. The primary speed limitation for the Internet is the *last mile*, the link between clients and their local Internet service providers (**ISP**).

Table 32.1 lists typical bit rates for different connection types. It is interesting to note the asymmetric speeds in many cases, where upstream bit rate (from the client to the Internet), are far slower than downstream bit rates (from the Internet to the client). These asymmetries introduce complexity into the network model

for teleoperation. Since the speed difference between the slowest modem link and the fastest Internet II node is over 10 000, designers of a networked telerobotic system should anticipate a large variance of communication speeds.

32.3.3 Wireless Links

Table 32.2 compares the speed, band, and range of wireless standards as of 2006. Increasing bit rate and communication range requires increasing power. The amount of radiofrequency (**RF**) transmission power required over a distance d is proportional to d^k , where $2 \leq k \leq 4$ depending on the antenna type. In Table 32.2, Bluetooth and Zigbee are typical low-power transmission standards that are good for short distances. WiMax and MWBA are currently under development.

By providing high-speed connectivity at low cost, WiFi is the most popular wireless standard in 2006. Its range is approximate 100 m line of sight and the WiFi wireless network usually consists of small-scale interconnected access points. The coverage range usually limits these networks to an office building, home, and other indoor environments. WiFi is a good option for indoor mobile robots and human operators. If the robot needs to navigate in the outdoor environment, the third-generation (3G) cellphone network can provide the best coverage available. Although obvious overlap exists among wireless standards in coverage and band-

width, there are two import issues that have not been covered by Table 32.2. One is mobility. We know that, if an RF source or receiver is moving, the corresponding Doppler effect causes a frequency shift, which could cause problems in communication. WiFi is not designed for fast-moving hosts. WiMax and 3G cellphone allows the host to move at a vehicle speed under 120 km/h. However, MWBA allows the host to move at a speed of 250 km/h, which is the only protocol that works for high-speed trains. Both WiMax and MWBA are designed with a transmission latency of less than 20 ms. However, 3G cellphone networks have a variable latency of 10–500 ms.

32.3.4 Properties of Networked Telerobotics

As defined by *Mason, Peshkin*, and others [32.43, 44], in *quasistatic* robot systems, accelerations and inertial forces are negligible compared to dissipative forces. In quasistatic robot systems, motions are often modeled as transitions between discrete atomic *configurations*.

We adopt a similar terminology for networked telerobots. In quasistatic telerobotics (QT), robot dynamics

and stability are handled locally. After each atomic motion, a new state report is presented to the remote user, who sends back an atomic command. The atomic state describes the status of the robot and its corresponding environment. Atomic commands refer to human directives, which are desired robotic actions.

Several issues arise

- *State-command presentation:* How should state and available commands be presented to remote human operators using the two-dimensional (2-D) screen display?
- *Command execution/state generation:* How should commands be executed locally to ensure that the desired state is achieved and maintained by the robot?
- *Command coordination:* How should commands be resolved when there are multiple human operators?

32.3.5 Building a Networked Telerobotic System

As illustrated in Fig. 32.4, a typical networked telerobotic system typically includes three components:

- users: anyone with an Internet connection and a web browser
- web server: a computer running a web server software
- robot: a robot manipulator, a mobile robot, or any device that can modify or affect its environment

Users access the system via their web browsers. Any web browser that is compatible with W3C's [HTML](#) standard can access a web server. In 2006, the most popular web browsers are Microsoft Internet Explorer, Netscape, Mozilla Firefox, Safari, and Opera. New browsers and updated versions with new features are introduced periodically.

A web server is a computer that responds to HTTP requests over the Internet. Depending upon the operating system of the web server, popular server software packages include Apache and Microsoft Internet Information Services (IIS). Most servers can be freely downloaded from the Internet.

To develop a networked telerobot, one needs a basic knowledge of developing, configuring, and maintaining web servers. As illustrated in Fig. 32.5, the development requires knowledge of [HTML](#) and at least one local programming languages such as C, [CGI](#), Javascript, Perl, PHP, or Java.

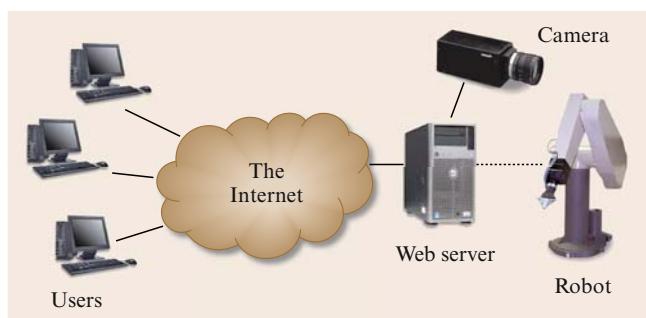

Fig. 32.4 Typical system architecture for a networked telerobot

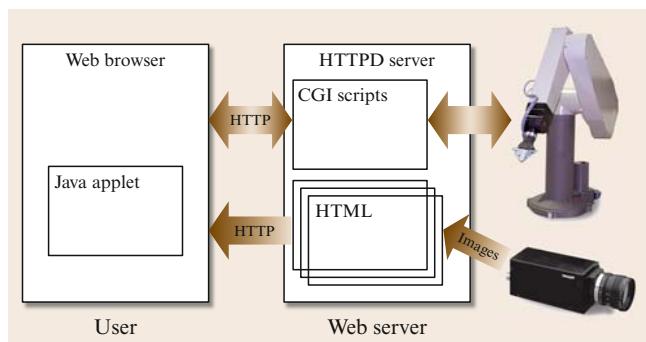

Fig. 32.5 A sample software architecture of a networked telerobot

It is important to consider compatibility with the variety of browsers. Although [HTML](#) is designed to be compatible with all browsers, there are exceptions. For example, Javascript, which is the embedded scripting language of web browsers, is not completely compatible between Internet Explorer and Netscape. One also needs to master the common [HTML](#) components such as forms that are used to accept user inputs, frames that are used to divide the interface into different functional regions, etc. An introduction to [HTML](#) can be found in [32.45].

User commands are usually processed by the web server using [CGI](#), the common gateway interface. Most sophisticated methods such as PHP, Java Server Pages ([JSP](#)), and socket programming can also be used. [CGI](#) is invoked by the HTTP server when the [CGI](#) script is referred in the Uniform Resource Locator ([URL](#)). The [CGI](#) program then interprets the inputs, which is often the next robot motion command, and sends commands to the robot via a local communication channel. [CGI](#) scripts can be written in almost any programming language. The most popular ones are Perl and C.

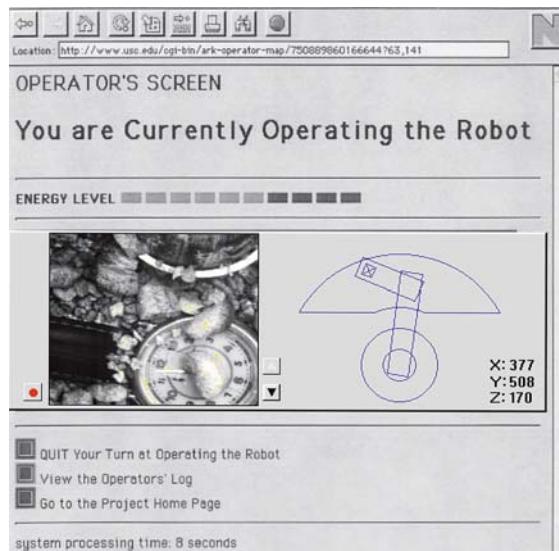

Fig. 32.6 Browser's view of the first networked telerobot interface [32.46]. The schematic at *lower right* gives an overhead view of position of the four-axis robot arm (with the camera at the end marked with X), and the image at the *lower left* indicates the current view of the camera. The small button marked with a dot at the left directs a 1 s burst of compressed air into the sand below the camera. The Mercury Project was online from August 1994 to March 1995

A simple networked telerobotic system can be constructed using only [HTML](#) and [CGI](#). However, if the robot requires a sophisticated control interface, a Java applet is recommended. Java applets run inside the web browser on the client's computer. Information about Java can be found at Sun Microsystems' official Java home page.

Most telerobotic systems also collect user data and robot data. Therefore, database design and data processing program are also needed. The most common used databases include MySQL and PostgreSQL. Both are open-source databases and support a variety of platforms and operation systems. Since a networked telerobotic system is online 24 hours a day, reliability is also an important consideration in system design. Website security is critical. Other common auxiliary developments include online documentation, online manual, and user feedback collection.

32.3.6 State-Command Presentation

To generate a correct and high-quality command depends on how effectively the human operator understands the state feedback. The state-command presentation contains three subproblems: the 2-D representation of the true robot state (state display), the assistance provided by the interface to generate new commands (spatial reasoning), and the input mechanism.

Browser Displays

Unlike traditional point-to-point teleoperation, where specialized training and equipment are available to ope-

Fig. 32.7 Browser interface to the Australian networked telerobot which was a six-axis arm that could pick up and move blocks [32.16]

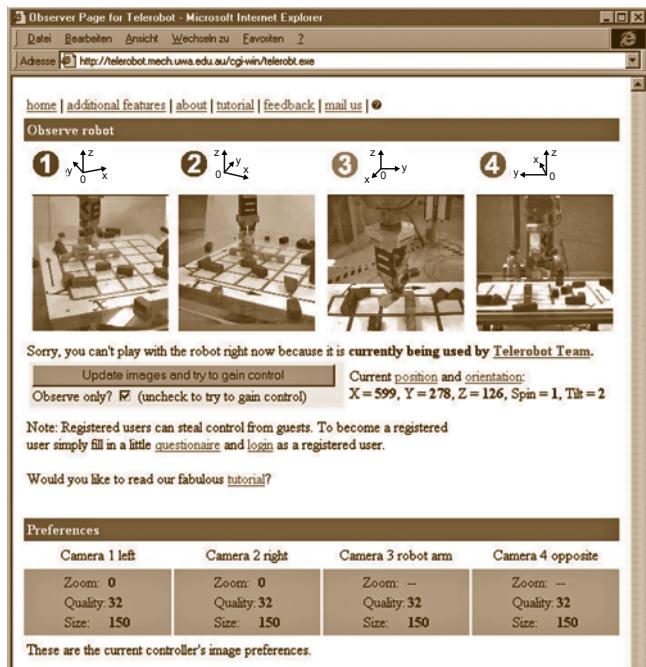

Fig. 32.8 Use of a multicamera system for multi-viewpoint state feedback [32.47]

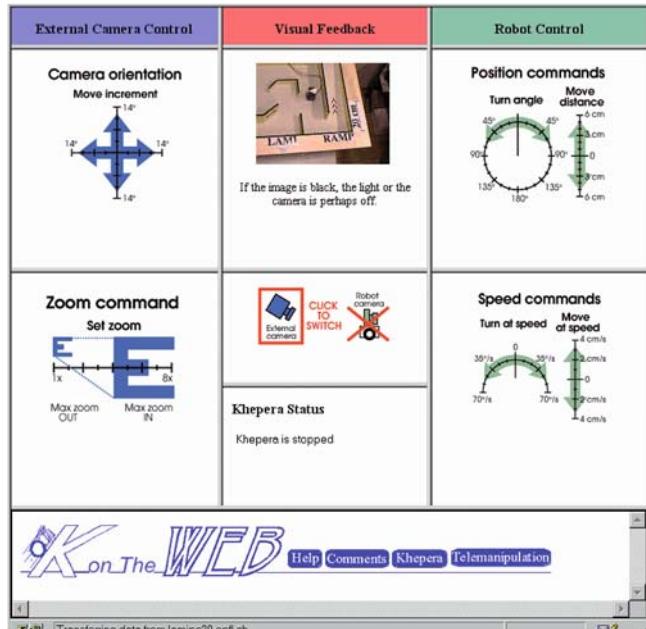

Fig. 32.9 Camera control and mobile robot control in Patrick Saucy and Francesco Mondada's Khep on the web project

rators, networked telerobots offer wide access to the general public. Designers cannot assume that operators have any prior experience with robots. As illustrated in Fig. 32.6, networked telerobotic systems must display the robot state on a 2-D screen display.

The states of the teleoperated robot are often characterized in either world coordinates or robot joint configuration, which are either displayed in numerical format or through a graphical representation. Figure 32.6 lists robot XYZ coordinates on the interface and draws a simple 2-D projection to indicate joint configurations. Figure 32.7 illustrates another example of teleoperation interface that was developed by *Taylor* and *Trevelyan* [32.36]. In this interface, XYZ coordinates are presented in a sliding bar near the video window.

The state of the robot is usually displayed in a 2-D view as shown in Figs. 32.6 and 32.7. In some systems, multiple cameras can help the human operator to understand the spatial relationship between the robot and the objects in the surrounding environment. Figure 32.8 shows an example with four distinct camera views for a six-degree-of-freedom industrial robot.

Figure 32.9 demonstrate an interface with a pan-tilt-zoom robotic camera. The interface in Fig. 32.9 is designed for a mobile robot.

More sophisticated spatial reasoning can eliminate the need for humans to provide low-level control by automatically generating a sequence of commands after it receives task-level commands from the human operator. This is particularly important when the robotic system is highly dynamic and requires a very fast response. In this case, it is impossible to ask the human to generate intermediate steps in the robot control; for example, *Belousov* et al. adopt a shared autonomy model to direct a robot to capture a moving rod [32.27]. *Fong* and *Thorpe* [32.48] summarize vehicle teleoperation systems that utilize these supervisory control techniques. *Su* et al. developed an incremental algorithm for better translation of the intention and motion of operators into remote robot action commands [32.32].

Human Operator Input

Most networked telerobotic systems only rely on mouse and keyboards for input. The design problem is what to click on in the interface. Given the fact that user commands can be quite different, we need to adopt an appropriate interface for inputs; for example, inputs could be Cartesian XYZ coordinates in world coordinate system or robot configurations in angular joint configurations.

For angular inputs, it is often suggested to use a round dial as a control interface, as illustrated in bottom left of Fig. 32.7 and the right-hand side of Fig. 32.9. For linear motion in Cartesian coordinate, arrows operated by either mouse clicks or the keyboard are often suggested. Position and speed control are often needed, as illustrated in Fig. 32.9. Speed control is usually controlled by mouse clicks on a linear progress bar for translation and a dial for rotation.

The most common control type is position control. The most straightforward way is to click on the video image directly. To implement the function, the software needs to translate the 2-D click inputs into three-dimensional (3-D) world coordinates. To simplify the problem, the system designer usually assumes that the clicked position is on a fixed plane; for example, a mouse click on the interface of Fig. 32.6 assumes the robot moves on the $X-Y$ plane. The combination of a mouse click on the image can also allow abstract task-level command. The example in Fig. 32.12 uses mouse clicks to place votes on an image to generate a com-

mand that directs a robot to pick up a test agent at the task level.

32.3.7 Command Execution/State Generation

When a robot receives a command, it executes the command and a new state is generated and transmitted back to the human operator. However, commands may not arrive in time or may get lost in transmission. Also, because users are often inexperienced, their commands may contain errors.

Belousov and colleagues demonstrated a system that allowed a web user to capture a fast rod that is thrown at a robot manipulator [32.27]. Over the limited communication channel, it is impossible to ask the human to control the manipulator directly. Computer vision and augmented-reality-based local intelligence is required

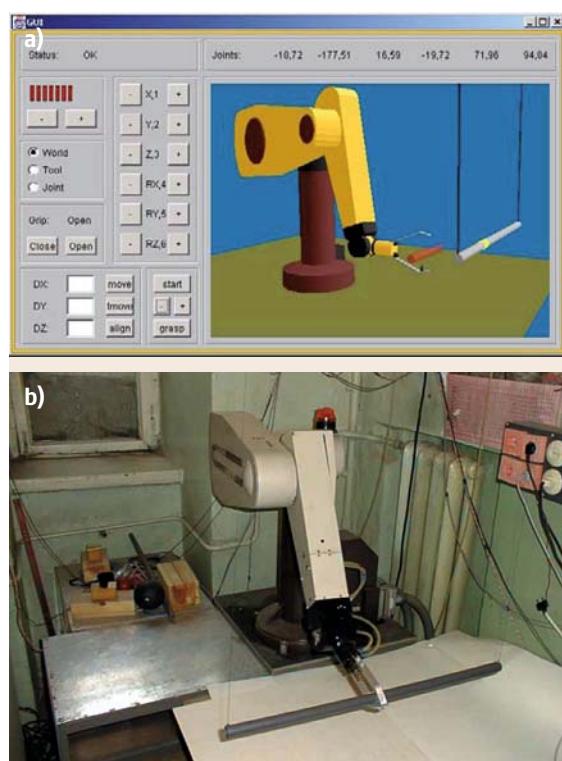

Fig. 32.10a,b A web-based teleoperation system that allows robot to capture a fast-moving rod [32.27] (a) User interface and (b) system setup

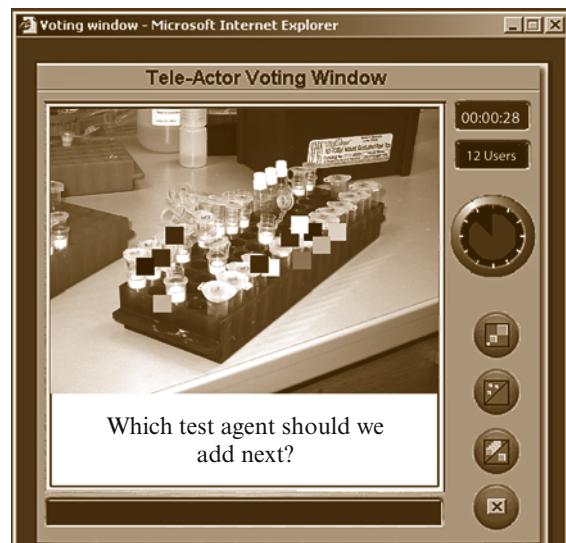

Fig. 32.11 Spatial dynamic voting interface for the Tele-Actor system [32.41]: the spatial dynamic voting (SDV) interface as viewed by each user. In the remote environment, the Tele-Actor takes images with a digital camera, which are transmitted over the network and displayed to all participants with a relevant question. With a mouse click, each user places a color-coded marker (*a votel* or voting element) on the image. Users view the position of all votels and can change their votel positions based on the group's response. Votel positions are then processed to identify a *consensus region* in the voting image that is sent back to the Tele-Actor. In this manner, the group collaborates to guide the actions of the Tele-Actor

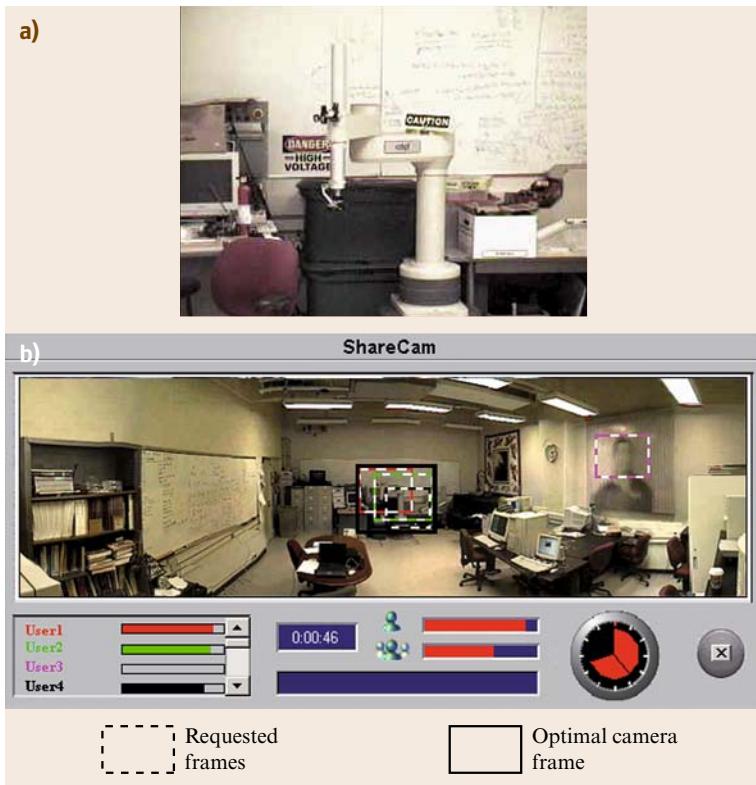

Fig. 32.12a,b Frame selection interface [32.49]. The user interface includes two image windows. The lower window (b) displays a fixed panoramic image based on the camera's full workspace (reachable field of view). Each user requests a camera frame by positioning a *dashed rectangle* in (b). Based on these requests, the algorithm computes an optimal camera frame (shown with a *solid rectangle*), moves the camera accordingly, and displays the resulting live streaming video image in the upper window (a)

to assist the human operator. The rod is on bifilar suspension, performing complicated oscillations. Belousov et al. designed a shared-autonomy control to implement the capture. First, an operator chooses the desired point for capture on the rod and the capture instant using a 3-D online virtual model of the robot and the rod. Then, the capturing operation is performed automatically using a motion prediction algorithm that is based on the rod's motion model and two orthogonal camera inputs, which perceive the rod's position locally in real time.

32.3.8 Collaborative Control

When more than one human is sharing control of the device, command coordination is needed. According to [32.50], multiple human operators can reduce the chance of errors, cope with malicious inputs, utilize operators' different expertise, and train new operators. In [32.51], a *collaborative telerobot* is defined as a tele-robot simultaneously controlled by many participants, where input from each participant is combined to generate a single control stream.

When group inputs are in the form of direction vectors, averaging can be used as an aggregation mechanism [32.52]. When decisions are distinct choices or at the abstract task level, voting is a better choice [32.41]. As illustrated in Fig. 32.12, Goldberg and Song develop the Tele-Actor system using spatial dynamic voting. The Tele-Actor is a human equipped with an audio/video device and controlled by a group of online users. Users indicate their intentions by positioning their votes on a 320×320 pixel voting image during the voting interval. Votes are collected at the server and used to determine the Tele-Actor's next action based on the most requested region on the voting image. (see <http://www.tele-actor.net>)

Song and Goldberg [32.49, 53] developed a controllable camera that allowed many clients to share control of its camera parameters, as illustrated in Fig. 32.12. Users indicate the area they want to view by drawing rectangles on a panoramic image. The algorithm computes an optimal camera frame with respect to the user satisfaction function, which is defined as the frame selection problem.

32.4 Conclusion and Future Directions

As this technology matures, networked telerobots will gradually go beyond university laboratories and find application in the real world. A new project, the Collaborative Observatory for Nature Environments (**CONE**) project, proposed by *Song* and *Goldberg* [32.54], aims to design a networked robotic camera system to collect data from the wilderness for natural scientists. The fast development of networked telerobot system is not limited to North America. Japan's Advanced Telecommunications Research Institute International (**ATR**) Intelligent Robotics and Communication Laboratory has also announced its networked robot project led by Norihiro Hagita (**ATR**). Its mission is to develop network-based intelligent robots for applications such as service, medical, and safety. Hideyuki Tokuda (Keio University) chaired the Networked Robot Forum in Spring 2005, which promotes research and development (R&D) and standardization on network robots through activities to support awareness campaigns and verification experiments in collaboration among wide-ranging parties, which includes over 100 industry and academic members. Korea's Ministry of Information and Communication has also announced the Ubiquitous Robotic Companion (**URC**) project to develop network-based intelligent robots.

Networked telerobots have allowed tens of thousands of nonspecialists around the world to interact with robots. The design of networked telerobots presents a number of engineering challenges to build reliable systems that can be operated by nonspecialists 24 hours a day, 7 days a week and remain online for years. Many new research challenges remain.

- *New interfaces:* As portable devices such as cell-phones and portable digital assistants (PDAs) becomes grow in computation power, networked telerobotics should be able to adopt them as new

interfaces. As computers becomes increasingly powerful, they become capable of visualizing more sophisticated sensor inputs. Designers of new interfaces should also keep track of new developments in hardware such as haptic interfaces and voice recognition systems. New software standards such as flash, extensible markup language (**XML**), extensible hyper text markup language (**XHTML**), virtual reality modeling language (**VRML**), and wireless markup language (**WML**) will also change the way we design interface.

- *New algorithms:* Algorithms determine performance. Scalable algorithms that are capable of handing large amounts of data such as video/sensor network inputs and utilize fast-evolving hardware capability such as distributed and parallel computation will become increasingly important in the networked telerobotics.
- *New protocols:* Although we have listed some pioneering work in changing the network environment to improve teleoperation, there are still a large number of open problems such as new protocols, appropriate bandwidth allocation [32.55], QoS [32.56], security, routing mechanisms [32.28], and many more. Network communication is a very fast-evolving field. The incorporation/modification of network communication ideas into networked telerobotic system design will continue to be an active research area. The common object request broker architecture (**CORBA**) or real-time **CORBA** [32.19, 20, 57, 58] have great potential for networked telerobotics.
- *Applications:* Many new applications are emerging in areas such as security, inspection, education, and entertainment. Application requirements such as reliability, security, and modularity will continuous to pose new challenges for system design.

33. Exoskeletons for Human Performance Augmentation

Homayoon Kazerooni

Although autonomous robotic systems perform remarkably in structured environments (e.g., factories), integrated human–robotic systems are superior to any autonomous robotic systems in unstructured environments that demand significant adaptation. The technology associated with exoskeleton systems and human power augmentation can be divided into lower-extremity exoskeletons and upper-extremity exoskeletons. The reason for this was twofold; firstly, one could envision a great many applications for either a stand-alone lower- or upper-extremity exoskeleton in the immediate future. Secondly, and more importantly for the division, is that these exoskeletons are in their early stages, and further research still needs to be conducted to ensure that the upper-extremity exoskeleton and lower-extremity exoskeleton can function well independently before one can venture an attempt to integrate them. This chapter first gives a description of the upper-extremity exoskeleton efforts and then will proceed with the

more detailed description of the lower-extremity exoskeleton.

33.1 Survey of Exoskeleton Systems

In the early 1960s, the US Defense Department expressed interest in the development of a man-amplifier, a *powered suit of armor* which would augment soldiers' lifting and carrying capabilities. In 1962, the Air Force had the Cornell Aeronautical Laboratory study the feasibility of using a master–slave robotic system as a man-amplifier. In later work, Cornell determined that an exoskeleton, an external structure in the shape of the human body which has far fewer degrees of freedom than a human, could accomplish most desired tasks [33.1]. From 1960 to 1971, General Electric developed and tested a prototype man-amplifier, a master–slave system called the Hardiman [33.2–6]. The Hardiman was a set of overlapping exoskeletons worn by a human operator.

The outer exoskeleton (the slave) followed the motions of the inner exoskeleton (the master), which followed the motions of the human operator. All these studies found that duplicating all human motions and using master–slave systems were not practical. Additionally, difficulties in human sensing and system complexity kept it from walking.

Vukobratovic et al. developed a few active orthoses for paraplegics [33.7]. The systems include hydraulic or pneumatic actuators for driving the hip and knee joints in the sagittal plane. These orthoses were coupled with the wearer via shoe bindings, cuffs, and a corset. The device was externally powered and controlled via a predetermined periodic motion. Although these early devices

were limited to predefined motions and had limited success, balancing algorithms developed for them are still used in many bipedal robots [33.8].

Seireg et al. also created an exoskeleton system for paraplegics where only the hip and knee were powered by hydraulic actuators in sagittal plane [33.9]. The hydraulic power unit consists of a battery-powered direct-current (DC) motor, pump, and accumulator. A bank of servo-valves drives the actuators at the knee and hip. The device was controlled to follow a set of

joint trajectories without the use of any sensory systems from its wearer.

The hybrid assisted limb (**HAL**) was developed at the University of Tsukuba ([33.13, 14]). This 15 kg battery-powered suit detects muscle myoelectrical signals on the skin surface below the hip and above the knee. The signals are picked up by the sensors and sent to the computer, which translates the nerve signals into signals of its own for controlling electric motors at the hips and knees of the exoskeleton, effectively amplifying

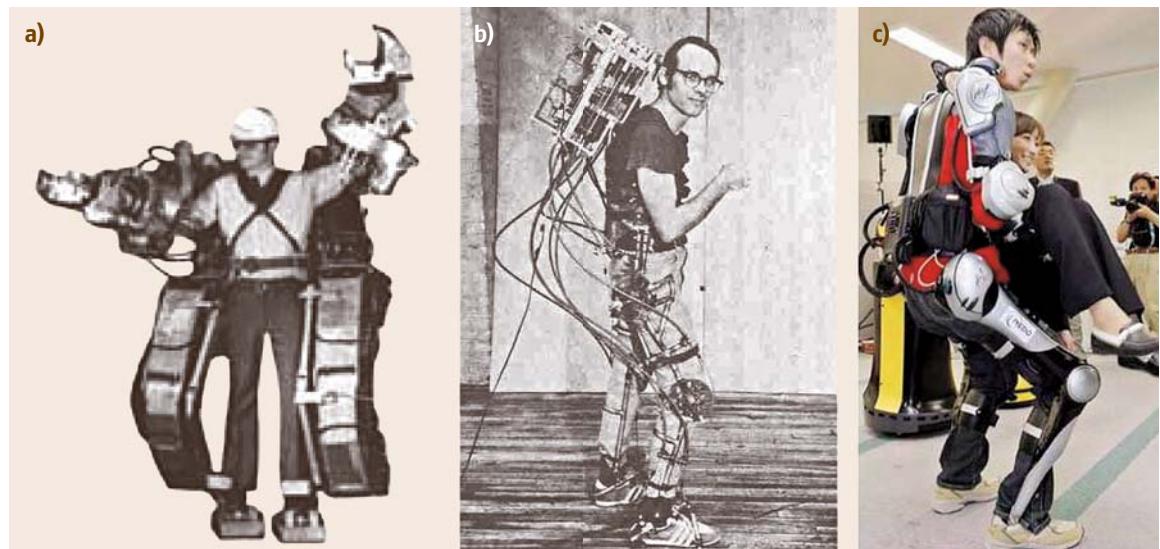

Fig. 33.1 (a) Hardiman; (b) An exoskeleton system designed for paraplegics by *Seireg et al.* [33.9]; (c) HAL

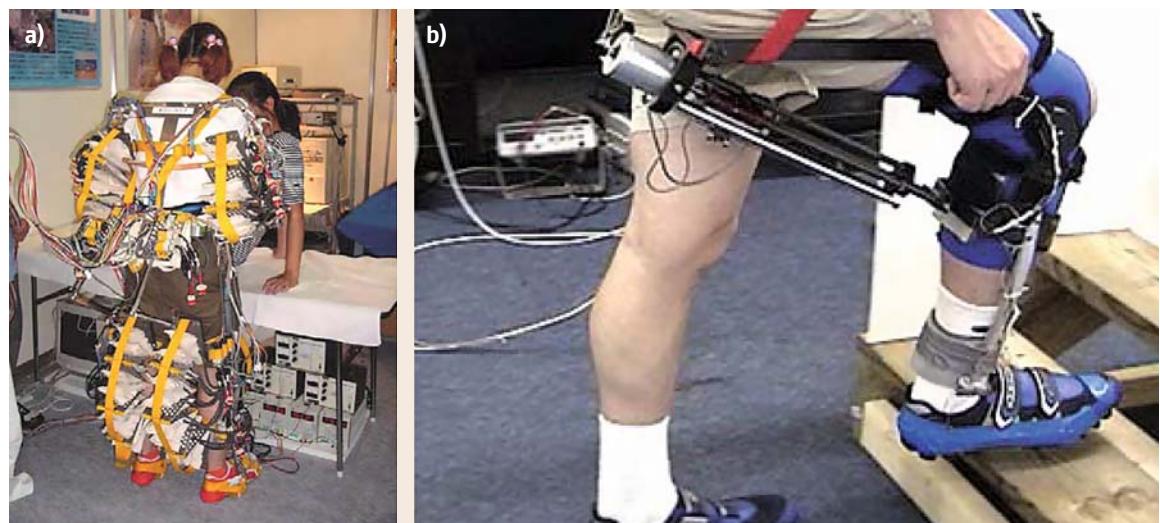

Fig. 33.2 (a) An exoskeleton for patient handling [33.10, 11]; (b) RoboKnee [33.12]

ing muscle strength. In addition to electromyography (**EMG**) signals, the device further includes potentiometers for measuring the joint angles, force sensors for measuring the ground reaction forces and a gyroscope and accelerometer for measuring the torso angle. Each leg of **HAL** powers the flexion/extension motion at the hip and knee in the sagittal plane through the use of DC motors integrated with harmonic drives. The ankle includes passive degrees of freedom.

Yamamoto et al. [33.10, 11] have created an exoskeleton system for assisting nurses during patient handling. The lower limbs include pneumatic actuators for the flexion/extension of the hips and knees in the sagittal plane. Air pumps are mounted directly onto each actuator to provide pneumatic power. User input is determined via force sensing resistors coupled to the wearer's skin. The measurement from force sensing resistor (**FSR**) and other information such as joint angles are used to determine the required input torques for various joints.

Pratt et al. developed a powered knee brace for adding power at the knee to assist in squatting [33.12]. The device is powered by a linear series-elastic actua-

tor coupling the upper and the lower portions of a knee brace. The control of this powered knee brace requires the ground reaction force measured by two load cells. The system uses a positive-feedback force controller to create an appropriate force for the actuator.

Kong et al. developed a full lower-limb exoskeleton system that works with a powered walker [33.15]. The walker houses the electric actuators, the controller, and the batteries, reducing the weight of the exoskeleton system. A transmission system transmits power to the wearer's joints from the actuators in the walker. The exoskeleton is powered at the hips and knees in sagittal plane. The input to drive the system is a set of pressure sensor that measure the force applied by the quadriceps muscle on the knee.

Agrawal et al. have conducted research projects on statically balanced leg orthoses that allow for less effort during swing [33.16]. In the passive version, the device uses springs in order to cancel the gravity force associated with the device links and the person leg. Through experiments the authors showed that the device reduced the required torque by the wearer substantially.

33.2 Upper-Extremity Exoskeleton

In the mid-1980s, researchers at Berkeley initiated several research projects on upper-extremity exoskeleton systems, billed as *human extenders* [33.17–23]. The main function of an upper-extremity exoskeleton is human power augmentation for the manipulation of heavy and bulky objects. Since upper-extremity exoskeletons are mostly used for factory floors, warehouse, and distribution centers, they are hung from overhead cranes. As can be seen in later sections, lower-extremity exoskeletons focus on supporting and carrying heavy payloads on the operator's back (like a backpack) during long-distance locomotion. Upper-extremity exoskeletons, which are also known as assist devices or human power extenders, can simulate forces on a worker's arms and torso. These forces differ from, and are usually much smaller than the forces needed to maneuver a load. When a worker uses an upper-extremity exoskeleton to move a load, the device bears the bulk of the weight by itself, while transferring to the user as a natural feedback a scaled-down value of the load's actual weight. For example, for every 20 kg of weight from an object, a worker might support only 2 kg while the device supports the remaining 18 kg. In this fashion, the worker can still sense the load's weight and judge his/her

movements accordingly, but the force he/she feels is much smaller than what he/she would feel without the device. In another example, suppose the worker uses the device to maneuver a large, rigid, and bulky object, such as an exhaust pipe. The device will convey the force to the worker as if it was a light, single-point mass. This limits the cross-coupled and centrifugal forces that increase the difficulty of maneuvering a rigid body and can sometimes produce injurious forces on the wrist. In a third example, suppose a worker uses the device to handle a powered torque wrench. The device will decrease and filter the forces transferred from the wrench to the worker's arm so the worker feels the low-frequency components of the wrench's vibratory forces instead of the high-frequency components that produce fatigue [33.24]. These assist devices not only filter out unwanted forces on a worker, but can also be programmed to follow a particular trajectory regardless of the exact direction in which the worker attempts to manipulate the device. For example, suppose an auto-assembly worker is using an assist device to move a seat to its final destination inside a car. The assist device can bring the seat to its final destination, moving it along a preprogrammed path with a speed that is proportional

Fig. 33.3a,b Two-handed upper-extremity exoskeleton where artificially built friction forces between the load and the arms allow for grasping objects [33.25]

to the magnitude of the worker's force on the device. Although the worker might be paying very little attention to the final destination of the seat, the device can still bring the seat to its proper place without the worker's guidance. The upper-extremity exoskeleton reflects on the worker's arm forces that are limited and much smaller than the forces needed to maneuver loads. With it, auto-assembly and warehouse workers can maneuver parts and boxes with greatly improved dexterity and precision, not to mention a marked decrease in muscle strain.

Fig. 33.4 One-handed upper-extremity exoskeleton where a gripper allows for grasping of heavy objects [33.21]

The upper-extremity exoskeleton will significantly reduce the incidence of back injury in the workplace, which will in turn greatly decrease the annual cost of treating back injuries.

Upper-extremity exoskeletons were designed based primarily on compliance control [33.26–29] schemes that relied on the measurement of interaction force between the human and the machine. Various experimental systems, including a hydraulic loader designed for loading aircrafts and an electric power extender built for two-handed operation, were designed to verify the theories (Fig. 33.3 and Fig. 33.4).

33.3 Intelligent Assist Device

The intelligent assist devices (**IAD**) are the simplest non-anthropomorphic form of the upper-extremity systems that augments human capabilities [33.30, 31]. Figure 33.5 illustrates an intelligent assist device (**IAD**). At the top of the device, a computer-controlled electric actuator is attached directly to a ceiling, wall, or an overhead crane and moves a strong wire rope precisely, and with a controllable speed. Attached to the wire rope is a sensory end-effector where the operator hand, the **IAD**, and the load come into contact. The end-effector includes a load interface subsystem and an operator interface subsystem. The load interface subsystem is designed to interface with a variety of loads and holding devices. Hooks, suction cups, and grippers are examples of other connections to the end-effector as shown in Fig. 33.6. In general, to grab complex objects, special tooling systems should be made and connected to the load interface subsystem. The operator interface sub-

system includes an ergonomic handle, which contains a high-performance sensor for measuring the magnitude of the vertical force exerted on the handle by the operator. A signal representing the operator force is transmitted to a computer controller, which controls the actuator of the **IAD**. Using the measurement of the operator force and other calculations, the controller assigns the necessary speed to either raise or lower the wire rope to create enough mechanical strength to assist the operator in the lifting task as required. If the operator pushes upwardly on the handle, the assist device lifts the load; and if the operator pushes downward on the handle, the assist device lowers the load. The load moves appropriately so that only a small preprogrammed proportion of the load force (weight plus acceleration) is supported by the operator, and the remaining force is provided by the actuator of the **IAD**. All of this happens so quickly that the operator's lifting efforts and the device's lifting efforts are

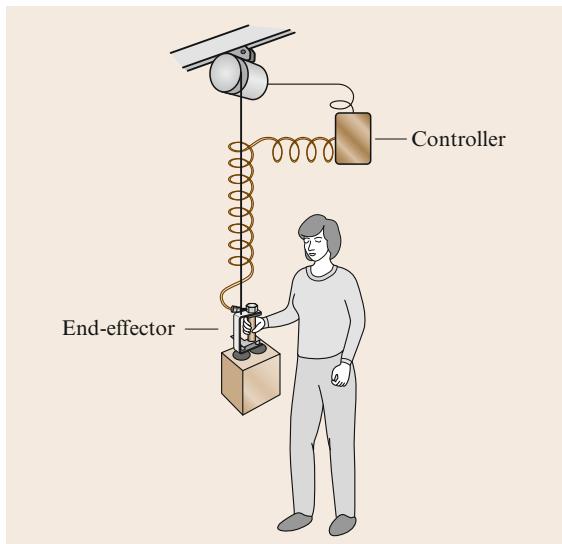

Fig. 33.5 Intelligent assist device: the simplest form of upper-extremity enhancers for industrial applications. The IAD can follow a worker's high-speed maneuvers very closely during manipulations without impeding the worker's motion.

synchronized perfectly and the load feels substantially lighter to the operator. With this load-sharing concept, the operator has the sense that he or she is lifting the load, but with far less force than would ordinarily be required. For example, with a 25 kg load force (gravity plus acceleration), the IAD supports 24 kg, while the operator supports and feels only 1 kg. With the assistance of the

intelligent assist device, a worker can manipulate any object in the same natural way that he/she would manipulate a lightweight object without any assistance. There are no push buttons, keyboards, switches, or valves to control the motion of the intelligent assist device; the user's natural movements, in conjunction with the device computer, controls the motion of the device and its load.

Figure 33.6 shows the end-effector that measures the operator forces at all times even in the presence of loading and unloading shock forces. This robust end-effector also includes a dead-man switch, which is installed on the handle and sends a signal to the controller via a signal cable. If the dead-man switch on the end-effector is not depressed, (i.e., if the operator is not holding onto the handle of the end-effector), the device will be suspended without any motion even if loads are added to or removed from the end-effector.

The IAD is engineered with variety of embedded safety features. One of the most important safety characteristics of the IAD is that the wire rope does not become slack if the end-effector is physically constrained from moving downward and the end-effector is pushed downward by the operator. Slack in the wire rope can have far more serious consequences than slowing down the workers at their jobs; the slack line could wrap around the operator's neck or hand, creating serious or even deadly injuries. The control algorithm in the computer of the IAD, employing the information from various sensors, ensures that the wire rope will never become slack [33.32].

Another form of IAD can be seen in Fig. 33.7 where a sensory glove measures the force the wearer imposes

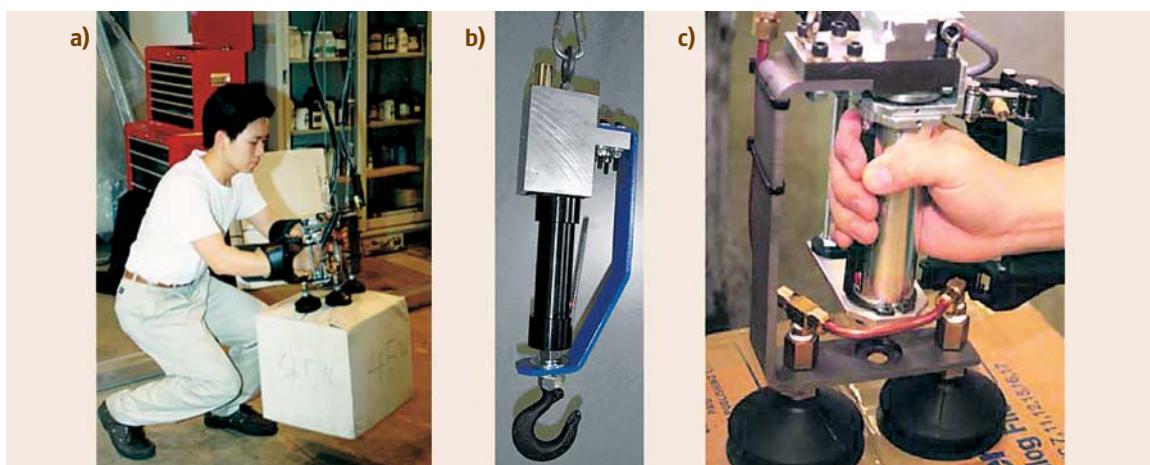

Fig. 33.6a–c The end-effector (a) contains a sensor (b) that measures the force that the operator applies to the handle (c) in the vertical direction

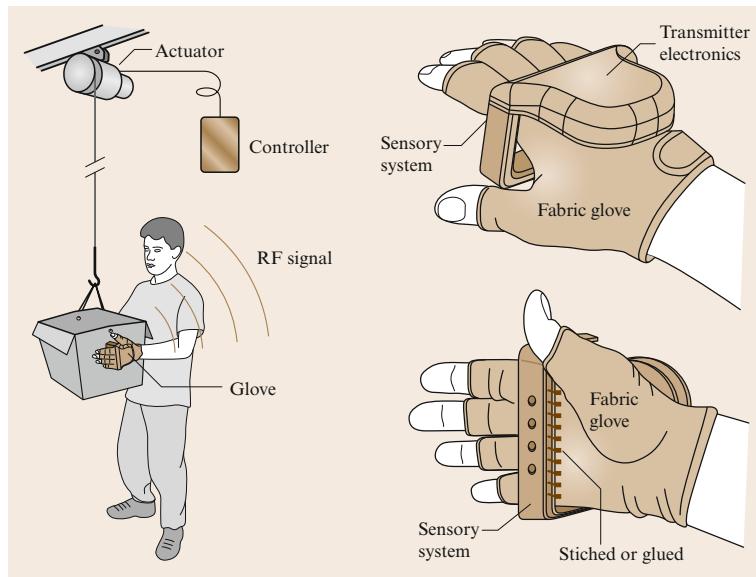

Fig. 33.7 An instrumented glove allows an operator to lift and lower objects naturally while using a hoist, similar to the way one maneuvers objects manually without activating switches or push buttons [33.34]

on any part of the material handling system or the object being maneuvered [33.33, 34]. This instrumented glove is always worn by the operator and therefore remains with the operator. The instrumented glove generates a set of signals as a function of the contact force between the glove and the object being manipulated or the material handling device itself. A set of signals representing the contact force is transmitted in the form of radiofrequency (RF) signals to a device controller so that a command signal is generated. The command sig-

nal is sent to the device actuator to provide the required assistance to maneuver or lift the load as a function of the force imposed by the operator, so that the operator provides only a small portion of the total force needed to maneuver the device and the object being manipulated by the device. For a person observing the operator and the IAD, this interaction seems rather magical since the device responds to the operator's touch regardless of whether the operator is pushing on the IAD or on the object being lifted by the device.

33.4 Control Architecture for Upper-Extremity Exoskeleton Augmentation

The linear system theory is employed here to model the dynamic behavior of the elements of an IAD. This allows us to disclose the system properties in their simplest and most commonly used form. The more general approach (nonlinear and multivariable models for upper-extremity assist devices) are presented in [33.19, 20], and [33.21], where they have been applied to the devices shown in Figs. 33.3 and 33.4. The block diagram of Fig. 33.8 shows the basic control technique. As discussed earlier, the force-sensing element in the end-effector delivers a signal to the controller, which is used to control the actuator. If e is the input command to the actuator, then the linear velocity of the end-effector v can be represented

by:

$$v = Ge + Sf_R, \quad (33.1)$$

where G is the actuator transfer function relating the input command to the actuator to the end-effector velocity; S is the actuator sensitivity transfer function relating the wire rope tensile force f_R to the end-effector velocity, v . A positive value for v represents a downward speed for the load. Also note that, since the load is connected to the end-effector, both terminologies *load velocity* and *end-effector velocity* refer to v as derived by (33.1). If a closed-loop velocity controller is designed for the actuator such that S is small, the actuator has only a small response to the line tensile

force. A high-gain controller in the closed-loop velocity system results in a small S and consequently a small change in velocity v in response to the line tensile force. Also note that non-back-drivable speed reducers (usually high transmission ratios) produce a small S for the system.

The rope tensile force f_R can be represented by:

$$f_R = f + p, \quad (33.2)$$

where f is the operator-applied force on the end-effector; the force p imposed by the load and the end-effector is referred to herein as the *load force* on the line. Positive values for f and p represent downward forces. Note that p is the force imposed on the line and is equal to the weight and inertia force of the load and end-effector taken together:

$$p = W - \frac{W}{g} \frac{d}{dt} v, \quad (33.3)$$

where W is the weight of the end-effector and load taken together as a whole and $\frac{d}{dt} v$ is the acceleration of the end-effector and load. If the load does not have any acceleration or deceleration, then p is exactly equal to the weight of the end-effector and load W . The operator force f is measured and passed to the controller delivering the output signal e . A positive number f_0 in the computer is subtracted from the measurement of the human force f . The role of f_0 is explained later. If the transfer function of the controller is represented by K , then the output of the controller e is:

$$e = K(f - f_0). \quad (33.4)$$

Substituting for f_R and e from (33.2) and (33.4) into (33.1) results in the following equation for the end-effector velocity v :

$$v = GK(f - f_0) + S(f + p). \quad (33.5)$$

Measuring an upward human force on the end-effector or on the load is only possible when the line is under tension from the weight of the end-effector. If the end-effector is light, then the full range of human upward forces may be neglected by the sensor in the instrumented glove. To overcome this problem, a positive number f_0 is introduced into (33.4). As (33.5) shows, the absence of f and p will cause the end-effector to move upwardly. Suppose the maximum downward force imposed by the operator is f_{\max} . Then f_0 is preferably set at approximately half of f_{\max} . Substituting for f_0 in (33.5), (33.6) represents the load velocity:

$$v = GK \left(f - \frac{f_{\max}}{2} \right) + S(f + P). \quad (33.6)$$

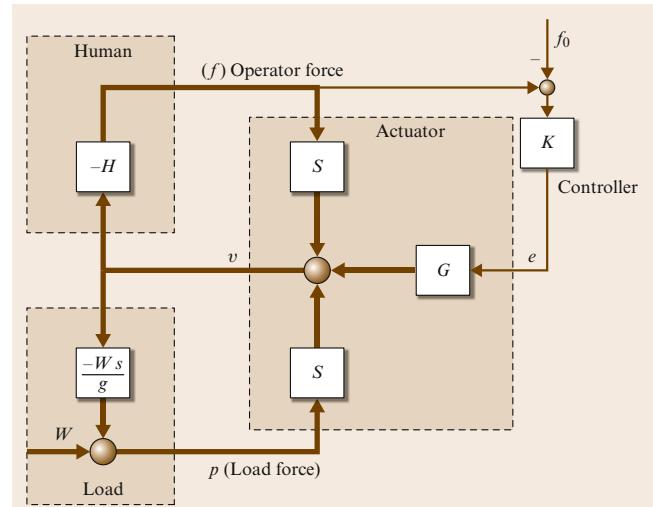

Fig. 33.8 The control block diagram of an intelligent assist device

If the operator pushes downward such that $f = f_{\max}$, then the maximum downward velocity of the load is:

$$v_{\text{down}} = GK \left(\frac{f_{\max}}{2} \right) + S(f + P). \quad (33.7)$$

If the operator does not push at all, then the maximum upward velocity of the end-effector or the load is:

$$v = -GK \left(\frac{f_{\max}}{2} \right) + S(f + P). \quad (33.8)$$

Therefore, by the introduction of f_0 in (33.4), one need not be concerned about the measurement of the upward human force. If $S = 0$, the upward and downward maximum speeds are identical in magnitude. However, in the presence of nonzero S , for a given load and under equal conditions, the magnitude of the maximum upward speed is smaller than the magnitude of the maximum downward speed. This is very natural and intuitive for the operator. Going back to (33.5), it can be observed that the more force an operator imposes on the load or on the line, the larger the velocity of the load and end-effector will be. Using the measurement of the operator force, the controller assigns the proper pulley speed to create sufficient mechanical strength, in order to assist the operator in the lifting task. In this way, the end-effector follows the human arm motions naturally. Equation (33.5) suggests that, when the operator increases or decreases the downward force on an object, a corresponding increase or decrease occurs in the downward speed of the object. Alternatively, an increase or decrease in the object's weight causes a decrease or increase, respectively, in the

upward object speed for a given operator force on the object. As Fig. 33.8 indicates, K may not be arbitrarily large. Rather, the choice of K must guarantee the closed-loop stability of the system. The human force f is a function of the human arm impedance H , whereas

the load force is a function of load dynamics, i.e., the weight and inertial forces generated by the load. One can find many methods to design the controller transfer function K . Reference [33.19] describes the conditions for the closed-loop stability of such systems.

33.5 Applications of Intelligent Assist Device

The IAD was designed with one vision in mind: minimizing the risk of injuries associated with repeated maneuvers, and maximizing the throughput while maintaining robustness and user-friendliness. The IAD has been evaluated extensively for three applications: warehousing and distribution centers, auto-assembly plants, and delivery services. A study on warehousing maneuvers at distribution centers demonstrated that palletizing, depalletizing, loading and unloading trucks, and placing boxes on and off of conveyor belts are the most common maneuvers. Initial studies of the distribution centers demonstrated that objects to be maneuvered in warehouses and distribution centers are mostly boxes weighing less than 27 kg that require workers to maneuver them rapidly (sometimes up to 15 boxes a minute). The use of the IADs in warehouses would have a considerable impact on reducing injuries to the worker population because of the large number of warehouse workers. Figure 33.6 shows the use of the IAD in a distribution center during a depalletizing operation.

Studies of auto-assembly maneuvers revealed that the installation of batteries, gas tanks, bumpers, instrument panels, exhaust pipes, and prop shafts are important maneuvers that would benefit from IADs (Fig. 33.9). Various load interface subsystems must be employed for connection to various auto parts.

Postal services across the world use sacks and trays to hold letters, magazines, and small boxes. These sacks and trays, which are manually handled by mail handlers, are usually fully filled with magazine bundles, envelopes and parcels, and can weigh up to 32 kg. In general, at all distribution centers, several factors contribute to the cre-

Fig. 33.9a,b The use of IADs for mail and package delivery service (a) and automobile industries (b)

ation of awkward and uncomfortable handling situations for mail handlers:

- the heavy weight of the sacks and letter trays and letter tubs
- the lack of handles, eyelets or any other helpful operator interface on the sacks and parcels
- the unpredictable shape, size, and weight of the sacks and letter trays and letter tubs at a work station

Intelligent assist devices greatly reduce the risk of back injuries when used by workers performing repetitive maneuvers. This reduction in injury, in turn, will greatly reduce the national cost of treating back injuries. See [33.35] and [33.36] for end-effectors that are designed for grasping postal sacks.

33.6 Lower-Extremity Exoskeleton

The first field-operational lower-extremity exoskeleton (commonly referred to as BLEEX) is comprised of two powered anthropomorphic legs, a power unit, and

a backpack-like frame on which a variety of heavy loads can be mounted. This system provides its pilot (i.e., the wearer) with the ability to carry significant loads

on his/her back with minimal effort over any type of terrain. **BLEEX** allows the pilot to comfortably squat, bend, swing from side to side, twist, and walk on ascending and descending slopes, while also offering the ability to step over and under obstructions while carrying equipment and supplies. Because the pilot can carry significant loads for extended periods of time without reducing his/her agility, physical effectiveness increases significantly with the aid of this class of lower-extremity exoskeletons. In order to address issues of field robustness and reliability, **BLEEX** is designed such that, in the case of power loss (e.g., from fuel exhaustion), the exoskeleton legs can be easily removed and the remainder of the device can be carried like a standard backpack.

BLEEX was first unveiled in 2004, at UC Berkeley's Human Engineering and Robotics Laboratory. In this initial model, **BLEEX** offered a carrying capacity of 34 kg (75 lbs), with weight in excess of that allowance being supported by the pilot. **BLEEX**'s unique design offers an ergonomic, highly maneuverable, mechanically robust, lightweight, and durable outfit to

surpass typical human limitations. **BLEEX** has numerous potential applications; it can provide soldiers, disaster relief workers, wildfire fighters, and other emergency personnel with the ability to carry heavy loads such as food, rescue equipment, first-aid supplies, communications gear, and weaponry, without the strain typically associated with demanding labor. Unlike unrealistic fantasy-type concepts fueled by movie-makers and science-fiction writers, the lower-extremity exoskeleton conceived at Berkeley is a practical, intelligent, load-carrying robotic device. It is our vision that **BLEEX** will provide a versatile and realizable transport platform for mission-critical equipment.

The effectiveness of the lower-extremity exoskeleton stems from the combined benefit of the human intellect provided by the pilot and the strength advantage offered by the exoskeleton; in other words, the human provides an intelligent control system for the exoskeleton while the exoskeleton actuators provide most of the strength necessary for walking. The control algorithm ensures that the exoskeleton moves in concert with the pilot with minimal interaction force between the two. The control scheme needs no direct measurements from the pilot or the human-machine interface (e.g., no force sensors between the two); instead, the controller estimates, based on measurements from the exoskeleton only, how to move so that the pilot feels very little force. This control scheme, which has never before been applied to any robotic system, is an effective method of generating locomotion when the contact location between the pilot and the exoskeleton is unknown and unpredictable (i.e., the exoskeleton and the pilot are in contact in variety of places). This control method differs from compliance control methods [33.27,28] employed for upper-extremity exoskeletons [33.17,21] and haptic systems [33.18,19] because it requires no force sensor between the wearer and the exoskeleton.

The basic principle for the control of an exoskeleton rests on the notion that the exoskeleton needs to shadow the wearer's voluntary and involuntary movements quickly, and without delay. This requires a high level of sensitivity in response to all forces and torques on the exoskeleton, particularly the forces imposed by the pilot. Addressing this need involves a direct conflict with control science's goal of minimizing system sensitivity in the design of a closed-loop feedback system. If fitted with a low sensitivity, the exoskeleton would not move in concert with its wearer. One should realize, however, that maximizing system sensitivity to external forces and torques leads to a loss of robustness in the system.

Fig. 33.10 Berkeley lower-extremity exoskeleton (**BLEEX**) and pilot Ryan Steger. 1: The load occupies the upper portion of the backpack and around the power unit; 2: rigid connection of the **BLEEX** spine to the pilot's vest; 3: the power unit and central computer occupies the lower portion of the backpack; 4: semirigid vest connecting **BLEEX** to the pilot; 5: one of the hydraulic actuators; 6: rigid connection of the **BLEEX** feet to the pilot's boots

Taking into account this new approach, the goal is to develop a controller for the exoskeleton with high sensitivity. One is faced with two realistic concerns; the first was that an exoskeleton with high sensitivity to external forces and torques would respond to other external forces not initiated by its pilot, for example, if someone pushed against an exoskeleton that had high sensitivity, the exoskeleton would move just as it would in response to forces from its pilot. Although the fact that it does not stabilize its behavior on its own in response to other forces may sound like a serious problem, if it did (e.g., using a gyro) the pilot would receive motion from the exoskeleton unexpectedly and would have to struggle with it to avoid unwanted movement. The key to

stabilizing the exoskeleton and preventing it from falling in response to external forces depends on the pilot's ability to move quickly (e.g., step back or sideways) to create a stable situation for himself and the exoskeleton. For this, a very wide control bandwidth is needed so that the exoskeleton can respond to both pilot's voluntary and involuntary movements (i.e., reflexes).

The second concern is that systems with high sensitivity to external forces and torques are not robust to variations and therefore the precision of the system performance will be proportional to the precision of the exoskeleton dynamic model. Various experimental systems in Berkeley have proved the overall effectiveness of the control method in shadowing the pilot's movement.

33.7 The Control Scheme of an Exoskeleton

The control of the exoskeleton is motivated here through the simple one-degree-of-freedom (1-DOF) example shown in Fig. 33.11. This figure schematically depicts a human leg attached or interacting with a 1-DOF exoskeleton leg in a swing configuration (no interaction with the ground). For simplicity, the exoskeleton leg is shown as a rigid link pivoting about a joint and powered by a single actuator. The exoskeleton leg in this example has an actuator that produces a torque about pivot point A.

Although the pilot is securely attached to the exoskeleton at the foot, other parts of the pilot leg, such as the shanks and thighs, can contact the exoskeleton and impose forces and torques on the exoskeleton leg. The location of the contacts and the direction of the contact forces (and sometimes contact torques) vary and are

therefore considered unknown values in this analysis. In fact, one of the primary objectives in designing BLEEX was to ensure a pilot's unrestricted interaction with the exoskeleton. The equivalent torque on the exoskeleton leg, resulting from the pilot's applied forces and torques, is represented by d .

In the absence of gravity, (33.9) and the block diagram of Fig. 33.12 represent the dynamic behavior of the exoskeleton leg regardless of any kind of internal feedback the actuator may have

$$v = Gr + Sd, \quad (33.9)$$

where G represents the transfer function from the actuator input r to the exoskeleton angular velocity v (the actuator dynamics are included in G). In the case where multiple actuators produce controlled torques on the system, r is the vector of torques imposed on the exoskeleton by the actuators. The form of G and the type of internal feedback for the actuator is immaterial for the discussion here. Also bear in mind the omission of the Laplace operator in all equations for the sake of compactness.

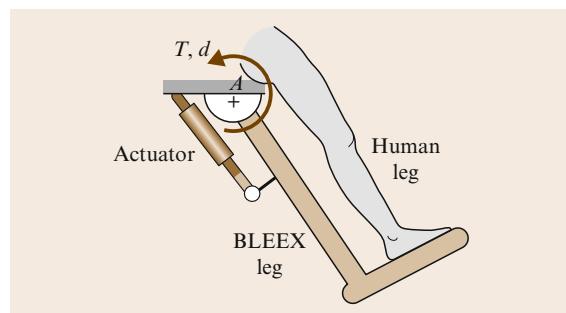

Fig. 33.11 Simple one-DOF exoskeleton leg interacting with the pilot leg. The exoskeleton leg has an actuator that produces a torque T about the pivot point A. The total equivalent torque associated with all forces and torques from the pilot on the exoskeleton is represented by d

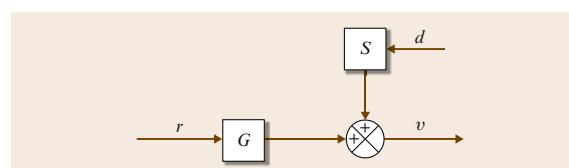

Fig. 33.12 The exoskeleton's angular velocity is shown as a function of the input to the actuators and the torques imposed by the pilot on the exoskeleton

The exoskeleton velocity, as shown by (33.9), is affected by forces and torques from its pilot. The sensitivity transfer function, S , represents how the equivalent human torque affects the exoskeleton angular velocity; S maps the equivalent pilot torque d onto the exoskeleton velocity v . If the actuator already has some sort of primary stabilizing controller, the magnitude of S will be small and the exoskeleton will only have a small response to the imposed forces and torques from the pilot or any other source. For example, a high-gain velocity controller in the actuator results in small S , and consequently a small exoskeleton response to forces and torques. Also, non-back-drivable actuators (e.g., large transmission ratios or servo-valves with overlapping spools) result in a small S , which leads to a correspondingly small response to pilot forces and torques.

Note that d (the resulting torque from pilot on the exoskeleton) is not an exogenous input; it is a function of the pilot dynamics and variables such as position and velocity of the pilot and the exoskeleton legs. These dynamics change from person to person, and within a person as a function of time and posture. It is assumed that d is only from the pilot and does not include any other external forces and torques.

The objective is to increase exoskeleton sensitivity to pilot forces and torques through feedback but without measuring d . Measuring d to create such systems develops several hard, but ultimately solvable, problems in the control of a lower-extremity exoskeleton. Some of those problems are briefly described below.

1. Depending on the architecture and the design of the exoskeleton, one needs to install several force and torque sensors to measure all forces from the pilot on the exoskeleton because the pilot is in contact with the exoskeleton at several locations. These locations are not known in advance. For example, we have found that some pilots are interested in having braces connecting an exoskeleton at the shanks while some are interested in having them on the thighs. Inclusion of sensors on a leg to measure all kinds of human forces and torques may result in a system suitable for a laboratory setting but not robust enough to be deployed in the field.
2. If the exoskeleton design is such that the forces and torques applied by the pilot on the exoskeleton are limited to a specified location (e.g., the pilot foot), the sensor that measures the pilot forces and torques will also inadvertently measure other forces and torques that are not intended for locomotion. This is a major difference between measuring forces

from, for example, the human hands, and measuring forces from the human lower limbs. Using our hands, we are able to impose controlled forces and torques on upper extremity exoskeletons and haptic systems with very few uncertainties. However, our lower limbs have other primary and nonvoluntary functions like load support that take priority over locomotion.

3. One option which was experimented with was the installation of sensing devices for forces on the bottom of the pilot's boots, where they are connected to the exoskeleton. Since the force on the bottom of the pilot's boot travels from heel to toe during normal walking, several sensors are required to measure the pilot force. Ideally, one would have a matrix of force sensors between the pilot and exoskeleton feet to measure the pilot forces at all locations and at all directions, though in practice, only a few sensors could be accommodated: at the toe, ball, midfoot, and the heel. Still, this option leads to thick and bulky soles.
4. The bottoms of the human boots experience cyclic forces and torques during normal walking that lead to fatigue and eventual sensor failure if the sensor is not designed and isolated properly.

For the above reasons and our experience in the design of various lower-extremity exoskeletons, it became evident that the existing state of technology in force sensing could not provide robust and repeatable measurement of the human lower limb force on the exoskeleton. Our goal then shifted to developing an exoskeleton with a large sensitivity to forces and torques from the operator using measurements only from the exoskeleton (i.e., no sensors on the pilot or the exoskeleton interface with the pilot). Creating a feedback loop from the exoskeleton variables only, as shown in Fig. 33.13 the new closed-loop sensitivity transfer function is presented in (33.10).

$$S_{\text{NEW}} = \frac{v}{d} = \frac{S}{1 + GC}. \quad (33.10)$$

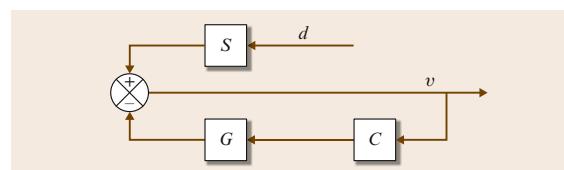

Fig. 33.13 The feedback control loop added to block diagram of Fig. 33.12; C is the controller operating only on the exoskeleton variables

Observation of (33.10) reveals that $S_{\text{NEW}} \leq S$, and therefore any negative feedback from the exoskeleton leads to an even smaller sensitivity transfer function. With respect to (33.10), our goal is to design a controller for a given S and G such that the closed-loop response from d to v (the new sensitivity function as given by (33.10)) is greater than the open-loop sensitivity transfer function (i.e., S) within some bounded frequency range. This design specification is given by inequality (33.11)

$$|S_{\text{NEW}}| > |S|, \quad \forall \omega \in (0, \omega_0), \quad (33.11)$$

or alternatively

$$|1 + GC| < 1 \quad \forall \omega \in (0, \omega_0), \quad (33.12)$$

where ω_0 is the exoskeleton maneuvering bandwidth.

In classical and modern control theory, every effort is made to minimize the sensitivity function of a system to external forces and torques. But for exoskeleton control, one requires a totally opposite goal: *to maximize the sensitivity of the closed-loop system to forces and torques*. In classical servo problems, negative feedback loops with large gains generally lead to small sensitivity within a bandwidth, which means that they reject forces and torques (usually called disturbances). However, the above analysis states that the exoskeleton controller needs a large sensitivity to forces and torques.

To achieve a large sensitivity function, it is suggested that one uses the inverse of the exoskeleton dynamics as a positive feedback controller so that the loop gain for the exoskeleton approaches unity (slightly less than 1). Assuming positive feedback, (33.10) can be written as

$$S_{\text{NEW}} = \frac{v}{d} = \frac{S}{1 - GC}. \quad (33.13)$$

If C is chosen to be $C = 0.9G^{-1}$, then the new sensitivity transfer function is $S_{\text{NEW}} = 10S$ (ten times the force amplification). In general we recommend the use of positive feedback with a controller chosen as:

$$C(1 - \alpha^{-1})G^{-1}, \quad (33.14)$$

where α is the amplification number greater than unity (for the above example, $\alpha = 10$ led to the choice of $C = 0.9G^{-1}$). Equation (33.14) simply states that a positive-feedback controller needs to be chosen as the inverse dynamics of the system dynamics scaled down by $(1 - \alpha^{-1})$. Note that (33.14) prescribes the controller in the absence of unmodeled high-frequency exoskeleton dynamics. In practice, C also includes a unity-gain low-pass filter to attenuate the unmodeled high-frequency exoskeleton dynamics.

The above method works well if the system model (i.e., G) is well known to the designer. If the model is not well known, then the system performance will differ greatly from the one predicted by (33.13), and in some cases instability will occur. The above simple solution comes with an expensive price: robustness to parameter variations. In order to get the above method working, one needs to know the dynamics of the system well, to understand the dynamics of the exoskeleton quite well, as the controller is heavily model based. One can see this problem as a tradeoff: the design approach described above requires no sensor (e.g., force or EMG) in the interface between the pilot and the exoskeleton; one can push and pull against the exoskeleton in any direction and at any location without measuring any variables on the interface. However, the control method requires a very good model of the system. At this time, the experiments with the exoskeleton have shown that this control scheme – which does not stabilize the exoskeleton – forces the system to follow wide-bandwidth human maneuvers while carrying heavy loads. We have come to believe, to rephrase Friedrich Nietzsche, that *that which does not stabilize, will only make us stronger*. Reference [33.37] describes a system identification method for BLEEX.

How does the pilot dynamic behavior affect the exoskeleton behavior? In our control scheme, there is no need to include the internal components of the pilot limb model; the detailed dynamics of nerve conduction, muscle contraction, and central nervous system processing are implicitly accounted for in constructing the dynamic model of the pilot limbs. The pilot force on the exoskeleton, d , is a function of both the pilot dynamics, H , and the kinematics of the pilot limb (e.g., velocity, position or a combination thereof). In general, H is determined primarily by the physical properties of the human dynamics. Here it is assumed H is a nonlinear operator representing the pilot impedance as a function of the pilot kinematics

$$d = -H(v). \quad (33.15)$$

The specific form of H is not known other than that it results in the human muscle force on the exoskeleton. Figure 33.14 represents the closed-loop system behavior when pilot dynamics is added to the block diagram of Fig. 33.13. Examining Fig. 33.14 reveals that (33.13), representing the new exoskeleton sensitivity function, is not affected by the feedback loop containing H .

Figure 33.14 shows an important characteristic of exoskeleton control. One can observe two feedback loops in the system. The upper feedback loop represents

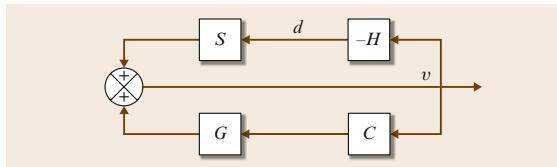

Fig. 33.14 Block diagram showing how an exoskeleton moves. The *upper loop* shows how the pilot moves the exoskeleton through applied forces. The *lower loop* shows how the controller drives the exoskeleton

how forces and torques from the pilot affect the exoskeleton. The lower loop shows how the controlled feedback loop affects the exoskeleton. While the lower feedback loop is positive (potentially destabilizing), the upper feedback loop stabilizes the overall system of pilot and exoskeleton taken as a whole. See [33.38] for detailed stability analysis where it can be seen that, unlike control methods utilized in the control of upper-extremity exoskeletons [33.19], the human dynamics in the control method described here has little potential to destabilize the system. Even though the feedback loop containing C is positive, the feedback loop containing H stabilizes the overall system of pilot and exoskeleton.

The above discussion motivated the design philosophy using a 1-DOF system. An exoskeleton, as shown is a system with many degrees of freedom and therefore implementation of the controller needs further attention. Below we extend the above control technique to the single support phase only. Refer to [33.38] and [33.39] for more details associated with multivariable control.

In the single support phase, the exoskeleton system is modeled as the seven-DOF serial link mechanism in the sagittal plane shown in Fig. 33.15. The inverse dynamics of the exoskeleton can be written in the general form as:

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + P(\theta) = T + d, \quad (33.16)$$

where $\theta = (\theta_1 \theta_2 \dots \theta_7)^\top$ and $T = (0, T_1 T_2 \dots T_6)^\top$.

M is a 7×7 inertia matrix and is a function of θ , $C(\theta, \dot{\theta})$ is a 7×7 centripetal and Coriolis matrix and is a function of θ and $\dot{\theta}$, and P is a 7×1 vector of gravitational torques and is a function of θ only. T is the 7×1 actuator torque vector with its first element set to zero since there is no actuator associated with joint angle θ_1 (i.e., angle between the exoskeleton foot and the ground); d is the effective 7×1 torque vector imposed by the pilot on the exoskeleton at various locations. According to (33.14), we choose the controller to be the exoskeleton inverse dynamics scaled by $(1 - \alpha^{-1})$, where α is

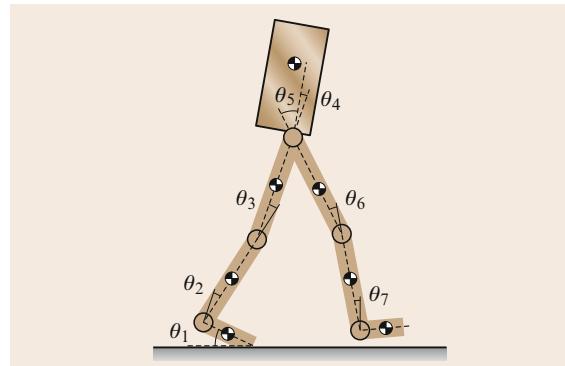

Fig. 33.15 Sagittal plane representation of the exoskeleton in the single stance phase. The *torso* includes the combined exoskeleton torso mechanism, payload, control computer, and power source

the amplification number

$$T = \hat{P} + (1 - \alpha^{-1})[\hat{M}(\theta)\ddot{\theta} + \hat{C}(\theta, \dot{\theta})\dot{\theta}], \quad (33.17)$$

$\hat{C}(\theta, \dot{\theta})$, $\hat{P}(\theta)$ and $\hat{M}(\theta)$ are the estimates of the Coriolis matrix, gravity vector, and the inertia matrix, respectively, for the system shown in Fig. 33.15. Note that (33.17) results in a 7×1 actuator torque. Since there is no actuator between the exoskeleton foot and the ground, the torque prescribed by the first element of T must be provided by the pilot. Substituting T from (33.17) into (33.16) yields,

$$\begin{aligned} & M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + P(\theta) \\ &= \hat{P}(\theta) + (1 - \alpha^{-1})[\hat{M}(\theta)\ddot{\theta} + \hat{C}(\theta, \dot{\theta})\dot{\theta}] + d. \end{aligned} \quad (33.18)$$

In the limit when $M(\theta) = \hat{M}(\theta)$, $C(\theta, \dot{\theta}) = \hat{C}(\theta, \dot{\theta})$, $P(\theta) = \hat{P}(\theta)$, and α are sufficiently large, d will approach zero, meaning the pilot can walk as if the exoskeleton did not exist. However, it can be seen from (33.18) that the force felt by the pilot is a function of α and the accuracy of the estimates $\hat{C}(\theta, \dot{\theta})$, $\hat{P}(\theta)$, and $\hat{M}(\theta)$. In general, the more accurately the system is modeled, the less the human force, d , will be. In the presence of variations in abduction–adduction angles, only $P(\theta)$ in (33.16) and (33.17) needs to be modified.

Exoskeleton systems use multivariable nonlinear algorithm to robustly control their behavior. Since all computations required to implement the control are conducted on a single computer, one needs a control platform to minimize the number of signal wires in the system. See [33.40] and [33.41] for a novel control platform.

33.8 Highlights of the Lower-Extremity Design

In designing an exoskeleton, several factors had to be considered: Firstly, the exoskeleton needed to exist in the same workspace of the pilot without interfering with his motion. Secondly, it had to be decided whether the exoskeleton should be anthropomorphic (i.e., kinematically

matching), or non-anthropomorphic (i.e., kinematically matching the operator only at the connection points between human and machine). Berkeley ultimately selected the anthropomorphic architecture because of its transparency to the pilot. It is also concluded that an exoskeleton that kinematically matches the wearer's legs gains the most psychological acceptance by the user and is therefore safer to wear. Consequently, the exoskeleton was designed to have the same degrees of freedom as the pilot: three degrees at the ankle and the hip, and one degree at the knee. This architecture also allowed the appropriately scaled clinical human walking data to be employed for the design of the exoskeleton components, including the workspace, actuators, and the power source.

A study of clinical gait analysis (CGA) data provides evidence that humans expend the most power through the sagittal plane joints of the ankle, knee, and hip while walking, squatting, climbing stairs, and most other common maneuvers. For this reason, the sagittal-plane joints of the first prototype exoskeleton are powered. However, to save energy, the nonsagittal degrees of freedom at the ankle and hip remain unpowered. This compels the pilot to provide the force to maneuver the exoskeleton abduction and rotation, where the required operational forces are smaller. To reduce the burden on the human operator further, the unactuated degrees of freedom are spring loaded to a neutral standing position.

Human joint angles and torques for a typical walking cycle were obtained in the form of independently collected CGA data. CGA angle data is typically collected via human video motion capture. CGA torque data is calculated by estimating limb masses and inertias and applying dynamic equations to the motion data. Given the variations in individual gait and measuring methods, three independent sources of CGA data [33.42–44] were utilized for the analysis and design of BLEEX. This data was modified to yield estimates of exoskeleton actuation requirements. The modifications included: (1) scaling the joint torques to a 75 kg person (the projected weight of the exoskeleton and its payload not including its pilot); (2) scaling the data to represent the walking speed of one cycle per second (or about 1.3 m/s); and (3) adding the pelvic tilt angle (or lower back angle depending on data available) to the hip angle to yield a single hip angle between the torso and the thigh, as shown in Fig. 33.16. This accounts for the reduced degrees of freedom of the exoskeleton. The following sections describe the use of CGA data and its implication for the exoskeleton design. The sign conventions used are shown in Fig. 33.16.

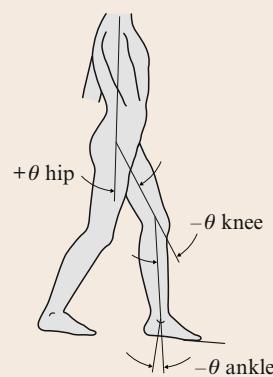

Fig. 33.16 Each joint angle is measured as the positive counterclockwise displacement of the distal link from the proximal link (zero in standing position) with the person oriented as shown. In the position shown, the hip angle is positive whereas both the knee and ankle angles are negative. Torque is measured as positive acting counterclockwise on the distal link

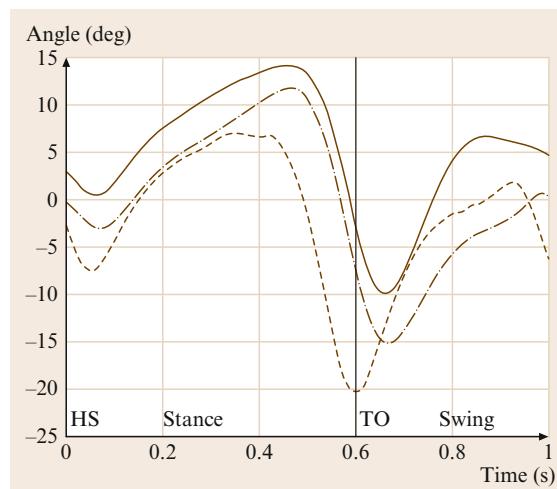

Fig. 33.17 Three sets of adjusted CGA data of the ankle flexion/extension angle. The minimum angle (extension) is $\approx -20^\circ$ and occurs just after toe-off. The maximum angle (flexion) is $\approx +15^\circ$ and occurs in late stance phase

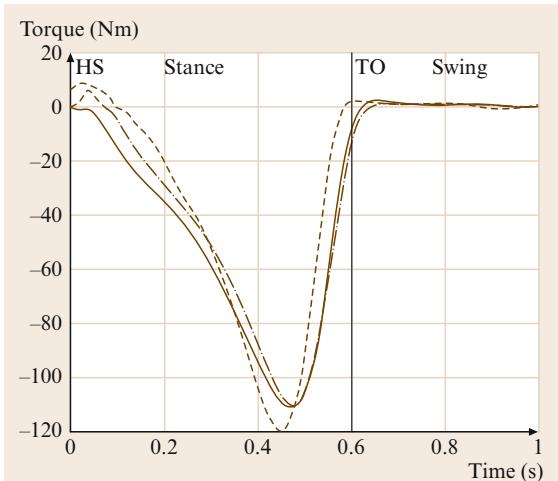

Fig. 33.18 Three sets of adjusted CGA data of the ankle flexion/extension torque. Peak negative torque (extension of the foot) is very large (≈ -120 Nm) and occurs in late stance phase. The ankle torque during swing is quite small

Figure 33.17 shows the CGA ankle angle data for a 75 kg human walking on flat ground at approximately 1.3 m/s versus time. Although Fig. 33.17 shows a small range of motion while walking (approximately -20° to $+15^\circ$), greater ranges of motion are required for other movements. An average person can flex their ankles anywhere from -38° to $+35^\circ$. The exoskeleton ankle was chosen to have a maximum flexibility of $\pm 45^\circ$ to compensate for the lack of several smaller degrees of freedom in the exoskeleton foot. Through all plots, TO stands for *toe-off* and HS stands for *heel-strike*.

Figure 33.18 shows the adjusted CGA data of the ankle flexion/extension torque. The ankle torque is almost entirely negative, making unidirectional actuators an ideal actuation choice. This asymmetry also implies a preferred mounting orientation for asymmetric actuators (one sided hydraulic cylinders). Conversely, if symmetric bidirectional actuators are considered, spring loading would allow the use of low-torque-producing actuators. Although the ankle torque is large during stance, it is negligible during swing. This suggests a system that disengages the ankle actuators from the exoskeleton during swing to save power.

The instantaneous ankle mechanical power (shown in Fig. 33.19) is calculated by multiplying the joint angular velocity (derived from Fig. 33.17) and the instantaneous joint torque (Fig. 33.18). The ankle absorbs energy during the first half of the stance phase and releases energy just before toe off. The average ankle

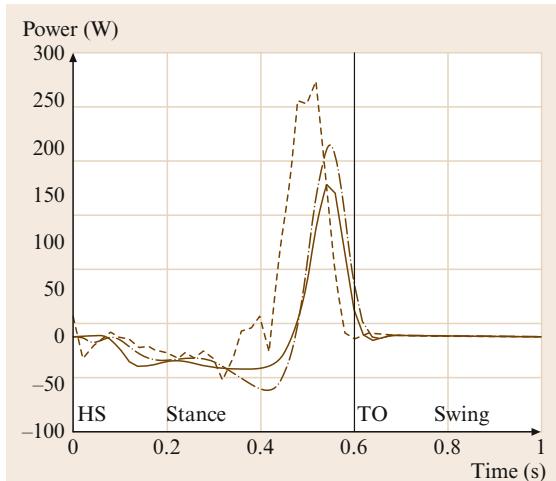

Fig. 33.19 Three sets of adjusted CGA data of the ankle flexion/extension instantaneous mechanical power. The average ankle power is positive, indicating that the ankle does positive work and requires actuation

power is positive, indicating that power production is required at the ankle.

Similar analyses were carried out for the knee and the hip [33.45] and [33.46]. The required knee torque has both positive and negative components, indicating the need for a bidirectional actuator. The highest peak torque is extension in early stance (≈ 60 Nm); hence asymmetric actuators should be biased to provide greater extension torque. The hip torque is relatively symmetric (-80 to $+60$ Nm); hence a bidirectional hip actuator is required. Negative extension torque is required in early stance as the hip supports the load on the stance leg.

Hip torque is positive in late stance and early swing as the hip propels the leg forward during swing. In late swing, the torque goes negative as the hip decelerates the leg prior to heel strike.

CGA data, which provided torque and speed information at each joint of a 75 kg person, was also used to size the exoskeleton power source. The information suggested that a typical person uses about 0.25 HP (185 W) to walk at an average speed of 3 mph. This figure, which represents the average product of speed and torque, is an expression of the purely mechanical power exhibited at the legs during walking. Since it is assumed that the exoskeleton is similar to a human in terms of geometry and weight, one of the key design objectives turned out to be designing a power unit and actuation system to deliver about 0.25 HP at the exoskeleton joints.

Table 33.1 BLEEX joint ranges of motion

| | Human walking maximum (degrees) | BLEEX maximum (degrees) | Average military male maximum (degrees) |
|-------------------------|----------------------------------------|--------------------------------|------------------------------------------------|
| Ankle flexion | 14.1 | 45 | 35 |
| Ankle extension | 20.6 | 45 | 38 |
| Ankle abduction | not available | 20 | 23 |
| Ankle adduction | not available | 20 | 24 |
| Knee flexion | 73.5 | 121 | 159 |
| Hip flexion | 32.2 | 121 | 125 |
| Hip extension | 22.5 | 10 | not available |
| Hip abduction | 7.9 | 16 | 53 |
| Hip adduction | 6.4 | 16 | 31 |
| Total rotation external | 13.2 | 35 | 73 |
| Total rotation internal | 1.6 | 35 | 66 |

The BLEEX kinematics are close to human leg kinematics, so the BLEEX joint ranges of motion are determined by examining human joint ranges of motion. At the very least, the BLEEX joint range of motion should be equal to the human range of motion during walking (shown in column 1 in Table 33.1), which can be found by examining CGA data [33.42–44]. Safety dictates that the BLEEX range of motion should not be more than the operator's range of motion (shown in column 3 of Table 33.1). For each degree of freedom, the second column of Table 33.1 lists the BLEEX range of motion which is in general larger than the human range of motion during walking and less than the maximum range of human motion.

The most maneuverable exoskeleton should ideally have ranges of motion slightly less than the human's maximum range of motion. However, BLEEX uses linear actuators, so some of the joint ranges of motion are reduced to prevent the actuators' axes of motion from passing through the joint center. If this had not been prevented, the joint could reach a configuration where the actuator would be unable to produce a torque about its joint. Additionally, all the joint ranges of motion were tested and revised during prototype testing. For example, mockup testing determined that the BLEEX ankle flexion/extension range of motion needs to be greater than the human ankle range of motion to accommodate the human foot's smaller degrees of freedom not modeled in the BLEEX foot.

It is natural to design a 3-DOF exoskeleton hip joint such that all three axes of rotation pass through the human ball-and-socket hip joint. However, through the design of several mockups and experiments, we learned that these designs have limited ranges of motion and result in singularities at some human hip postures.

Therefore the rotation joint was moved so it does not align with the human's hip joint. Initially the rotation joint was placed directly above each exoskeleton leg (labeled 'alternate rotation' in Fig. 33.20). This worked well for the lightweight plastic mockup, but created problems in the full-scale prototype because the high mass of the torso and payload created a large moment about the unactuated rotation joint. Therefore, the current hip rotation joint for both legs was chosen to be a single axis of rotation directly behind the person and under the torso (labeled 'current rotation' in Fig. 33.20). The current rotation joint is typically spring loaded towards its illustrated position using sheets of spring steel.

Like the human's ankle, the BLEEX ankle has three DOFs. The flexion/extension axis coincides with the human ankle joint. For design simplification, the abduction/adduction and rotation axes on the BLEEX ankle do not pass through the human's leg and form a plane outside of the human's foot (Fig. 33.21). To take load

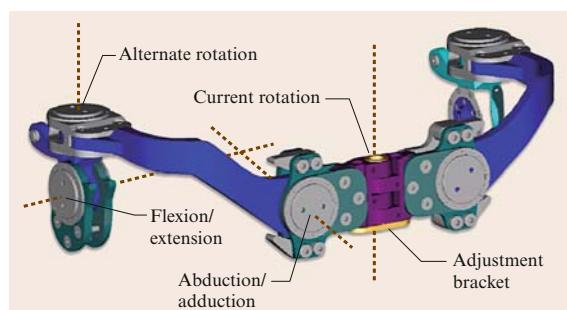

Fig. 33.20 The exoskeleton hip degrees of freedom (back view). Only the rotation axis does not pass through the human hip ball and socket joint. The adjustment bracket is replaceable to accommodate various sized operators

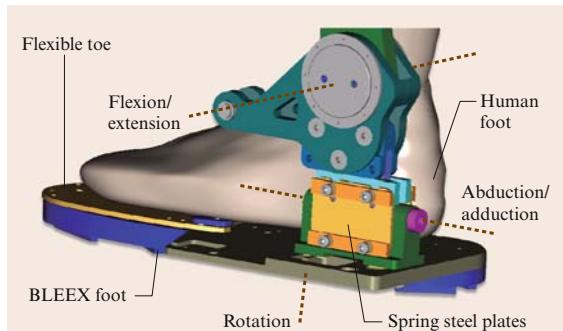

Fig. 33.21 The exoskeleton ankle degrees of freedom. Only the flexion/extension axis passes through the human's ankle joint. Abduction/adduction and rotation axes are not powered, but are equipped with appropriate impedances

off of the human's ankle, the **BLEEX** ankle abduction/adduction joint is sprung towards vertical, but the rotation joint is completely free. Additionally, the front of the exoskeleton foot, under the operator's toes, is compliant to allow the exoskeleton foot to flex with the human's foot. Since the human and exoskeleton leg kinematics are not exactly the same (merely similar), the human and exoskeleton are only rigidly connected at the extremities (feet and torso).

The **BLEEX** foot is a critical component due to its variety of functions.

- It measures the location of the foot's center of pressure and therefore identifies the foot's configuration on the ground. This information is necessary for **BLEEX** control.
- It measures the human's load distribution (how much of the human's weight is on each leg), which is also used in **BLEEX** control.

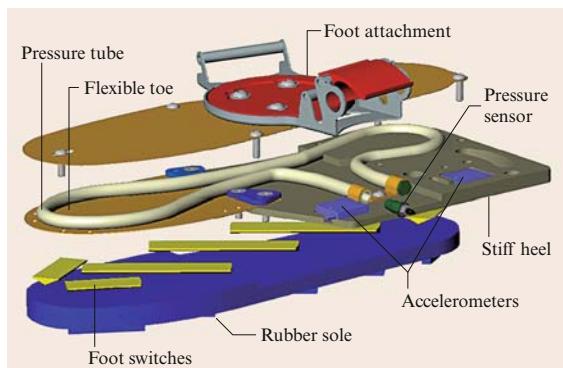

Fig. 33.22 **BLEEX** foot design (exploded view)

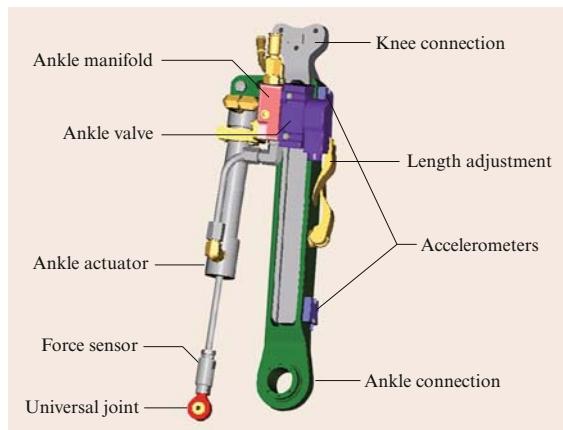

Fig. 33.23 **BLEEX** shank design

- It transfers **BLEEX**'s weight to the ground, so it must have structural integrity and exhibit long life in the presence of periodic environmental forces.
- It is one of two places where the human and exoskeleton are rigidly connected, so it must be comfortable for the operator.

As shown in Fig. 33.21, the main structure of the foot has a stiff heel to transfer the load to the ground and a flexible toe for comfort. The operator's boot rigidly attaches to the top of the exoskeleton foot via a quick-release binding. Along the bottom of the foot, switches detect which parts of the foot are in contact with the ground. For ruggedness, these switches are molded into a custom rubber sole. Also illustrated in Fig. 33.21 is the load distribution sensor, a rubber *pressure tube* filled with hydraulic oil and sandwiched between the human's

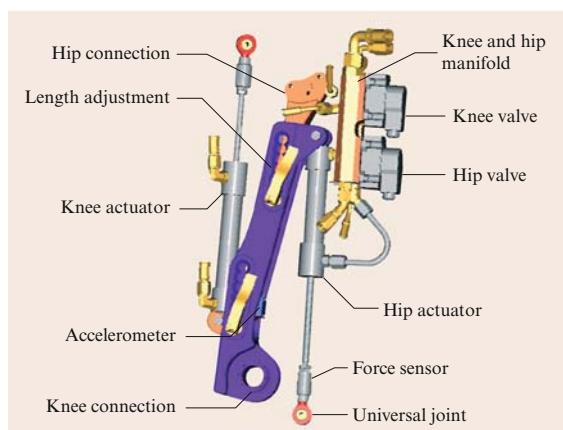

Fig. 33.24 **BLEEX** thigh design

foot and the main exoskeleton foot structure. Only the weight of the human (not the exoskeleton) is transferred onto the pressure tube and measured by the sensor. This sensor is used by the control algorithm to detect how much weight the human places on their left leg versus their right leg.

The main function of the BLEEX shank and thigh are for structural support and to connect the flexion/extension joints together (Figs. 33.23 and 33.24). Both the shank and thigh are designed to adjust to fit 90% of the population; they consist of two pieces that slide within each other and then lock at the desired length. To minimize the hydraulic routing, manifolds were designed to route the fluid between the valves, actuators, supply, and return lines. These manifolds mount directly to the cylinders to reduce the hydraulic distance between the valves and actuator, maximizing the actua-

tor's performance. The actuator, manifold, and valve for the ankle mount to the shank, while the actuators, manifold, and valves for the knee and hip are on the thigh. One manifold, mounted on the knee actuator, routes the hydraulic fluid for the knee and hip actuators.

Shown in Fig. 33.26, the BLEEX torso connects to the hip structure (shown in Fig. 33.20). The power supply [33.47–49], controlling computer, and payload mount to the rear side of the torso. An inclinometer mounted to the torso gives the absolute angle reference for the control algorithm. A custom harness (Fig. 33.27) mounts to the front of the torso to hold the exoskeleton to the operator. Besides the feet, the harness is the only other location where the user and exoskeleton are rigidly connected. Figure 33.26 also illustrates the actuator, valve, and manifold for the hip abduction/adduction joint.

33.9 Field-Ready Exoskeleton Systems

This section describes two field-ready exoskeletons developed by members of Berkeley Bionics in conjunction with researchers from the University of California.

Element on trails in the Rocky Mountains, and in the laboratory environment of the Natick Soldier Systems Center.

33.9.1 The ExoHiker Exoskeleton

The ExoHiker exoskeleton (shown in Fig. 33.25) was the first exoskeleton created by the team of Berkeley Bionics and the University of California, and was the first human exoskeleton in the world capable of rigorous customer evaluations as a load-carrying device. It was designed for carrying heavy backpacks for long missions with small changes in altitude. It weighs only 14.5 kg including a power unit and onboard computer. Its payload capacity is 90 kg while the wearer feels negligible load. The noise from this device is imperceptible. A production version of such an exoskeleton would be capable of traveling 68 km with 0.5 kg of batteries (lithium polymer) at an average speed 4.0 km/h while carrying a 68 kg backpack. When supplemented with a small solar panel, its mission time could be unlimited. The ExoHiker is adjustable to fit individuals ranging in height from approximately 1.65 m to 1.91 m tall. All control adjustments can be accessed by the user through a simple handheld liquid-crystal display (LCD) controller equipped with a graphical user interface menu system. This exoskeleton has been evaluated by the Special Operations Research Support

Fig. 33.25 The ExoHiker™ field-ready exoskeleton is suitable for small slopes and can carry a load of 90 kg (courtesy of Berkeley Bionics, Jan 2005)

Fig. 33.28 The ExoClimber™ field-ready exoskeleton is suitable for rapid ascent of stairs and steep slopes (courtesy of Berkeley Bionics, Oct 2005)

33.9.2 The ExoClimber Exoskeleton

This exoskeleton (shown in Fig. 33.28) is designed to allow rapid ascent of stairs and steep slopes while providing the same long term load carrying capability of ExoHiker. It weighs 23 kg including power source and onboard computer while its payload capacity is 90 kg. This exoskeleton is as loud as an office printer. Its battery requirements are the same as ExoHiker in all situations except ascending steep slopes. During a steep ascent, the ExoClimber is capable of ascending 300 m per 0.5 kg of battery added to the system (while carrying a 68 kg backpack). This exoskeleton has been evaluated by the Special Operations Research Support Element on trails in the Rocky Mountains, and in the laboratory environment of the Natick Soldier Systems Center. The evaluation included hiking on snow with and without snow shoes. The resulting report was extremely favorable, and during one experiment the distance an operator could walk with a 45 kg pack was increased by 900% using the ExoClimber.

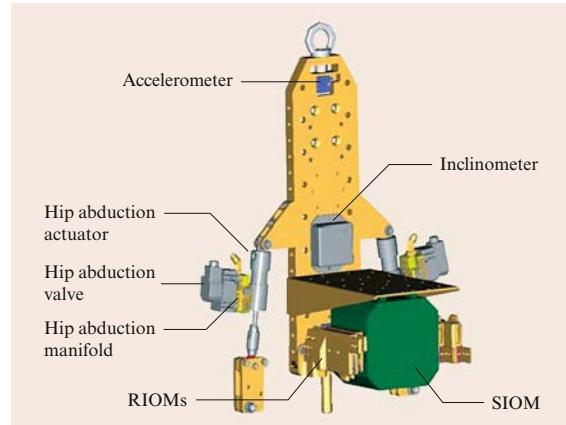

Fig. 33.26 BLEEX torso design (back view)

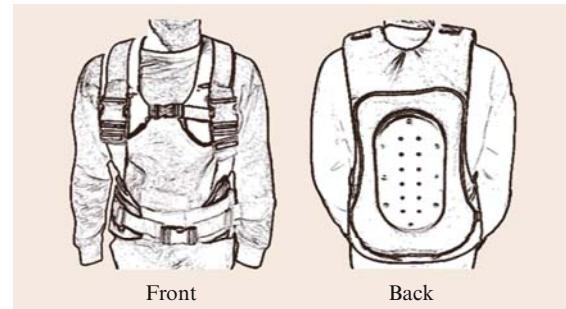

Fig. 33.27 The pilot vests in Fig. 33.10 are designed to distribute the BLEEX-pilot force uniformly on the pilot's upper body

The recent exoskeleton system from Berkeley Bionics now has two independent characteristics: (1) it increases its wearer's maximal load carrying capacity (68 kg to 90 kg), and (2) it decreases its wearer's metabolic cost. During some preliminary evaluations in late 2006 and early 2007, the oxygen consumption of the users walking at a speed of 3.2 km/h, was decreased by 5%–12% when using the latest exoskeleton without a payload. When the users carried a load, the effect was more pronounced. The oxygen consumption of these users carrying a load of 37 kg at a speed of 3.2 km/h was decreased by about 15% when using this exoskeleton. This is the very first exoskeleton in the world that has demonstrated a decrease in oxygen consumption of the user.

33.10 Conclusion and Further Reading

Exoskeleton technology is in its infancy. Although the exoskeleton systems in this analysis are generally considered robotics system worn by humans to carry loads, the reader should be aware that the field of medical orthotics also offers a wealth of knowledge and awareness associated with systems collaborating with patients either as rehabilitation devices or assist de-

vices. For examples of such systems, we invite the readers to see references [33.50, 51] associated with pneumatic ankle orthoses for rehabilitation. At this time, the most limiting issue in exoskeleton technology is the power supply and actuators. Without a viable power supply, exoskeleton systems will be limited to indoor applications.

Part E. Mobile Robotics started as a research domain in its own right in the late 1960s with the *Shakey* project at SRI. The seminal paper by N.J. Nilsson "A Mobile Automaton: An Application of Artificial Intelligence Techniques" at IJCAI 1969, already addressed perception, mapping, motion planning, and the notion of control architecture. Those issues would indeed be at the core of mobile robotics research for the following decades. The 1980s boomed with mobile robot projects, and as soon as it was necessary to cope with the reality of the physical world, problems appeared that fostered novel research directions, actually moving away from the original concept in which the robot was just an application of AI techniques. This part addresses all the issues that, put together, are necessary to build and control a mobile robot, except for the mechanical design itself.

Sensing as such is the subject of Part C but the use of sensing for environment mapping and robot localization, central to mobile robot navigation, are developed in this part in Chaps. 36 and 37, with very close links to estimation theory (Part A, Chap. 4). Several issues presented in the foundations (Part A) are revisited in this part and placed in the context and specificities of mobile robots, such as motion control (Chap. 6, Part A and Chap. 34 in this part). Motion planning is addressed in Part A, Chap. 5, whereas the specific problems of motion planning and obstacle avoidance are the subject of Chap. 35. A mobile robot is a system integrating sensing, decision making, and action. Therefore control architecture issues were very much developed in robotics through mobile robotics, often raising controversy. Chapter 38, focusing on behavior-based systems, should probably be read bearing in mind Chap. 8 (Part A) on robotic systems architectures and programming, and Chap. 9 (Part A) on AI reasoning and learning methods for robotics.

What happens when several mobile robots meet together? How does collective behavior emerge and how can it be controlled? These questions arose very early. Answers are developed in Chaps. 39, 40, and 41

With the development of mobile robots, control issues became a major concern when it appeared necessary to achieve smooth and efficient motion and to follow determined trajectories. In addition, the design of the locomotion structure of wheeled robots was often similar to that of a car, i.e., nonholonomic. Kinematics and control, which were essentially studied in manipulators, entered the field of mobile robotics. The techniques for steering control using mainly feedback control and linear control theory are presented in Chapter 34.

Chapter 35 addresses motion planning from the viewpoint of mobile robotics. In this context, nonholonomic kinematic constraints appeared as a major difficulty and differential geometry as a major tool for achieving the motions computed by classical motion planners. Another difference from classical motion planning addressed here is negotiating unknown or mobile obstacles in uncertain environments, which led to the development of approaches using sensor-based motion.

Mobile robot navigation requires building maps of the environment. The first question addressed in Chapter 36 is therefore: what representations are the most adequate, considering for example that on uneven terrain, the very notion of *obstacle* has a different meaning than indoors? And another question is: how should sensing uncertainties be processed? Furthermore, mobile robots need to map their environment incrementally, while moving in it. Hence partial representations, built from different positions, need to be fused together to construct a consistent map. This requires the robot to know those positions, which are only defined with respect to the environment map itself. Hence localization and mapping must be achieved simultaneously, and Chapter 37 overviews the techniques for solving this SLAM problem.

The mid 1980s was a very rich period for mobile robotics. It is then that three main topics were first addressed: SLAM, nonholonomy, and control architectures. Probably one of the most exciting controversies in the field was raised by Rodney Brooks' subsumption architecture which, by eliminating deliberative components from the architecture, became the paradigm for behavior-based robots. Chapter 38 discusses those architectural concepts.

This part includes three chapters on distributed robotics. Interaction among multiple mobile robots for achieving a common mission or for coordination, through direct or indirect communication, or even no communication at all, robot systems composed of a few machines or large swarms with emerging behaviors, and the underlying algorithms are described in Chapter 40. In that chapter, each robot has its own capacity and individual behavior. Can we design robots from other robots? Can robots reconfigure their own body? Can robots replicate? Chapter 39 overviews modular robots, i.e., robots built from interchangeable parts, that can reconfigure themselves according to the task, to the motion or situation.

Finally, with the development of miniaturization and wireless communication, the notion of distributed robots itself has taken another dimension. Robots can

be scattered everywhere and become pervasive. These new problems are the subject of [Chapter 41](#), which concludes this part.

As soon as technology enabled the design at an affordable cost of robots integrating sensing decision and

motion and as research results became available, potential applications in all domains became a serious investigation issue in numerous projects, as will be described in Part F.

34. Motion Control of Wheeled Mobile Robots

Pascal Morin, Claude Samson

This chapter may be seen as a follow up to Chap. 17, devoted to the classification and modeling of basic wheeled mobile robot (WMR) structures, and a natural complement to Chap. 35, which surveys motion planning methods for WMRs. A typical output of these methods is a feasible (or admissible) reference state trajectory for a given mobile robot, and a question which then arises is how to make the physical mobile robot track this reference trajectory via the control of the actuators with which the vehicle is equipped. The object of the present chapter is to bring elements of the answer to this question based on simple and effective control strategies. A first approach would consist in applying *open-loop* steering control laws like those developed in Chap. 35. However, it is well known that this type of control is not robust to modeling errors (the sources of which are numerous) and that it cannot guarantee that the mobile robot will move along the desired trajectory as planned. This is why the methods here presented are based on *feedback* control. Their implementation supposes that one is able to measure the variables involved in the control loop (typically the position and orientation of the mobile robot with respect to either a fixed frame or a path that the vehicle should follow). Throughout this chapter we will assume that these measurements are available continuously in time and that they are not corrupted by noise. In a general manner, robustness considerations will not be discussed in detail, one reason being that, beyond imposed space limitations, a large part of the presented approaches are based on linear control theory. The feedback control laws then inherit the strong robustness properties associated with stable linear systems.

34.1 Background

The control of wheeled mobile robots has been, and still is, the subject of numerous research studies. In particular, nonholonomy constraints associated with these systems have motivated the development of highly nonlinear control techniques. These approaches are addressed in the present chapter, but their exposition is deliberately limited in order to give priority to more classical techniques whose bases, both practical and theoretical, are better established.

For the sake of simplicity, the control methods are developed mainly for unicycle-type and car-like mobile robots, which correspond respectively to the types (2, 0) and (1, 1) in the classification proposed in Chap. 17. Most of the results can in fact be extended/adapted to other mobile robots, in particular to systems with trailers. We will mention the cases where such extensions are straightforward. All reported simulation results, illustrating various control problems and solutions, are carried out for a car-like vehicle, whose kinematics is slightly more complex than that of unicycle-type vehicles.

Recall (Fig. 34.1) that:

1. A *unicycle-type mobile robot* is schematically composed of two independent actuated wheels on a common axle whose direction is rigidly linked to the robot chassis, and one or several passively orientable—or caster—wheels, which are not controlled and serve for sustentation purposes.
2. A (rear-drive) *car-like mobile robot* is composed of a motorized wheeled axle at the rear of the chassis, and one (or a pair of) orientable front steering wheel(s).

Note also, as illustrated by the diagram below (Fig. 34.2), that a car-like mobile robot can be viewed (at least kinematically) as a unicycle-type mobile robot to which a trailer is attached.

Three generic control problems are studied in this chapter, as described below.

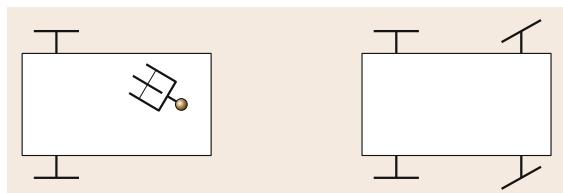

Fig. 34.1 Unicycle-type (left) and car-like (right) mobile robots

34.1.1 Path Following

Given a curve \mathcal{C} on the plane, a (nonzero) longitudinal velocity v_0 for the robot chassis, and a point P attached to the chassis, the goal is to have the point P follow the curve \mathcal{C} when the robot moves with the velocity v_0 . The variable that one has to stabilize at zero is thus the distance between the point P and the curve (i. e., the distance between P and the closest point M on \mathcal{C}). This type of problem typically corresponds to driving on a road while trying to maintain the distance between the vehicle chassis and the side of the road constant. Automatic wall following is another possible application.

34.1.2 Stabilization of Trajectories

This problem differs from the previous one in that the vehicle's longitudinal velocity is no longer predetermined because one also aims to monitor the distance gone along the curve \mathcal{C} . This objective supposes that the geometric curve \mathcal{C} is complemented with a time schedule, i. e., that it is parameterized with the time variable t . This boils down to defining a trajectory $t \mapsto (x_r(t), y_r(t))$ with respect to a reference frame \mathcal{F}_0 . Then the goal is to stabilize the position error vector $(x(t) - x_r(t), y(t) - y_r(t))$ at zero, with $(x(t), y(t))$ denoting the coordinates of point P in \mathcal{F}_0 at time t . The problem may also be formulated as one of controlling the vehicle in order to track a reference vehicle whose trajectory is given by $t \mapsto (x_r(t), y_r(t))$. Note that perfect tracking is achievable only if the reference trajectory is feasible for the physical vehicle, and that a trajectory which is feasible for a unicycle-type vehicle is not necessarily feasible for a car-like vehicle. Also, in addition to monitoring the position $(x(t), y(t))$ of the robot, one may be willing to control the chassis orientation $\theta(t)$ at a desired reference value $\theta_r(t)$ associated with the orientation of the reference vehicle. For a nonholonomic unicycle-type robot, a reference trajectory $(x_r(t), y_r(t), \theta_r(t))$ is feasible if it is produced by a reference vehicle which has the

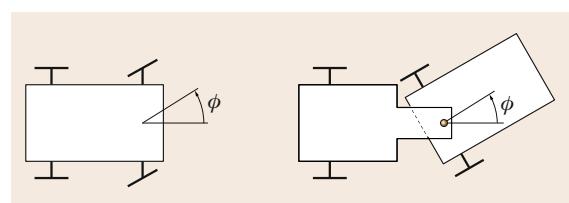

Fig. 34.2 Analogy car/unicycle with trailer

same kinematic limitations as the physical robot. For instance, most trajectories produced by an omnidirectional vehicle (omnibile vehicle in the terminology of Chap. 17) are not feasible for a nonholonomic mobile robot. However, nonfeasibility does not imply that the reference trajectory cannot be tracked in an approximate manner, i. e., with small (although nonzero) tracking errors. This justifies the introduction of the concept of *practical stabilization*, as opposed to *asymptotic stabilization* when the tracking errors converge to zero. The last part of this chapter will be devoted to a recent, and still prospective, control approach for the practical stabilization of trajectories which are not necessarily feasible.

34.1.3 Stabilization of Fixed Postures

Let \mathcal{F}_1 denote a frame attached to the robot chassis. In this chapter, we call a robot posture (or situation) the association of the position of a point P located on the robot chassis with the orientation $\theta(t)$ of \mathcal{F}_1 with respect to a fixed frame \mathcal{F}_0 in the plane of motion. For this last problem, the objective is to stabilize at zero the posture vector $\xi(t) = (x(t), y(t), \theta(t))$, with $(x(t), y(t))$ denoting the position of P expressed in \mathcal{F}_0 . Although a fixed desired (or reference) posture is obviously a particular case of a feasible trajectory, this problem cannot be solved by classical control methods.

The chapter is organized as follows. Section 34.2 is devoted to the choice of control models and the determination of modeling equations associated with the path-following control problem. In Sect. 34.3, the problems of path following and trajectory stabilization in position are studied under an assumption upon the location of the point P chosen on the robot chassis. This assumption implies that the motion of this point is not constrained. It greatly simplifies the resolution of the considered problems. However, a counterpart of this simplification is that the stability of the robot's orientation is not always guaranteed, in particular during phases when the sign of the robot's longitudinal velocity is not constant. The assumption upon P is removed in Sect. 34.4, and both problems are reconsidered, together with the problem of stabilizing a fixed posture. At the end of this section, a certain number of shortcomings and limitations inherent to the objective of asymptotic stabilization are pointed out. They can be circumvented by considering an objective of practical stabilization instead. Some elements of a recent, and still prospective, control approach developed with this point of view – based on the use of so-called *transverse functions* – are presented in the Sect. 34.4.6. Finally, a few complementary issues on the feedback control of mobile robots are briefly discussed in the concluding Sect. 34.5, with a list of commented references for further reading on WMRs motion control.

34.2 Control Models

34.2.1 Kinematics Versus Dynamics

Relation (17.29) in Chap. 17 provides a general configuration dynamic model for WMRs. Its particularization to the case of unicycle-type and car-like mobile robots gives

$$\mathbf{H}(\mathbf{q})\dot{\mathbf{u}} + \mathbf{F}(\mathbf{q}, \mathbf{u})\mathbf{u} = \boldsymbol{\Gamma}(\phi)\boldsymbol{\tau} \quad (34.1)$$

with \mathbf{q} denoting a robot's configuration vector, \mathbf{u} a vector of independent velocity variables associated with the robot's degrees of freedom, $\mathbf{H}(\mathbf{q})$ a reduced inertia matrix (which is invertible for any \mathbf{q}), $\mathbf{F}(\mathbf{q}, \mathbf{u})\mathbf{u}$ a vector of forces combining the contribution of Coriolis and wheel–ground contact forces, ϕ the orientation angle of the car's steering wheel, $\boldsymbol{\Gamma}$ an invertible control matrix (which is constant in the case of a unicycle-type vehicle), and $\boldsymbol{\tau}$ a vector of independent motor torques (whose dimension is equal to the number of degrees of freedom in the case of full actuation, i. e., equal to two for the

vehicles considered herein). In the case of a unicycle-type vehicle, a configuration vector is composed of the components of the chassis posture vector ξ and the orientation angles of the castor wheels (with respect to the chassis). In the case of a car-like vehicle, a configuration vector is composed of the components of ξ and the steering wheel angle ϕ .

To be complete, this dynamic model must be complemented with kinematic equations in the form (the relation (17.30))

$$\dot{\mathbf{q}} = \mathbf{S}(\mathbf{q})\mathbf{u} \quad (34.2)$$

from which one can extract a reduced kinematic model (the relation (17.33))

$$\dot{\mathbf{z}} = \mathbf{B}(\mathbf{z})\mathbf{u} \quad (34.3)$$

with $\mathbf{z} = \xi$, in the case of a unicycle-type vehicle, and $\mathbf{z} = (\xi, \phi)$ in the case of a car-like vehicle.

In the automatic control terminology, the complete dynamic model (34.1–34.2) forms a *control system* which can be written as $\dot{X} = f(X, \tau)$ with $X = (q, u)$ denoting the state vector of this system, and τ the vector of control inputs. The kinematic models (34.2) and (34.3) are also control systems with respective state vectors q and z and control vector u . Any of these models can be used for control design and analysis purposes. In the remainder of this chapter, we have chosen to work with the kinematic model (34.3). By analogy with the motion control of manipulator arms, this boils down to using a model with velocity control inputs, rather than a model with torque control inputs. The main reasons for this choice are the following:

1. The kinematic model is simpler than the dynamic one. In particular, it does not involve a certain number of matrix-valued functions whose precise determination relies on the knowledge of numerous parameters associated with the vehicle and its actuators (geometric repartition of constitutive bodies, masses and mass moments of inertia, coefficients of reduction in the transmission of torques produced by the motors, etc.). For many applications, it is not necessary to know all these terms precisely.
2. In the case of robots actuated with electrical motors, these motors are frequently supplied with *low-level* velocity control loops which take a desired angular velocity as input and stabilize the motor angular velocity at this value. If the regulation loop is efficient, the difference between the desired and actual velocities remains small, even when the desired velocity and the motor load vary continuously (at least within a certain range). This type of robustness allows in turn to view the desired velocity as a free control variable. Many controllers supplied with industrial manipulator arms are based on this principle.

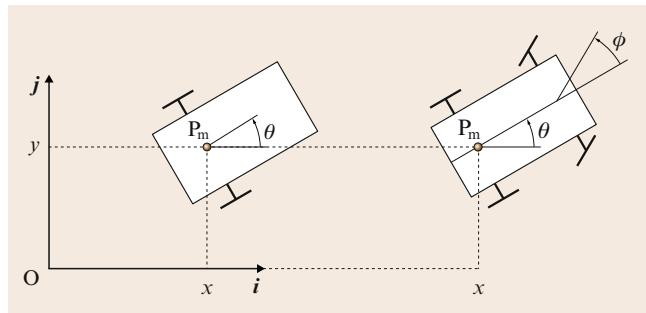

Fig. 34.3 Configuration variables

3. If the servo loops evoked above, whose role is to decouple the kinematics from the dynamics of the vehicle, are not present, one can design them and even improve their performance by using the information that one has of the terms involved in the dynamic equation (34.1). For instance, assume that the torques produced by the actuators can be used as control inputs, a simple way to proceed (at least theoretically) consists in applying the so-called *computed torque* method. The idea is to linearize the dynamic equation by setting

$$\tau = \Gamma(\phi)^{-1} [\mathbf{H}(q)\mathbf{w} + \mathbf{F}(q, u)u].$$

This yields the simple decoupled linear control system $\dot{\mathbf{u}} = \mathbf{w}$ with the variable \mathbf{w} , homogeneous to a vector of accelerations, playing the role of a new control input vector. This latter equation indicates that the problem of controlling the vehicle with motor torques can be brought back to a problem with acceleration control inputs. It is usually not difficult to deduce a control solution to this problem from a velocity control solution devised by using a kinematic model. For instance,

$$\mathbf{w} = -k(\mathbf{u} - \mathbf{u}^*(z, t))$$

$$+ \frac{\partial \mathbf{u}^*}{\partial z}(z, t) \mathbf{B}(z) \mathbf{u} + \frac{\partial \mathbf{u}^*}{\partial t}(z, t)$$

with $k > 0$ is a solution if \mathbf{u}^* is a differentiable kinematic solution and

$$\mathbf{u} = \mathbf{u}^*(z, t) + (\mathbf{u}(0) - \mathbf{u}^*(z_0, 0)) e^{-kt}$$

is also a solution.

For the unicycle-type mobile robot, the kinematic model (34.3) used from now on is

$$\begin{cases} \dot{x} = u_1 \cos \theta, \\ \dot{y} = u_1 \sin \theta, \\ \dot{\theta} = u_2, \end{cases} \quad (34.4)$$

where (x, y) represents the coordinates of the point P_m located at mid-distance of the actuated wheels, and the angle θ characterizes the robot's chassis orientation (Fig. 34.3). In this equation, u_1 represents the intensity of the vehicle's longitudinal velocity, and u_2 is the chassis instantaneous velocity of rotation. The variables u_1 and u_2 are themselves related to the angular velocity of the actuated wheels via the one-to-one relations

$$u_1 = \frac{r}{2}(\dot{\psi}_r + \dot{\psi}_\ell)$$

$$u_2 = \frac{r}{2R}(\dot{\psi}_r - \dot{\psi}_\ell)$$

with r the wheels' radius, R the distance between the two actuated wheels, and $\dot{\psi}_r$ (resp. $\dot{\psi}_l$) the angular velocity of the right (resp. left) rear wheel.

For the car-like mobile robot, the kinematic model (34.3) used from now on is

$$\begin{cases} \dot{x} = u_1 \cos \theta, \\ \dot{y} = u_1 \sin \theta, \\ \dot{\theta} = \frac{u_1}{L} \tan \phi, \\ \dot{\phi} = u_2, \end{cases} \quad (34.5)$$

where ϕ represents the vehicle's steering wheel angle, and L is the distance between the rear and front wheels' axles. In all forthcoming simulations, L is set equal to 1.2 m.

34.2.2 Modeling in a Frénet Frame

The object of this subsection is to generalize the previous kinematic equations when the reference frame is a Frénet frame. This generalization will be used later on when addressing the path following problem.

Let us consider a curve C in the plane of motion, as illustrated on Fig. 34.4, and let us define three frames \mathcal{F}_0 , \mathcal{F}_m , and \mathcal{F}_s , as follows. $\mathcal{F}_0 = \{0, \mathbf{i}, \mathbf{j}\}$ is a fixed frame, $\mathcal{F}_m = \{P_m, \mathbf{i}_m, \mathbf{j}_m\}$ is a frame attached to the mobile robot with its origin – the point P_m – located on the rear wheels axle, at the mid-distance of the wheels, and $\mathcal{F}_s = \{P_s, \mathbf{i}_s, \mathbf{j}_s\}$, which is indexed by the curve's curvilinear abscissa s , is such that the unit vector \mathbf{i}_s tangents C .

Consider now a point P attached to the robot chassis, and let (l_1, l_2) denote the coordinates of P expressed in the basis of \mathcal{F}_m . To determine the equations of motion of P with respect to the curve C let us introduce three variables s , d , and θ_e , defined as follows.

- s is the curvilinear abscissa at the point P_s obtained by projecting P orthogonally on C . This point exists and is unique if the point P is close enough to the curve. More precisely, it suffices that the distance between P and the curve be smaller than the lower bound of the curve radii. We will assume that this condition is satisfied.
- d is the ordinate of P in the frame \mathcal{F}_s ; its absolute value is also the distance between P and the curve.
- $\theta_e = \theta - \theta_s$ is the angle characterizing the orientation of the robot chassis with respect to the frame \mathcal{F}_s .

Let us now determine \dot{s} , \dot{d} , and $\dot{\theta}_e$. By definition of the curvature $c(s)$ of C at P_s , i.e., $c(s) = \partial\theta_s/\partial s$, one

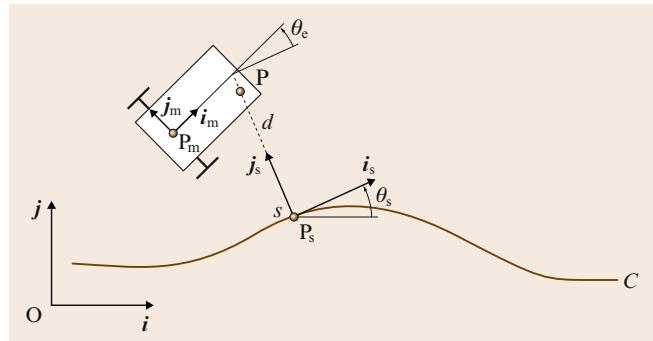

Fig. 34.4 Representation in a Frénet frame

deduces from (34.4) that

$$\dot{\theta}_e = u_2 - \dot{s}c(s). \quad (34.6)$$

Since $P_s P = d \mathbf{j}_s$, by using the equality $dOP_s/dt = \dot{s} \mathbf{i}_s$ it first emerges that

$$\begin{aligned} \frac{\partial \mathbf{OP}}{\partial t} &= \frac{\partial \mathbf{OP}_s}{\partial t} + \dot{d} \mathbf{j}_s - dc(s) \dot{s} \mathbf{i}_s \\ &= \dot{s}(1 - dc(s)) \mathbf{i}_s + \dot{d} \mathbf{j}_s. \end{aligned} \quad (34.7)$$

One also has $\mathbf{P}_m \mathbf{P} = l_1 \mathbf{i}_m + l_2 \mathbf{j}_m$. Since $d\mathbf{OP}_m/dt = u_1 \mathbf{i}_m$, one gets

$$\begin{aligned} \frac{\partial \mathbf{OP}}{\partial t} &= \frac{\partial \mathbf{OP}_m}{\partial t} + l_1 u_2 \mathbf{j}_m - l_2 u_2 \mathbf{i}_m \\ &= (u_1 - l_2 u_2) \mathbf{i}_m + l_1 u_2 \mathbf{j}_m \\ &= (u_1 - l_2 u_2)(\cos \theta_e \mathbf{i}_s + \sin \theta_e \mathbf{j}_s) \\ &\quad + l_1 u_2(-\sin \theta_e \mathbf{i}_s + \cos \theta_e \mathbf{j}_s) \\ &= [(u_1 - l_2 u_2) \cos \theta_e - l_1 u_2 \sin \theta_e] \mathbf{i}_s \\ &\quad + [(u_1 - l_2 u_2) \sin \theta_e + l_1 u_2 \cos \theta_e] \mathbf{j}_s. \end{aligned} \quad (34.8)$$

By forming the scalar products of the vectors in (34.7) and (34.8) with \mathbf{i}_s and \mathbf{j}_s , and by using (34.6), one finally obtains the following system of equations:

$$\begin{cases} \dot{s} = \frac{1}{1 - dc(s)} [(u_1 - l_2 u_2) \cos \theta_e - l_1 u_2 \sin \theta_e], \\ \dot{d} = (u_1 - l_2 u_2) \sin \theta_e + l_1 u_2 \cos \theta_e, \\ \dot{\theta}_e = u_2 - \dot{s}c(s). \end{cases} \quad (34.9)$$

These equations are a generalization of (34.4). To verify this, it suffices to take P as the origin of the frame \mathcal{F}_m (i.e., $l_1 = l_2 = 0$) and identify the axis (O, \mathbf{i}) of the frame \mathcal{F}_0 with the curve C . Then $s = x$, $c(s) = 0$ ($\forall s$), and, by setting $y \equiv d$ and $\theta \equiv \theta_e$, one recovers (34.4) exactly.

For car-like vehicles, one easily verifies, by using (34.5), that the system (34.9) becomes

$$\begin{cases} \dot{s} = \frac{u_1}{1-dc(s)} \left[\cos \theta_e - \frac{\tan \phi}{L} (l_2 \cos \theta_e + l_1 \sin \theta_e) \right], \\ \dot{d} = u_1 \left[\sin \theta_e + \frac{\tan \phi}{L} (l_1 \cos \theta_e - l_2 \sin \theta_e) \right], \\ \dot{\theta}_e = \frac{u_1}{L} \tan \phi - \dot{s} c(s), \\ \dot{\phi} = u_2, \end{cases} \quad (34.10)$$

(it suffices to replace $u_2 = \dot{\theta}$ in (34.9) by the new value of $\dot{\theta}$: $(u_1 \tan \phi)/L$). To summarize, we have shown the following result.

Proposition 34.1

The kinematic equations of unicycle-type and car-like vehicles, expressed with respect to a Frénet frame, are given by the systems (34.9) and (34.10), respectively.

34.3 Adaptation of Control Methods for Holonomic Systems

We address in this section the problems of trajectory stabilization and path following. When we defined these problems in the introduction, we considered a reference point P attached to the robot chassis. It turns out that the choice of this point is important. Indeed, consider for instance the equations (34.9) for a unicycle point P when \mathcal{C} is the axis (O, i) . Then, $s = x_p$, $d = y_p$, and $\theta_e = \theta$ represent the robot's posture with respect to the fixed reference frame \mathcal{F}_0 . There are two possible cases depending on whether P is, or is not, located on the actuated wheels axle. Let us consider the first case, for which $l_1 = 0$. From the first two equations of (34.9), one has

$$\dot{x}_P = (u_1 - l_2 u_2) \cos \theta, \quad \dot{y}_P = (u_1 - l_2 u_2) \sin \theta.$$

These relations indicate that P can move only in the direction of the vector $(\cos \theta, \sin \theta)$. This is a direct consequence of the nonholonomy constraint to which the vehicle is subjected. Now, if P is not located on the wheels axle, then

$$\begin{pmatrix} \dot{x}_P \\ \dot{y}_P \end{pmatrix} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} 1 & -l_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}. \quad (34.11)$$

The fact that the two square matrices in the right-hand side of this equality are invertible indicates that \dot{x}_P and \dot{y}_P can take any values, and thus that the motion of P is not constrained. By analogy with holonomic manipulator arms, this means that P may be seen as the extremity of a two-degree-of-freedom (2-DOF) manipulator, and thus that it can be controlled by applying the same control laws as those used for manipulators. In this section, we assume that the point P, used to characterize the robot's position, is chosen away from the rear wheels axle. In this case we will see that the problems of trajectory stabilization and path following can be solved very

simply. However, as shown in the subsequent section, choosing P on the wheels axle may also be of interest in order to better control the vehicle's orientation.

34.3.1 Stabilization of Trajectories for a Nonconstrained Point

Unicycle

Consider a differentiable reference trajectory $t \mapsto (x_r(t), y_r(t))$ in the plane. Let $e = (x_p - x_r, y_p - y_r)$ denote the tracking error in position. The control objective is to asymptotically stabilize this error at zero. In view of (34.11), the error equations are

$$\dot{e} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} u_1 - l_2 u_2 \\ u_2 \end{pmatrix} - \begin{pmatrix} \dot{x}_r \\ \dot{y}_r \end{pmatrix}. \quad (34.12)$$

Introducing new control variables (v_1, v_2) defined by

$$\begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} u_1 - l_2 u_2 \\ u_2 \end{pmatrix} \quad (34.13)$$

the equations (34.12) become simply

$$\dot{e} = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} - \begin{pmatrix} \dot{x}_r \\ \dot{y}_r \end{pmatrix}.$$

The classical techniques of stabilization for linear systems can then be used. For instance, one may consider a proportional feedback control with precompensation such as

$$v_1 = \dot{x}_r - k_1 e_1 = \dot{x}_r - k_1 (x_p - x_r), \quad (k_1 > 0),$$

$$v_2 = \dot{y}_r - k_2 e_2 = \dot{y}_r - k_2 (y_p - y_r), \quad (k_2 > 0),$$

which yields the closed-loop equation $\dot{e} = -Ke$. Of course, this control can be rewritten for the initial control variables u , since the mapping $(u_1, u_2) \mapsto (v_1, v_2)$ is bijective.

Unicycle with Trailers

The previous technique extends directly to the case of a unicycle-type vehicle to which one or several trailers are hooked, provided that the point P is chosen away from the actuated wheels axle and on the side opposite to the trailers. Besides, it is preferable in practice that the robot's longitudinal velocity u_1 remains positive all the time in order to prevent the relative orientations between all vehicles (i.e., the non-actively controlled variables involved in the system's *zero dynamics*) to take overly large values (the jackknife effect). This issue will be discussed further in Sect. 34.4.

Car

This technique also extends to car-like vehicles by choosing a point P attached to the steering wheel frame and not located on the steering wheel axle.

34.3.2 Path Following with No Orientation Control

Unicycle

Let us adopt the notation of Fig. 34.4 to address the problem of following a path associated with a curve C in the plane. The control objective is to stabilize the distance d at zero. From (34.9), one has

$$\dot{d} = u_1 \sin \theta_e + u_2 (-l_2 \sin \theta_e + l_1 \cos \theta_e). \quad (34.14)$$

Recall that in this case the vehicle's longitudinal velocity u_1 is either imposed or prespecified. We will assume that the product $l_1 u_1$ is positive, i.e., the position of the point P with respect to the actuated wheels axle is chosen in relation to the sign of u_1 . This assumption will be removed in Sect. 34.4. To simplify, we will also assume that $l_2 = 0$, i.e., the point P is located on the axis (P_m, i_m) . Let us then consider the following feedback control law

$$u_2 = -\frac{u_1}{l_1 \cos \theta_e} \sin \theta_e - \frac{u_1}{\cos \theta_e} k(d, \theta_e) d \quad (34.15)$$

with k a continuous, strictly positive, function on $\mathbb{R} \times (-\pi/2, \pi/2)$ such that $k(d, \pm\pi/2) = 0$. Since $l_2 = 0$, applying the control (34.15) to (34.14) gives

$$\dot{d} = -l_1 u_1 k(d, \theta_e) d.$$

Since $l_1 u_1$ and k are strictly positive, this relation implies that $|d|$ is nonincreasing along any trajectory of the controlled system. For convergence of d to zero, it suffices that

1. the sign of u_1 remains the same,

2. $\pi/2 - |\theta_e(t)| > \epsilon > 0$ for all t , and

3.

$$\int_0^t |u_1(s)| ds \rightarrow +\infty \quad \text{when } t \rightarrow +\infty.$$

This latter condition is satisfied, for instance, when u_1 is constant. In this case, d converges to zero exponentially. There just remains to examine the conditions under which u_2 , as given by (34.15), is always defined. Since the function in the right-hand side of (34.15) is not defined when $\cos \theta_e = 0$, we are going to determine conditions on the system parameters and the initial state values the satisfaction of which implies that $\cos \theta_e$ cannot approach zero. To this purpose, let us consider the limit value of $\dot{\theta}_e$ when θ_e tends to $\pi/2$ (resp. $-\pi/2$) from below (resp. from above). By using (34.9), (34.15), and the fact that $l_2 = 0$, a simple calculation shows that

$$\begin{aligned} \dot{\theta}_e = u_1 & \left[-\frac{c(s)}{1-dc(s)} \cos \theta_e \right. \\ & - \left(1 + \frac{l_1 c(s)}{1-dc(s)} \sin \theta_e \right) \\ & \left. \times \left(\frac{\tan \theta_e}{l_1} + \frac{k(d, \theta_e) d}{\cos \theta_e} \right) \right]. \end{aligned}$$

Let us assume first that θ_e tends to $\pi/2$ from below. Then the sign of $\dot{\theta}_e$ is given, in the limit, by the sign of

$$-u_1 \left(1 + \frac{l_1 c(s)}{1-dc(s)} \right) \frac{1}{l_1}.$$

To prevent θ_e from reaching $\pi/2$ it suffices that this sign be negative. It is so if

$$\left| \frac{l_1 c(s)}{1-dc(s)} \right| < 1. \quad (34.16)$$

Now, if θ_e tends to $-\pi/2$ from above, the sign of $\dot{\theta}_e$ is given, in the limit, by the sign of

$$-u_1 \left(1 - \frac{l_1 c(s)}{1-dc(s)} \right) \left(\frac{-1}{l_1} \right).$$

To prevent θ_e from reaching $-\pi/2$ it suffices that this sign be positive, and such is the case if (34.16) is true. From this analysis one obtains the following proposition.

Proposition 34.2

Consider the path following problem for a unicycle-type mobile robot with

- [A.] a strictly positive, or strictly negative, longitudinal velocity u_1 .
- [B.] a reference point P of coordinates $(l_1, 0)$ in the vehicle's chassis frame, with $l_1 u_1 > 0$.

Let k denote a continuous function, strictly positive on $\mathbb{R} \times (-\pi/2, \pi/2)$, and such that $k(d, \pm\pi/2) = 0$ for every d (for instance, $k(d, \theta_e) = k_0 \cos \theta_e$). Then, for any initial conditions $(s(0), d(0), \theta_e(0))$ such that

$$\theta_e(0) \in \left(-\frac{\pi}{2}, \frac{\pi}{2}\right), \quad \frac{l_1 c_{\max}}{1 - |d(0)|c_{\max}} < 1$$

with $c_{\max} = \max_s |c(s)|$, the feedback control

$$u_2 = -\frac{u_1 \tan \theta_e}{l_1} - u_1 \frac{k(d, \theta_e)d}{\cos \theta_e}$$

makes the distance $|d|$ between P and the curve nonincreasing, and makes it converge to zero if

$$\int_0^t |u_1(s)| ds \rightarrow +\infty \quad \text{when } t \rightarrow +\infty.$$

Unicycle with Trailers

The above result applies also to this system, except that u_1 has to be positive in order to avoid jackknife effects which otherwise may (will, if u_1 is kept negative long enough) occur because the orientation angles between the vehicles are not actively monitored.

Car

This control technique thus also applies to this case by considering a point P attached to the steering wheel frame, with u_1 positive.

34.4 Methods Specific to Nonholonomic Systems

The control technique presented in the previous section has the advantage of being simple. However, it is not well suited for all control purposes. One of its main limitations is that it relies on the invariance of the sign of the robot's longitudinal velocity (see the assumptions in Proposition 34.2). For systems with trailers, this velocity is further required to be positive. This condition/restriction is related to the fact that the orientation variables are not actively monitored. To understand its nature better, let us consider the control solution given in Proposition 34.2 for $u_1 > 0$, and assume that this control is applied with u_1 negative (and constant, for instance), with the point P being unchanged. Figure 34.5 illustrates a possible scenario. The chosen curve is a simple straight line and we assume that, at time $t = 0$, P is already on this curve (i.e., $d = 0$). If u_1 is negative, while

P is bound to stay on the line, the magnitude $|\theta_e|$ of the robot's orientation angle increases rapidly. The angle θ_e reaches $-\pi/2$ at $t = 1$. At this time the control expression is no longer defined (explosion in finite time) and, since the velocity vector has become orthogonal to the curve, the point P can no longer stay on the curve.

The explanation for this behavior is as follows. Since the orientation is not controlled, the variable θ_e has its own, a priori unknown, dynamics. It can be stable, or unstable. For the considered control solution, we have shown that it is stable when $u_1 > 0$. In particular, θ_e remains in the domain of definition $(-\pi/2, \pi/2)$ of the feedback law for u_2 . When $u_1 < 0$, this dynamics becomes unstable and θ_e reaches the border of the control law's domain of definition $(-\pi/2, \pi/2)$. This instability upon the part of the system which is not directly controlled (the system's *zero dynamics*, in the control terminology) occurs in the same manner when trailers are hooked to a leading vehicle. When the longitudinal velocity is positive, the vehicle has a *pulling* action which tends to align the followers along the curve. In the other case, the leader has a *pushing* action which tends to misalign them (the jackknife effect). In order to remove this constraint on the sign of the longitudinal velocity, the control has to be designed so that all orientation angles are actively stabilized. An indirect way to do this consists in choosing the point P on the actuated wheels axle, at the mid-distance of the wheels, for instance. In

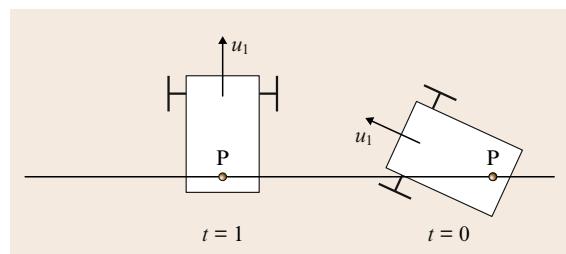

Fig. 34.5 Path-following instability with reverse longitudinal velocity

this case, the nonholonomy constraints intervene much more explicitly, and the control can no longer be obtained by applying the techniques used for holonomic manipulators.

This section is organized as follows. First, the modeling equations with respect to a Frénet frame are recast into a canonical form called the chained form. From there, a solution to the path-following problem with active stabilization of the vehicle's orientation is worked out. The problem of (feasible) trajectory stabilization is also revisited with the complementary objective of controlling the vehicle's orientation. The asymptotic stabilization of fixed postures is then addressed. Finally, some comments on the limitations of the proposed control strategies, in relation to the objective of asymptotic stabilization, serve to motivate and introduce a new control approach developed in the subsequent section.

34.4.1 Transformation of Kinematic Models into the Chained Form

In the next chapter dedicated to path planning, it is shown how the kinematic equations of the mobile robots here considered (unicycle-type, car-like, with trailers) can be transformed into the chain form via a change of state and control variables. In particular, the equations of a unicycle (34.4), and those of a car (34.5), can be transformed into a three-dimensional and a four-dimensional chained system, respectively. Those of a unicycle-type vehicle with N trailers yield a chained system of dimension $N+3$ when the trailers are hooked to each other in a specific way. As shown below, this transformation can be generalized to the kinematic models derived with respect to a Frénet frame. The result will be given only for the unicycle and car cases (equations (34.9) and (34.10)), but it also holds when trailers are hooked to such vehicles. The reference point P is now chosen at the mid-distance of the vehicle's rear wheels (or at the mid-distance of the wheels of the last trailer, when trailers are involved).

Let us start with the unicycle case. Under the assumption that P corresponds to the origin of \mathcal{F}_m , one has $l_1 = l_2 = 0$ so that the system (34.9) simplifies to

$$\begin{cases} \dot{s} = \frac{u_1}{1-dc(s)} \cos \theta_e, \\ \dot{d} = u_1 \sin \theta_e, \\ \dot{\theta}_e = u_2 - \dot{s}c(s). \end{cases} \quad (34.17)$$

Let us determine a change of coordinates and control variables $(s, d, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, v_1, v_2)$ allowing to (locally) transform (34.17) into the three-

dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2. \end{cases} \quad (34.18)$$

By first setting

$$z_1 = s, \quad v_1 = \dot{s} = \frac{u_1}{1-dc(s)} \cos \theta_e,$$

we already obtain $\dot{z}_1 = v_1$. This implies that

$$\begin{aligned} \dot{d} &= u_1 \sin \theta_e = \frac{u_1}{1-dc(s)} \cos \theta_e [1-dc(s)] \tan \theta_e \\ &= v_1 [1-dc(s)] \tan \theta_e. \end{aligned}$$

We then set $z_2 = d$ et $z_3 = [1-dc(s)] \tan \theta_e$, so that the above equation becomes $\dot{z}_2 = v_1 z_3$. Finally, we define

$$\begin{aligned} v_2 &= \dot{z}_3 \\ &= [-\dot{dc}(s) - d \frac{\partial c}{\partial s}] \tan \theta_e \\ &\quad + [1-dc(s)](1+\tan^2 \theta_e) \dot{\theta}_e. \end{aligned}$$

The equations (34.18) are satisfied with the variables z_i and v_i so defined.

From this construction it is simple to verify that the mapping $(s, d, \theta_e) \mapsto z$ is a *local* change of coordinates defined on $\mathbb{R}^2 \times (-\pi/2, \pi/2)$ (to be more rigorous, one should also take the constraint $|d| < 1/c(s)$ into account). Let us finally remark that the change of control variables involves the derivative $(\partial c / \partial s)$ of the path's curvature (whose knowledge is thus needed for the calculations). One can similarly transform the car's equations into a four-dimensional chained system, although the calculations are slightly more cumbersome. Let us summarize these results in the following proposition.

Proposition 34.3

The change of coordinates and of control variables $(s, d, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, v_1, v_2)$ defined by

$$\begin{aligned} (z_1, z_2, z_3) &= (s, d, [1-dc(s)] \tan \theta_e) \\ (v_1, v_2) &= (\dot{z}_1, \dot{z}_3) \end{aligned}$$

transforms the model (34.17) of a unicycle-type vehicle into a three-dimensional chained system.

Similarly, the change of coordinates and control variables $(s, d, \theta_e, \phi, u_1, u_2) \mapsto (z_1, z_2, z_3, z_4, v_1, v_2)$

defined by

$$(z_1, z_2, z_3, z_4) = \left\{ \begin{array}{l} s, d, [1 - dc(s)] \tan \theta_e, \\ -c(s)[1 - dc(s)](1 + 2\tan^2 \theta_e) \\ -d \frac{\partial c}{\partial s} \tan \theta_e \\ + [1 - dc(s)]^2 \frac{\tan \phi}{L} \frac{1 + \tan^2 \theta_e}{\cos \theta_e} \end{array} \right\},$$

$$(v_1, v_2) = (\dot{z}_1, \dot{z}_4)$$

transforms the model (34.10) of a car-like vehicle (with $l_1 = l_2 = 0$) into a four-dimensional chained system.

34.4.2 Tracking of a Reference Vehicle with the Same Kinematics

Let us now consider the problem of tracking, in both position and orientation, a reference vehicle (Fig. 34.6). Contrary to what happens when the control objective is limited to the tracking in position only (Sect. 34.3.1), the choice of the reference point P is of lesser importance because, whatever P, most reference trajectories $t \mapsto (x_r(t), y_r(t), \theta_r(t))$ are not feasible for the state vector (x_p, y_p, θ) . For simplicity, we choose P as the origin P_m of the robot's chassis frame \mathcal{F}_m .

Although the terminology is rather loose, the *tracking problem* is usually associated, in the control literature, with the problem of *asymptotically stabilizing* the reference trajectory. In this case, a necessary condition for the existence of a control solution is that the reference is feasible. Feasible trajectories $t \mapsto (x_r(t), y_r(t), \theta_r(t))$ are smooth time functions which are solution to the robot's kinematic model for some specific control input $t \mapsto \mathbf{u}_r(t) = (u_{1,r}(t), u_{2,r}(t))^T$, called the *reference control*. For a unicycle-type robot for example, this means in view of (34.4) that

$$\begin{cases} \dot{x}_r = u_{1,r} \cos \theta_r, \\ \dot{y}_r = u_{1,r} \sin \theta_r, \\ \dot{\theta}_r = u_{2,r}. \end{cases} \quad (34.19)$$

In other words, feasible reference trajectories correspond to the motion of a reference frame $\mathcal{F}_r = \{P_r, i_r, j_r\}$ rigidly attached to a reference unicycle-type robot, with P_r (alike $P = P_m$) located at the mid-distance of the actuated wheels (see Fig. 34.6). From there, the problem is to determine a feedback control which asymptotically stabilizes the tracking error $(x - x_r, y - y_r, \theta - \theta_r)$

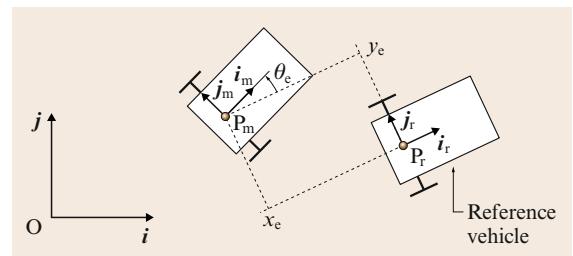

Fig. 34.6 Reference vehicle and error coordinates

at zero, with (x_r, y_r) being the coordinates of P_r in \mathcal{F}_0 , and θ_r the oriented angles between i and i_r . One can proceed as in the path-following case, first by establishing the error equations with respect to the frame \mathcal{F}_r , then by transforming these equations in the chain form via a change of variables like the one used to transform the kinematic equations of a mobile robot into a chained system, and finally by designing stabilizing control laws for the transformed system.

Expressing the tracking error in position $(x - x_r, y - y_r)$ with respect to the frame \mathcal{F}_r gives the vector (Fig. 34.6)

$$\begin{pmatrix} x_e \\ y_e \end{pmatrix} = \begin{pmatrix} \cos \theta_r & \sin \theta_r \\ -\sin \theta_r & \cos \theta_r \end{pmatrix} \begin{pmatrix} x - x_r \\ y - y_r \end{pmatrix}. \quad (34.20)$$

Calculating the time derivative of this vector yields

$$\begin{aligned} \begin{pmatrix} \dot{x}_e \\ \dot{y}_e \end{pmatrix} &= \dot{\theta}_r \begin{pmatrix} -\sin \theta_r & \cos \theta_r \\ -\cos \theta_r & -\sin \theta_r \end{pmatrix} \begin{pmatrix} x - x_r \\ y - y_r \end{pmatrix} \\ &\quad + \begin{pmatrix} \cos \theta_r & \sin \theta_r \\ -\sin \theta_r & \cos \theta_r \end{pmatrix} \begin{pmatrix} \dot{x} - \dot{x}_r \\ \dot{y} - \dot{y}_r \end{pmatrix} \\ &= \begin{pmatrix} u_{2,r} y_e + u_1 \cos(\theta - \theta_r) - u_{1,r} \\ -u_{2,r} x_e + u_1 \sin(\theta - \theta_r) \end{pmatrix}. \end{aligned}$$

By denoting $\theta_e = \theta - \theta_r$, the orientation error between the frames \mathcal{F}_m and \mathcal{F}_r , we obtain

$$\begin{cases} \dot{x}_e = u_{2,r} y_e + u_1 \cos \theta_e - u_{1,r}, \\ \dot{y}_e = -u_{2,r} x_e + u_1 \sin \theta_e, \\ \dot{\theta}_e = u_2 - u_{2,r}. \end{cases} \quad (34.21)$$

To determine a control (u_1, u_2) which asymptotically stabilizes the error (x_e, y_e, θ_e) at zero, let us consider the following change of coordinates and control variables

$$(x_e, y_e, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, w_1, w_2)$$

defined by

$$\begin{aligned} z_1 &= x_e, \\ z_2 &= y_e, \\ z_3 &= \tan \theta_e, \\ w_1 &= u_1 \cos \theta_e - u_{1,r}, \\ w_2 &= \frac{u_2 - u_{2,r}}{\cos^2 \theta_e}. \end{aligned}$$

Note that, around zero, this mapping is only defined when $\theta_e \in (-\pi/2, \pi/2)$. In other words, the orientation error between the physical robot and the reference robot has to be smaller than $\pi/2$.

It is immediate to verify that, in the new variables, the system (34.21) can be written as

$$\begin{cases} \dot{z}_1 = u_{2,r} z_2 + w_1, \\ \dot{z}_2 = -u_{2,r} z_1 + u_{1,r} z_3 + w_1 z_3, \\ \dot{z}_3 = w_2. \end{cases} \quad (34.22)$$

We remark that the last term in each of the above three equations corresponds to the one of a chained system. We then have the following result:

Proposition 34.4

The control law

$$\begin{cases} w_1 = -k_1 |u_{1,r}|(z_1 + z_2 z_3) & (k_1 > 0), \\ w_2 = -k_2 u_{1,r} z_2 - k_3 |u_{1,r}| z_3, & (k_2, k_3 > 0), \end{cases} \quad (34.23)$$

renders the origin of the system (34.22) globally asymptotically stable if $u_{1,r}$ is a bounded differentiable function whose derivative is bounded and which does not tend to zero as t tends to infinity.

Remark

By comparison with the results of Sect. 34.3, we note that $u_{1,r}$ may well pass through zero and change its sign.

Proof

Consider the following positive-definite function

$$V(z) = \frac{1}{2} \left(z_1^2 + z_2^2 + \frac{1}{k_2} z_3^2 \right).$$

The time derivative of V along the trajectories of the controlled system (34.22–34.23) is given by

$$\dot{V} = z_1 w_1 + z_2 (u_{1,r} z_3 + w_1 z_3) + \frac{1}{k_2} z_3 w_2$$

$$\begin{aligned} &= w_1(z_1 + z_2 z_3) + z_3 \left(u_{1,r} z_2 + \frac{1}{k_2} w_2 \right) \\ &= -k_1 |u_{1,r}|(z_1 + z_2 z_3)^2 - \frac{k_3}{k_2} |u_{1,r}| z_3^2. \end{aligned}$$

Therefore, along any of these trajectories, V is non-increasing and converges to some limit value $V_{\lim} \geq 0$. This implies that the variables z_1, z_2 , and z_3 are bounded. Since $u_{1,r}$ is continuous, and since its derivative is bounded, $|u_{1,r}|$ is uniformly continuous. Therefore, \dot{V} is uniformly continuous and, by application of Barbalat's lemma, \dot{V} tends to zero when t tends to infinity. In view of the expression of \dot{V} , this implies that $u_{1,r} z_3$ and $u_{1,r}(z_1 + z_2 z_3)$ (and thus $u_{1,r} z_1$ also) tend to zero. On the other hand, by using the expression of $w_2 (= \dot{z}_3)$ one has

$$\frac{d}{dt}(u_{1,r}^2 z_3) = 2\dot{u}_{1,r} u_{1,r} z_3 - k_3 u_{1,r}^2 |u_{1,r}| z_3 - k_2 u_{1,r}^3 z_2$$

and one deduces from what precedes that

$$\frac{d}{dt}(u_{1,r}^2 z_3) + k_2 u_{1,r}^3 z_2$$

tends to zero. Since $u_{1,r}^3 z_2$ is uniformly continuous (it is continuous and its derivative is bounded), and since $u_{1,r}^2 z_3$ tends to zero, one deduces by application of a slightly extended version of Barbalat's lemma that $u_{1,r}^3 z_2$ (and thus $u_{1,r} z_2$ also) tends to zero. In view of the expression of V , the convergence of $u_{1,r} z_i (i = 1, 2, 3)$ to zero implies the convergence of $u_{1,r} V$ to zero. Therefore, $u_{1,r} V_{\lim} = 0$, and $V_{\lim} = 0$ by using the assumption that $u_{1,r}$ does not tend to zero.

The linearization of the control (34.23) yields the simpler control

$$\begin{cases} w_1 = -k_1 |u_{1,r}| z_1, \\ w_2 = -k_2 u_{1,r} z_2 - k_3 |u_{1,r}| z_3. \end{cases}$$

Since $w_1 \approx u_1 - u_{1,r}$ and $w_2 \approx u_2 - u_{2,r}$ near the origin, it is legitimate to wonder if the control

$$\begin{cases} u_1 = u_{1,r} - k_1 |u_{1,r}| z_1, \\ u_2 = u_{2,r} - k_2 u_{1,r} z_2 - k_3 |u_{1,r}| z_3. \end{cases}$$

can also be used for the system (34.21). In fact, it is not difficult to verify, via a classical pole-placement calculation, that this control asymptotically stabilizes the origin of the linear system which approximates the system (34.21) when $u_{1,r}$ and $u_{2,r}$ are constant, with $u_{1,r} \neq 0$. Therefore, it also locally asymptotically stabilizes the origin of the system (34.21) when these conditions on

$u_{1,r}$ and $u_{2,r}$ are satisfied. This means also that the tuning of the gains $k_{1,2,3}$ can be performed by using classical linear control techniques applied to the linear approximation of the system (34.21). The control (34.23) is in fact designed so that its tuning for the specific velocities $u_{1,r} = 1$ and $u_{2,r} = 0$ gives good results for all other velocities (except, of course, $u_{1,r} = 0$, for which the linear approximation of the system (34.21) is not controllable and the control vanishes). Indeed, the multiplication of all control gains by $\pm u_{1,r}$ reduces to normalizing the equations of the controlled system with respect to the longitudinal velocity, so that the transient path followed by the vehicle in the process of catching up with the reference vehicle is independent of the intensity of the longitudinal velocity.

Generalization to a Car-Like Vehicle

The previous method extends to the car case. We provide below the main steps of this extension, and leave to the interested reader the task of verifying the details.

Consider the car's kinematic model (34.5), complemented with the following model of the reference car that one wishes to track

$$\begin{cases} \dot{x}_r = u_{1,r} \cos \theta_r, \\ \dot{y}_r = u_{1,r} \sin \theta_r, \\ \dot{\theta}_r = \frac{u_{1,r}}{L} \tan \phi_r, \\ \dot{\phi}_r = u_{2,r}. \end{cases} \quad (34.24)$$

We assume that there exists $\delta \in (0, \pi/2)$ such that the steering angle ϕ_r belongs to the interval $[-\delta, \delta]$.

By defining x_e , y_e , and θ_e as in the unicycle case, and by setting $\phi_e = \phi - \phi_r$, one easily obtains the following system (to be compared with (34.21))

$$\begin{cases} \dot{x}_e = (\frac{u_{1,r}}{L} \tan \phi_r) y_e + u_1 \cos \theta_e - u_{1,r}, \\ \dot{y}_e = -(\frac{u_{1,r}}{L} \tan \phi_r) x_e + u_1 \sin \theta_e, \\ \dot{\theta}_e = \frac{u_1}{L} \tan \phi - \frac{u_{1,r}}{L} \tan \phi_r, \\ \dot{\phi}_e = u_2 - u_{2,r}. \end{cases} \quad (34.25)$$

Introduce the new state variables

$$\begin{cases} z_1 = x_e, \\ z_2 = y_e, \\ z_3 = \tan \theta_e, \\ z_4 = \frac{\tan \phi - \cos \theta_e \tan \phi_r}{L \cos^3 \theta_e} + k_2 y_e, \quad (k_2 > 0). \end{cases}$$

We note that for any $\phi_r \in (-\pi/2, \pi/2)$, the mapping $(x_e, y_e, \theta_e, \phi) \mapsto z$ defines a diffeomorphism between

$\mathbb{R}^2 \times (-\pi/2, \pi/2)^2$ and \mathbb{R}^4 . Introduce now the new control variables

$$\begin{cases} w_1 = u_1 \cos \theta_e - u_{1,r}, \\ w_2 = \dot{z}_4 = k_2 \dot{y}_e + \left(\frac{3 \tan \phi}{\cos \theta_e} - 2 \tan \phi_r \right) \frac{\sin \theta_e}{L \cos^3 \theta_e} \dot{\theta}_e \\ \quad - \frac{u_{2,r}}{L \cos^2 \phi \cos^2 \theta_e} + \frac{u_2}{L \cos^2 \phi \cos^3 \theta_e}. \end{cases} \quad (34.26)$$

One shows that $(u_1, u_2) \mapsto (w_1, w_2)$ defines a change of variables for θ_e , ϕ , and ϕ_r , inside the interval $(-\pi/2, \pi/2)$. These changes of state and control variables transform the system (34.25) into

$$\begin{cases} \dot{z}_1 = (\frac{u_{1,r}}{L} \tan \phi_r) z_2 + w_1, \\ \dot{z}_2 = -(\frac{u_{1,r}}{L} \tan \phi_r) z_1 + u_{1,r} z_3 + w_1 z_3, \\ \dot{z}_3 = -k_2 u_{1,r} z_2 + u_{1,r} z_4 \\ \quad + w_1 \left(z_4 - k_2 z_2 + (1 + z_3^2) \frac{\tan \phi_r}{L} \right), \\ \dot{z}_4 = w_2. \end{cases} \quad (34.27)$$

Proposition 34.4 then becomes:

Proposition 34.5

The control law

$$\begin{cases} w_1 = -k_1 |u_{1,r}| \left(z_1 + \frac{z_3}{k_2} \left[z_4 + (1 + z_3^2) \frac{\tan \phi_r}{L} \right] \right), \\ w_2 = -k_3 u_{1,r} z_3 - k_4 |u_{1,r}| z_4, \end{cases} \quad (34.28)$$

with $k_{1,2,3,4}$ denoting positive numbers, renders the origin of the system (34.27) globally asymptotically stable if (i) $u_{1,r}$ is a bounded differentiable function whose derivative is bounded and which does not tend to zero when t tends to infinity, and (ii) $|\phi_r|$ is smaller or equal to $\delta < \pi/2$.

As in the case of the unicycle, the gain parameters k_i can be tuned from the controlled system's linearization. More precisely, one can verify from (34.25), (34.26), and (34.28), that in the coordinates $\eta = (x_e, y_e, \theta_e, \phi_e/L)^\top$, the linearization of the controlled system at the equilibrium $\eta = 0$ yields, when $u_r = (1, 0)$, the linear system $\dot{\eta} = A\eta$ with

$$A = \begin{pmatrix} -k_1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & -k_2 k_4 & -k_3 & -k_4 \end{pmatrix}$$

The control gains k_i can then be chosen to give desired values to the roots of the corresponding characteristic polynomial $P(\lambda) = (\lambda + k_1)(\lambda^3 + k_4\lambda^2 + k_3\lambda + k_2k_4)$. The nonlinear feedback law (34.28) is designed so that this choice also yields good results when the intensity of $u_{1,r}$ is different from 1 and/or varies arbitrarily, provided that the convergence conditions specified in Proposition 34.5 are satisfied.

The simulation shown on Fig. 34.7 illustrates this control scheme. The gain parameters k_i have been chosen as $(k_1, k_2, k_3, k_4) = (1, 1, 3, 3)$. The initial configuration of the reference vehicle (i.e. at $t = 0$), which is represented in Fig. 34.7a by dashed lines, is $(x_r, y_r, \theta_r)(0) = (0, 0, 0)$. The reference control u_r is defined by (34.29). The initial configuration of the controlled robot, represented in the figure by plain lines, is $(x, y, \theta)(0) = (0, -1.5, 0)$. The configurations at time $t = 10, 20$, and 30 , are also represented on the figure. Due to the fast convergence of the tracking error to zero (see the time evolution of the components x_e, y_e, θ_e of the tracking error in Fig. 34.7b), one can basically consider that the configurations of both vehicles coincide after time $t = 10$.

$$u_r(t) = \begin{cases} (1, 0)^\top, & \text{if } t \in [0, 10], \\ (-1, 0.5 \cos(2\pi(t-10)/5))^\top, & \text{if } t \in [10, 20], \\ (1, 0)^\top, & \text{if } t \in [20, 30]. \end{cases} \quad (34.29)$$

34.4.3 Path Following with Orientation Control

We reconsider the path-following problem with the reference point P now located on the actuated wheels axle, at the mid-distance of the wheels. The objective is to synthesize a control law which allows the vehicle to follow the path in a stable manner, independently of the sign of the longitudinal velocity.

Unicycle Case

We have seen in Sect. 34.4.1 how to transform kinematic equations with respect to a Frénet frame into the three-dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2. \end{cases} \quad (34.30)$$

Recall that $(z_1, z_2, z_3) = (s, d, (1 - dc(s)) \tan \theta_e)$ and that $v_1 = u_1 / (1 - dc(s) \cos \theta_e)$. The objective is to determine a control law which asymptotically stabilizes $(d = 0, \theta_e = 0)$ and also ensures that the constraint on the distance d to the path (i.e., $|dc(s)| < 1$) is satisfied along the trajectories of the controlled system. For the control law, a first possibility consists in considering a proportional feedback like

$$v_2 = -v_1 k_2 z_2 - |v_1| k_3 z_3, \quad (k_2, k_3 > 0). \quad (34.31)$$

It is then immediate to verify that the origin of the closed-loop subsystem

$$\begin{cases} \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = -v_1 k_2 z_2 - |v_1| k_3 z_3 \end{cases} \quad (34.32)$$

is asymptotically stable when v_1 is constant, either positive or negative. Since u_1 (not v_1) is the intensity of

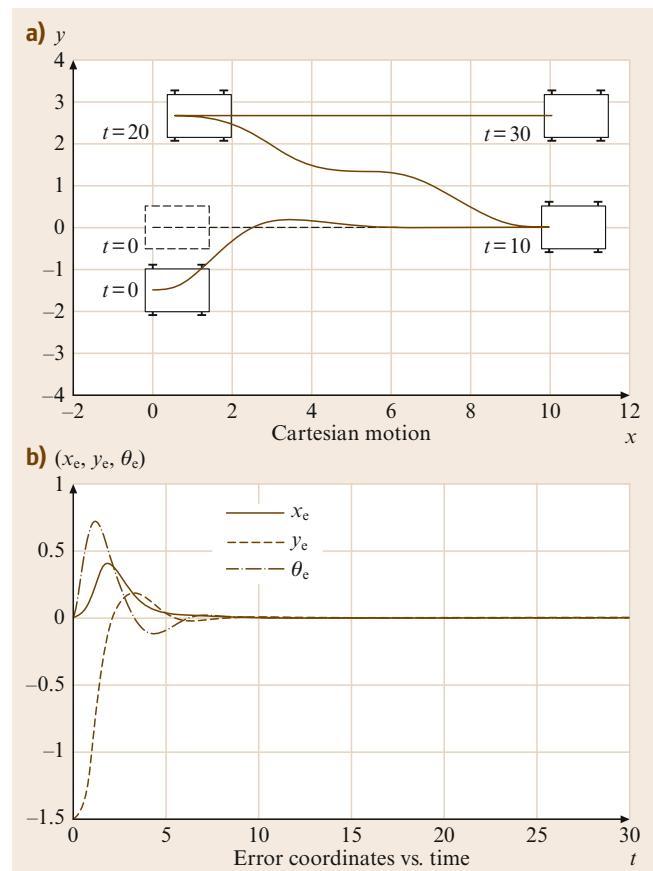

Fig. 34.7a,b Tracking of a reference vehicle

the vehicle's longitudinal velocity, one would rather establish stability conditions which depend on u_1 . The following result provides a rather general stability condition and gives a sufficient condition for the satisfaction of the constraint $|dc(s)| < 1$.

Proposition 34.6

Consider the system (34.30) controlled with (34.31), and assume that the initial conditions $[z_2(0), z_3(0)] = [d(0), \{1 - d(0)c[s(0)]\} \tan \theta_e(0)]$ verify

$$z_2^2(0) + \frac{1}{k_2} z_3^2(0) < \frac{1}{c_{\max}^2}$$

with $c_{\max} = \max_s |c(s)|$. Then, the constraint $|dc(s)| < 1$ is satisfied along any solution to the controlled system. Moreover, the function

$$V(z) = \frac{1}{2} \left(z_2^2 + \frac{1}{k_2} z_3^2 \right) \quad (34.33)$$

is nonincreasing along any trajectory $z(t)$ of the system, and $V[z(t)]$ tends to zero as t tends to infinity if, for instance, u_1 is a bounded differentiable time function whose derivative is bounded and which does not tend to zero as t tends to infinity.

The proof is similar to the one of Proposition 34.4: a simple calculation shows that the function V is non-increasing so that, along any solution to the controlled system, it converges to some limit value V_{\lim} . The same arguments as those used in the proof of Proposition 34.4 can then be repeated to show that $V_{\lim} = 0$.

Note that the constraints upon u_1 are rather weak. In particular, the sign of u_1 does not have to be constant.

From a practical point of view it can be useful to complement the control action with an integral term. More precisely, let us define a variable z_0 by

$$\dot{z}_0 = v_1 z_2, \quad z_0(0) = 0.$$

The control (34.31) can be modified as follows:

$$\begin{aligned} v_2 &= -|v_1| k_0 z_0 - v_1 k_2 z_2 - |v_1| k_3 z_3, \\ &= -|v_1| k_0 \int_0^t v_1 z_2 - v_1 k_2 z_2 - |v_1| k_3 z_3, \\ &\quad (k_0, k_2, k_3 > 0) \end{aligned} \quad (34.34)$$

and Proposition 34.6 becomes:

Proposition 34.7

Consider the system (34.30) controlled by (34.34) with k_0, k_2 , and k_3 such that the polynomial

$$s^3 + k_3 s^2 + k_2 s + k_0$$

is Hurwitz stable (all roots of this polynomial have a negative real part.). Assume also that the initial conditions $[z_2(0), z_3(0)] = [d(0), \{1 - d(0)c[s(0)]\} \tan \theta_e(0)]$ verify:

$$z_2^2(0) + \frac{1}{k_2 - \frac{k_0}{k_3}} z_3^2(0) < \frac{1}{c_{\max}^2}.$$

Then the constraint $|dc(s)| < 1$ is satisfied along any solution to the controlled system. Moreover, the function

$$\frac{k_0}{k_3} \left(\int_0^t v_1 z_2 \right)^2 + z_2^2(t) + \frac{1}{k_2 - \frac{k_0}{k_3}} z_3^2(t)$$

is nonincreasing along any trajectory of the system, and it tends to zero as t tends to infinity if, for instance, u_1 is a bounded differentiable time-function whose derivative is bounded and which does not converge to zero as t tends to infinity.

Generalization to a Car-Like Vehicle and to a Unicycle-Type Vehicle with Trailers

One of the assets of this type of approach, besides the simplicity of the control law and little demanding conditions of stability associated with it, is that it can be generalized in a straightforward manner to car-like vehicles and unicycle-type vehicles with trailers. The result is summarized in the next proposition by considering a n -dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \vdots \\ \dot{z}_{n-1} = v_1 z_n, \\ \dot{z}_n = v_2, \end{cases} \quad (34.35)$$

with $n \geq 3$. Its proof is a direct extension of the one in the three-dimensional case. The dimension $n = 4$ corresponds to the car case (Sect. 34.4.1). As for a unicycle-type vehicle with N trailers, one has $n = N + 3$. Recall also that, in all cases, z_2 represents the distance d between the path and the point P located at the mid-distance of the rear wheels of the last vehicle.

Proposition 34.8

Let k_2, \dots, k_n denote parameters such that the polynomial

$$s^{n-1} + k_n s^{n-2} + k_{n-1} s^{n-3} + \dots + k_3 s + k_2$$

is Hurwitz stable. With these parameters, let us associate the control law

$$v_2 = -v_1 \sum_{i=2}^n \text{sign}(v_1)^{n+1-i} k_i z_i. \quad (34.36)$$

Then, there exists a positive-definite matrix \mathbf{Q} (whose entries depend on the coefficients k_i) such that, if the initial conditions $[z_2(0), z_3(0), \dots, z_n(0)]$ verify

$$\|[z_2(0), z_3(0), \dots, z_n(0)]\|_{\mathbf{Q}} < \frac{1}{c_{\max}} \quad (34.37)$$

the constraint $|dc(s)| < 1$ is satisfied along any solution to the controlled system. Moreover, the function

$$\|[z_2(t), z_3(t), \dots, z_n(t)]\|_{\mathbf{Q}}$$

is nonincreasing along any trajectory of the system, and it tends to zero as t tends to infinity if, for instance, u_1 is a bounded differentiable function whose derivative is bounded and which does not converge to zero as t tends to infinity.

Remark

The condition (34.37) is always satisfied when $c(s) = 0$ for every s (i.e., when the path is a straight line). It is little demanding in practice when c_{\max} is small. Note also that it is possible to calculate the matrix \mathbf{Q} explicitly as a function of the parameters k_i (see [34.1] for more details).

As in the three-dimensional case, it is possible to add an integral term to the control. In this case, the control is calculated from the expression of an *extended system* whose state vector is composed of the variables z_1, \dots, z_n , and a complementary variable z_0 such that $\dot{z}_0 = v_1 z_2$. Since adding the variable z_0 preserves the chained structure of the system, the control expression is simply adapted from the one determined for a system of dimension $n + 1$ with no integral term. More precisely, one obtains

$$v_2 = -k_0 v_1 \text{sign}(v_1)^n \\ \times \int_0^t v_1 z_2 - v_1 \sum_{i=2}^n \text{sign}(v_1)^{n+1-i} k_i z_i$$

with the parameters k_i chosen so that the polynomial $s^n + k_n s^{n-1} + k_{n-1} s^{n-3} + \dots + k_2 s + k_0$ is Hurwitz stable.

The simulation results reported in Fig. 34.8 illustrate how this control scheme performs for a car-like vehicle. The reference curve is the circle of radius equal to four, centered at the origin. The robot's longitudinal velocity u_1 is defined by $u_1 = 1$ for $t \in [0, 5]$,

and $u_1 = -1$ for $t > 5$. The control gains have been chosen as $(k_2, k_3, k_4) = (1, 3, 3)$. The motion of the car-like robot in the plane is represented in Fig. 34.8a, and its configuration at times $t = 0, 5$, and 25 are also depicted in the figure. The time evolution of the variables z_2, z_3, z_4 (defined in Proposition 34.3) is represented in Fig. 34.8b. One can observe that the (discontinuous) change of the longitudinal velocity u_1 at $t = 5$ does not affect the convergence of these variables to zero.

34.4.4 Asymptotic Stabilization of Fixed Postures

We now consider the problem of asymptotic stabilization of a fixed desired (reference) posture (i.e., position

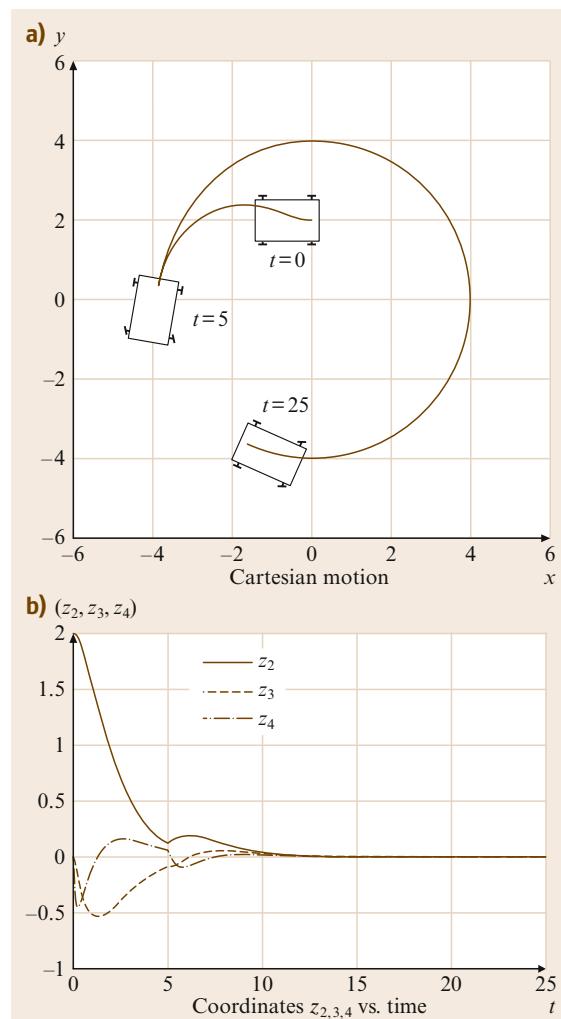

Fig. 34.8a,b Path following along a circle

and orientation) for the robot chassis. This problem may be seen as a limit case of the trajectory tracking problem. However, none of the feedback controllers proposed previously in this chapter provides a solution to this problem. For instance, in Sect. 34.3, although the result about the stabilization in position of feasible trajectories did not exclude the case of a trajectory reduced to a single point, the stability of the vehicle's orientation was not granted in this case. As for the results in Sect. 34.4, the convergence of the posture error to zero has been proven when the robot's longitudinal velocity did not converge to zero (which excludes the case of fixed postures).

From the automatic control point of view, the asymptotic stabilization of fixed postures is very different from the problems of path following and trajectory tracking with nonzero longitudinal velocity, much in the same way as a human driver knows, from experience, that parking a car at a precise location involves techniques and skills different from those exercised when cruising on a road. In particular, it cannot be solved by any classical control method for linear systems (or based on linearization). Technically, the underlying general problem is the one of asymptotic stabilization of equilibria of controllable driftless systems with less control inputs than state variables. This problem motivated numerous studies during the last decade of the last century, from many authors and with various angles of attack, and it has remained a subject of active research five years later. The variety of candidate solutions proposed until now, the mathematical technicalities associated with several of them, together with unsolved difficulties and limitations, particularly (but not only) in terms of robustness (an issue on which we will return), prevent us from attempting to cover the subject exhaustively. Instead, we have opted for a somewhat informal exposition of approaches which have been considered, with the illustration of a few control solutions, without going into technical and mathematical details.

A central aspect of the problem, which triggered much of the subsequent research on the control of nonholonomic systems, is that asymptotic stabilization of equilibria (or fixed points) cannot be achieved by using continuous feedbacks which depend on the state only (i.e., continuous pure-state feedbacks). This is a consequence of an important result due to Brockett in 1983 (see also related comments in Sect. 17.4.2). The original result by Brockett concerned differentiable feedbacks; it has later been extended to the larger set of feedbacks which are only continuous.

Theorem 34.1

(Brockett [34.2]) Consider a control system $\dot{x} = f(x, u)$ ($x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$), with f a differentiable function and $(x, u) = (0, 0)$ an equilibrium of this system. A necessary condition for the existence of a continuous feedback control $u(x)$ which renders the origin of the closed-loop system $\dot{x} = f(x, u(x))$ asymptotically stable is the local surjectivity of the application $(x, u) \mapsto f(x, u)$. More precisely, the image by f of any neighborhood Ω of $(0, 0)$ in \mathbb{R}^{n+m} must be a neighborhood of 0 in \mathbb{R}^n .

This result implies that the equilibria of many controllable (nonlinear) systems are not asymptotically stabilizable by continuous pure-state feedbacks. All nonholonomic WMRs belong to this category of systems. This will be shown in the case of a unicycle-type vehicle; the proof for the other mobile robots is similar. Let us thus consider a unicycle-type vehicle, whose kinematic equations (34.4) can be written as $\dot{x} = f(x, u)$ with $x = (x_1, x_2, x_3)^\top$, $u = (u_1, u_2)^\top$, and $f(x, u) = (u_1 \cos x_3, u_1 \sin x_3, u_2)^\top$, and let us show that f is not locally onto in the neighborhood of $(x, u) = (0, 0)$. To this purpose, take a vector in \mathbb{R}^3 of the form $(0, \delta, 0)^\top$. It is obvious that the equation $f(x, u) = (0, \delta, 0)^\top$ does not have a solution in the neighborhood of $(x, u) = (0, 0)$ since the first equation, namely $u_1 \cos x_3 = 0$, implies that $u_1 = 0$, so that the second equation cannot have a solution if δ is different from zero.

It is also obvious that the linear approximation (about the equilibrium $(x, u) = (0, 0)$) of the unicycle kinematic equations is not controllable. If it were, it would be possible to (locally) asymptotically stabilize this equilibrium with a linear (thus continuous) state feedback.

Therefore, by application of the above theorem, a unicycle-type mobile robot (like other nonholonomic robots) cannot be asymptotically stabilized at a desired posture (position/orientation) by using a continuous pure-state feedback. This impossibility has motivated the development of other control strategies in order to solve the problem. Three major types of controls have been considered:

1. *continuous time-varying feedbacks*, which, besides from depending on the state x , depend also on the exogenous time variable (i.e., $u(x, t)$ instead of $u(x)$ for classical feedbacks),
2. *discontinuous feedbacks*, in the classical form $u(x)$, except that the function u is not continuous at the equilibrium that one wishes to stabilize,

3. *hybrid discrete/continuous feedbacks.* Although this class of feedbacks is not defined as precisely as the other two sets of controls, it is mostly composed of time-varying feedbacks, either continuous or discontinuous, such that the part of the control which depends upon the state is only updated periodically, e.g., $\mathbf{u}(t) = \bar{\mathbf{u}}[\mathbf{x}(kT), t]$ for any $t \in [kT, (k+1)T]$, with T denoting a constant period, and $k \in \mathbb{N}$.

We will now illustrate these approaches. In fact, only time-varying and hybrid feedbacks will be considered here. The main reason is that discontinuous feedbacks involve difficult questions (existence of solutions, mathematical meaning of these solutions, etc.) which complicate their analysis and for which complete answers are not available. Moreover, for most of the discontinuous control strategies described in the literature, the property of stability in the sense of Lyapunov is either not granted or remains an open issue.

Time-Varying Feedbacks

The use of time-varying feedbacks for the asymptotic stabilization of a fixed desired equilibrium, for a nonholonomic WMR, in order to circumvent the obstruction pointed out by Brockett's Theorem, was first proposed in [34.3]. Since then, very general results about the stabilization of nonlinear systems by means of time-varying feedbacks have been obtained. For instance, it has been proved that any controllable driftless system can have any of its equilibria asymptotically stabilized with a control of this type [34.4]. This includes the kinematic models of the nonholonomic mobile robots here considered. We will illustrate this approach in the case of unicycle-type and car-like mobile robots modeled by three- and four-dimensional chained systems, respectively. In order to consider the three-dimensional case, let us come back on the results obtained in Sect. 34.4.3 for path following. We have established (Proposition 34.6) that the control $v_2 = -v_1 k_2 z_2 - |v_1| k_3 z_3$ applied to the system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2, \end{cases}$$

renders the function $V(z)$ defined by (34.33) nonincreasing along any trajectory of the controlled system, i.e.,

$$\dot{V} = -\frac{k_3}{k_2} |v_1| z_3^2,$$

and ensures the convergence of z_2 and z_3 to zero if, for instance, v_1 does not tend to zero as t tends to infinity. For example, if $v_1(t) = \sin t$, the proposition applies, z_2 and z_3 tend to zero, and

$$\begin{aligned} z_1(t) &= z_1(0) + \int_0^t v_1(s) ds = z_1(0) + \int_0^t \sin s ds \\ &= z_1(0) + 1 - \cos t \end{aligned}$$

so that $z_1(t)$ oscillates around the mean value $z_1(0) + 1$. To reduce these oscillations, one can multiply v_1 by a factor which depends on the current state. Take, for example, $v_1(z, t) = \|(z_2, z_3)\| \sin t$, that we complement with a stabilizing term like $-k_1 z_1$ with $k_1 > 0$, i.e.,

$$v_1(z, t) = -k_1 z_1 + \|(z_2, z_3)\| \sin t.$$

The feedback control so obtained is time-varying and asymptotically stabilizing.

Proposition 34.9

The continuous time-varying feedback

$$\begin{cases} v_1(z, t) = -k_1 z_1 + \alpha \|(z_2, z_3)\| \sin t, \\ v_2(z, t) = -v_1(z, t) k_2 z_2 - |v_1(z, t)| k_3 z_3, \end{cases} \quad (34.38)$$

with $\alpha, k_{1,2,3} > 0$, renders the origin of the three-dimensional chained system globally asymptotically stable [34.5].

The above proposition can be extended to chained systems of arbitrary dimension [34.5]. For the case $n = 4$, which corresponds to the car-like robot, one has the following result.

Proposition 34.10

The continuous time-varying feedback

$$\begin{cases} v_1(z, t) = -k_1 z_1 + \alpha \|(z_2, z_3, z_4)\| \sin t, \\ v_2(z, t) = -|v_1(z, t)| k_2 z_2 - v_1(z, t) k_3 z_3 \\ \quad - |v_1(z, t)| k_4 z_4, \end{cases} \quad (34.39)$$

with $\alpha, k_{1,2,3,4} > 0$ chosen such that the polynomial $s^3 + k_4 s^2 + k_3 s + k_2$ is Hurwitz-stable, renders the origin of the four-dimensional chained system globally asymptotically stable [34.5].

Figure 34.9 below illustrates the previous result. For this simulation, the parameters $\alpha, k_{1,2,3,4}$ in the feedback law (34.39) have been chosen as $\alpha = 3$ and $k_{1,2,3,4} = (1.2, 10, 18, 17)$. Figure 34.9a shows the motion of the

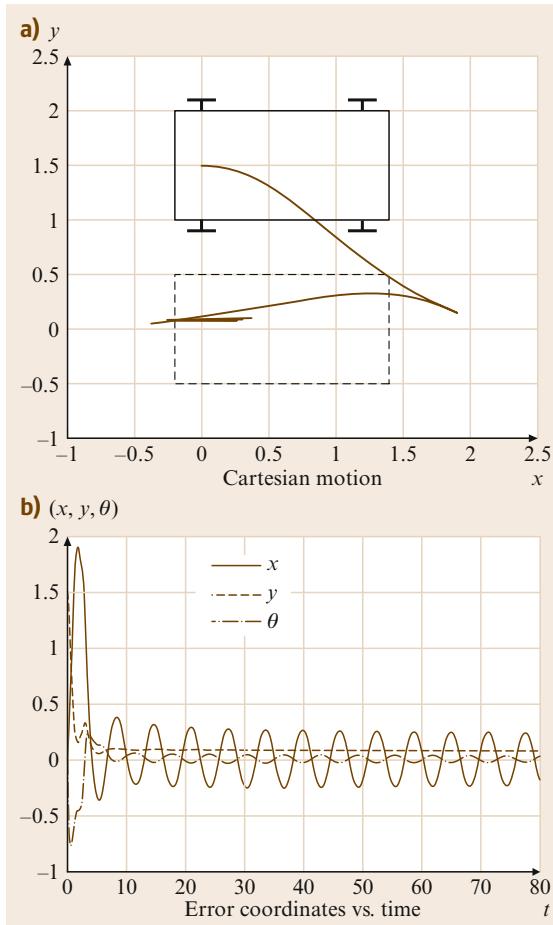

Fig. 34.9a,b Asymptotic stabilization with a Lipschitz-continuous controller

car-like robot in the plane. The initial configuration, at time $t = 0$, is depicted in plain lines, whereas the desired configuration is shown in dashed lines. The time evolution of the variables x , y , and θ (i.e., the position and orientation variables corresponding to the model (34.5)) is shown in Fig. 34.9b.

A shortcoming of this type of control, very clear from this simulation, is that the system's state converges to zero quite slowly. One can show that the rate of convergence is only polynomial, i.e., it is commensurable with $t^{-\alpha}$ (for some $\alpha \in (0, 1)$) for most of the trajectories of the controlled system. This slow rate of convergence is related to the fact that the control function is Lipschitz-continuous with respect to x . It is a characteristic of systems the linear approximation of which is not stabilizable, as specified in the following proposition.

Proposition 34.11

Consider the control system $\dot{x} = f(x, u)$ ($x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$) with f being differentiable, and $(x, u) = (0, 0)$ an equilibrium point of this system. Assume that the linear approximation of this system is not stabilizable. Consider also a continuous time-varying feedback $u(x, t)$, periodic with respect to t , such that $u(0, t) = 0$ for any t , and such that $u(\cdot, t)$ is $k(t)$ -Lipschitz continuous with respect to x , for some bounded function k . This feedback cannot yield uniform exponential convergence to zero of the closed-loop system's solutions: there do not exist constants $K > 0$ and $\gamma > 0$ such that, along any trajectory $x(\cdot)$ of the controlled system, one has

$$|x(t)| \leq K|x(t_0)|e^{-\gamma(t-t_0)}. \quad (34.40)$$

The intuitive reason behind this impossibility can easily be illustrated on the unicycle example. When using the chain form representation, the second equation is $\dot{z}_2 = v_1 z_3$. Since the linearization around $(z = 0, v = 0)$ of this equation gives $\dot{z}_2 = 0$, the linear approximation of the system is not controllable (nor stabilizable). In these conditions, exponential convergence, when applying a linear feedback, would necessitate the use of gains growing to infinity, thus ruling out the property of Lipschitz-continuity. This type of reasoning, coupled to the need of better performance and efficiency, has triggered the development of stabilizing time-varying feedbacks which are continuous, but not Lipschitz-continuous. Examples of such feedbacks, yielding uniform exponential convergence, are given in the following propositions for chained systems of dimension three and four, respectively.

Proposition 34.12

Let $\alpha, k_{1,2,3} > 0$ denote scalars such that the polynomial $p(s) = s^2 + k_3 s + k_2$ is Hurwitz stable. For any integers $p, q \in \mathbb{N}^*$, let $\rho_{p,q}$ denote the function defined on \mathbb{R}^2 by

$$\begin{aligned} \forall \bar{z}_2 = (z_2, z_3) \in \mathbb{R}^2, \rho_{p,q}(\bar{z}_2) \\ = \left(|z_2|^{\frac{p}{q+1}} + |z_3|^{\frac{p}{q}} \right)^{\frac{1}{p}}. \end{aligned}$$

Then, there exists $q_0 > 1$ such that, for any $q \geq q_0$ and $p > q + 2$, the continuous state feedback

$$\begin{cases} v_1(z, t) = -k_1(z_1 \sin t - |z_1|) \sin t \\ \quad + \alpha \rho_{p,q}(\bar{z}_2) \sin t \\ v_2(z, t) = -v_1(z, t) k_2 \frac{z_2}{\rho_{p,q}^2(\bar{z}_2)} - |v_1(z, t)| k_3 \frac{z_3}{\rho_{p,q}(\bar{z}_2)} \end{cases} \quad (34.41)$$

renders the origin of the three-dimensional chained system globally asymptotically stable, with a uniform exponential rate of convergence [34.1].

The parenthood of the controls (34.38) and (34.41) is noticeable. One can also verify that the control (34.41) is well defined (by continuity) at $\bar{z}_2 = 0$. More precisely, the ratios

$$\frac{z_2}{\rho_{p,q}^2(\bar{z}_2)} \quad \text{and} \quad \frac{z_3}{\rho_{p,q}(\bar{z}_2)},$$

which are obviously well defined when $\bar{z}_2 \neq 0$, tend to zero when \bar{z}_2 tends to zero. This guarantees the continuity of the control law.

The property of exponential convergence pointed out in the above result calls for some remarks. Indeed, this property does not exactly correspond to the classical exponential convergence property associated with stable linear systems. In this latter case, exponential convergence implies that the relation (34.40) is satisfied. This corresponds to the common notion of *exponential stability*. In the present case, this inequality becomes

$$\rho[z(t)] \leq K \rho[z(t_0)] e^{-\gamma(t-t_0)}$$

for some function ρ , defined for example by $\rho(z) = |z_1| + \rho_{p,q}(z_2, z_3)$, with $\rho_{p,q}$ as specified in Proposition 34.12. Although the function ρ shares common features with the Euclidean norm of the state vector (it is definite positive and it tends to infinity when $\|z\|$ tends to infinity), it is not equivalent to this norm. Of course, this does not change the fact that each component z_i of z converges to zero exponentially. However, the transient behavior is different because one only has

$$|z_i(t)| \leq K \|z(t_0)\|^\alpha e^{-\gamma(t-t_0)}$$

with $\alpha < 1$, instead of

$$|z_i(t)| \leq K \|z(t_0)\| e^{-\gamma(t-t_0)}.$$

In the case of the four-dimensional chained system, one can establish the following result, which is similar to Proposition 34.12.

Proposition 34.13

Let $\alpha, k_1, k_2, k_3, k_4 > 0$ be chosen such that the polynomial $p(s) = s^3 + k_4 s^2 + k_3 s + k_2$ is Hurwitz stable. For any integers $p, q \in \mathbb{N}^*$, let $\rho_{p,q}$ denote the function defined on \mathbb{R}^3 by

$$\rho_{p,q}(\bar{z}_2) = \left(|z_2|^{\frac{p}{q+2}} + |z_3|^{\frac{p}{q+1}} + |z_4|^{\frac{p}{q}} \right)^{\frac{1}{p}}$$

with $\bar{z}_2 = (z_2, z_3, z_4) \in \mathbb{R}^3$. Then, there exists $q_0 > 1$ such that, for any $q \geq q_0$ and $p > q+2$, the continuous state feedback

$$\begin{cases} v_1(z, t) = -k_1(z_1 \sin t - |z_1|) \sin t \\ \quad + \alpha \rho_{p,q}(\bar{z}_2) \sin t, \\ v_2(z, t) = -|v_1(z, t)| k_2 \frac{z_2}{\rho_{p,q}^3(\bar{z}_2)} - v_1(z, t) k_3 \frac{z_3}{\rho_{p,q}^2(\bar{z}_2)} \\ \quad - |v_1(z, t)| k_4 \frac{z_4}{\rho_{p,q}(\bar{z}_2)}, \end{cases} \quad (34.42)$$

renders the origin of the four-dimensional chained system globally asymptotically stable, with a uniform exponential rate of convergence [34.1].

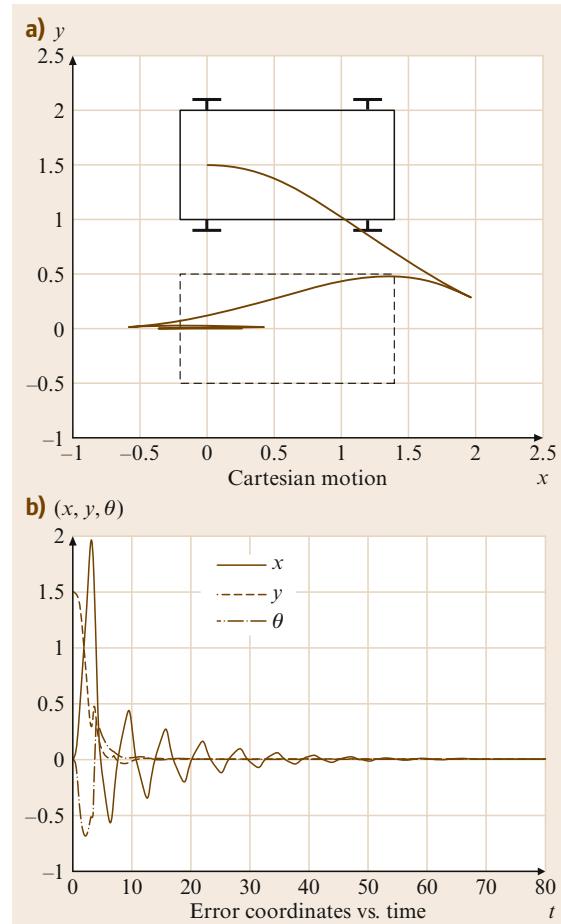

Fig. 34.10a,b Asymptotic stabilization with a continuous (non-Lipschitz) time-varying feedback

The performance of the control law (34.42) is illustrated by the simulation results shown in Fig. 34.10. The control parameters have been chosen as follows: $\alpha = 0.6$, $k_{1,2,3,4} = (1.6, 10, 18, 17)$, $q = 2$, $p = 5$. The comparison with the simulation results of Fig. 34.9 shows a clear gain in performance.

Hybrid Feedbacks

These feedbacks constitute an alternative for the asymptotic stabilization of fixed postures. They may be seen as a mix of open-loop and feedback controls in the sense that the dependence on the state is, in general, only updated periodically (by contrast with time-varying feedbacks which are updated continuously). Between two updates, the control works in open-loop mode. Nonetheless, this type of control may present some advantages with respect to time-varying feedbacks. This point is briefly commented upon a little further. An example of a hybrid feedback is provided in the following proposition.

Proposition 34.14

The hybrid feedback law v defined by

$$v(t) = \bar{v}[z(kT), t], \quad \forall t \in [kT, (k+1)T], \quad (34.43)$$

with

$$\begin{cases} \bar{v}_1(z, t) = \frac{1}{T}[(k_1 - 1)z_1 + 2\pi\rho(z)\sin(\omega t)], \\ \bar{v}_2(z, t) = \frac{1}{T}[(k_4 - 1)z_4 + 2(k_3 - 1)\frac{z_3}{\rho(z)}\cos(\omega t)] + 8(k_2 - 1)\frac{z_2}{\rho^2(z)}\cos(2\omega t)], \end{cases}$$

and

$$\begin{aligned} k_{1,2,3} &\in (-1, 1), \quad \omega = \frac{2\pi}{T}, \\ \rho(z) &= \alpha_2|z_2|^{1/2}, \quad (\alpha_2 > 0) \end{aligned}$$

is a $\mathcal{K}(T)$ -exponential stabilizer for the three-dimensional chained system [34.6].

The property of $\mathcal{K}(T)$ -exponential stabilizer evoked in the above proposition means that there exist positive constants K , η , and γ , with $\gamma < 1$, such that for any z_0 , the solution at time t of the controlled system associated with the initial condition z_0 at time $t = 0$, which we denote as $z(t, 0, z_0)$, satisfies for any $k \in \mathbb{N}$ and any $s \in [0, T)$ the inequalities

$$\|z((k+1)T, 0, z_0)\| \leq \gamma \|z(kT, 0, z_0)\|$$

and

$$\|z(kT + s, 0, z_0)\| \leq K \|z(kT, 0, z_0)\|^{\eta}.$$

These relations imply the exponential convergence of the system's trajectories to the origin $z = 0$. They do not imply the stability of this point because $\|z(t, 0, z_0)\|$ may vanish at some time $t = \bar{t}$ and not remain equal to zero thereafter. Note, however, that if $\|z(kT, 0, z_0)\| = 0$ for some $k \in \mathbb{N}$, then the above relations imply that $\|z(t, 0, z_0)\| = 0$ for all $t \geq kT$.

In the case of four-dimensional systems, a result similar to Proposition 34.14 can also be established.

Proposition 34.15

The hybrid feedback law v defined by

$$v(t) = \bar{v}[z(kT), t], \quad \forall t \in [kT, (k+1)T] \quad (34.44)$$

with

$$\begin{cases} \bar{v}_1(z, t) = \frac{1}{T}[(k_1 - 1)z_1 + 2\pi\rho(z)\sin(\omega t)], \\ \bar{v}_2(z, t) = \frac{1}{T}[(k_4 - 1)z_4 + 2(k_3 - 1)\frac{z_3}{\rho(z)}\cos(\omega t)] + 8(k_2 - 1)\frac{z_2}{\rho^2(z)}\cos(2\omega t)], \end{cases}$$

$k_{1,2,3,4} \in (-1, 1)$, $\omega = \frac{2\pi}{T}$, and $\rho(z) = \alpha_2|z_2|^{1/4} + \alpha_3|z_3|^{1/3}$ ($\alpha_{2,3} > 0$), is a $\mathcal{K}(T)$ -exponential stabilizer for the four-dimensional chained system [34.6].

The simulation results reported in Fig. 34.11 illustrate the application of the feedback law (34.44). The control parameters have been chosen as $T = 3$, $k_{1,2,3,4} = 0.25$, and $\alpha_{2,3} = 0.95$. The control performance is similar to the one observed in Fig. 34.10, as could be expected from the fact that both controls yield exponential convergence to the origin.

34.4.5 Limitations Inherent to the Control of Nonholonomic Systems

Let us first mention some problems associated with the nonlinear time-varying and hybrid feedbacks just presented. An ever important issue, when studying feedback control, is robustness. Indeed, if it were not for the sake of robustness, feedback control would lose much of its value and interest with respect to open-loop control solutions. There are various robustness issues. One of them concerns the sensitivity to modeling errors. For instance, in the case of a unicycle-type robot whose kinematic equations are in the form $\dot{x} = u_1 b_1(x) + u_2 b_2(x)$, one would like to know whether a feedback law which stabilizes an equilibrium of this system also stabilizes this equilibrium for the *neighbor* system $\dot{x} = u_1[b_1(x) + \varepsilon g_1(x)] + u_2[b_2(x) + \varepsilon g_2(x)]$, with g_1 and g_2 denoting continuous applications, and ε a parameter which quantifies the modeling error. This type of error can account,

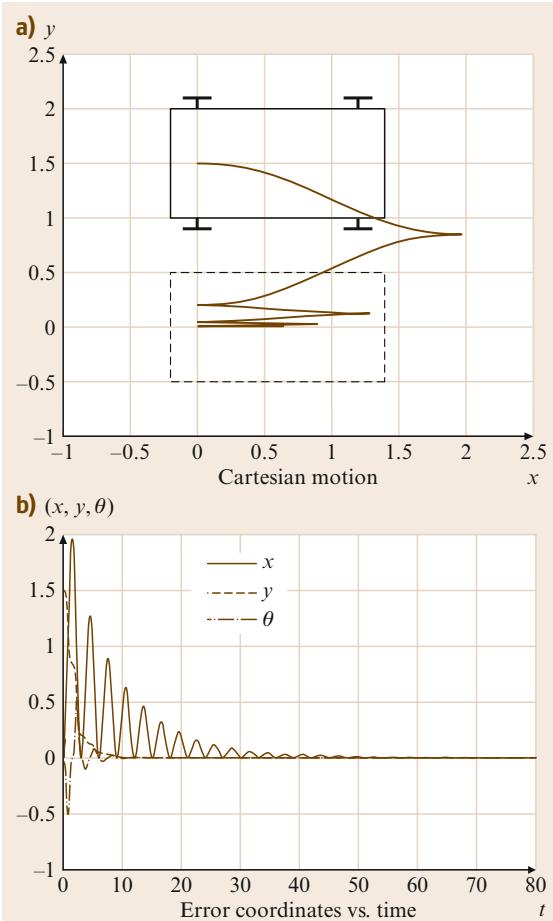

Fig. 34.11a, b Asymptotic stabilization with a hybrid discrete/continuous controller

for example, for a small uncertainty concerning the orientation of the actuated wheels axle with respect to the chassis, which results in a bias in the measurement of this orientation. One can show that time-varying control laws like (34.41) are not robust with respect to this type of error in the sense that, for certain functions g_1 and g_2 , and for ε arbitrarily small, the system's solutions end up oscillating in the neighborhood of the origin, instead of converging to the origin. In other words, both the properties of stability of the origin and of convergence to this point can be jeopardized by arbitrarily small modeling errors, even in the absence of measurement noise. In this respect, the hybrid control law (34.43) is more robust: the exponential convergence to the origin of the controlled system's solutions is still obtained when ε is small enough. However, the slightest discretization un-

certainty can produce the same type of local instability. In view of these problems, one is brought to question the existence of fast (exponential) stabilizers endowed with robustness properties similar to those of stabilizing linear feedbacks for linear systems. The answer is that, to our knowledge, no such control solution (either continuous or discontinuous) has ever been found. More than likely such a solution does not exist for nonholonomic systems. Robustness of the stability property against modeling errors, and control discretization and delays, has been proved in some cases, but this could only be achieved with Lipschitz-continuous feedbacks which, as we have seen, yield slow convergence. The classical compromise between robustness and performance thus seems much more acute than in the case of stabilizable linear systems (or nonlinear systems whose linear approximation is stabilizable).

A second issue is the proven nonexistence of a *universal* feedback controller capable of stabilizing any feasible reference state trajectory asymptotically [34.7]. This is another notable difference with the linear case. Indeed, given a controllable linear system $\dot{x} = Ax + Bu$, the feedback controller $u = u_r + K(x - x_r)$, with K a gain matrix such that $A + BK$ is Hurwitz stable, exponentially stabilizes any feasible reference trajectory x_r (solution to the system) associated with the control input u_r . The nonexistence of such a controller, in the case of nonholonomic mobile robots, is related to the conditions upon the longitudinal velocity stated in previous propositions concerning trajectory stabilization (Propositions 34.4 and 34.5). This basically indicates that such conditions cannot be removed entirely: whatever the chosen feedback controller, there always exists a feasible reference trajectory that this feedback cannot asymptotically stabilize. Note that this limitation persists when considering nonstandard feedbacks (such as, e.g., time-varying periodic feedbacks capable of asymptotically stabilizing reference trajectories which are reduced to a single point). Moreover, it has clear practical consequences because there are applications (automatic tracking of a human-driven car, for instance) for which the reference trajectory, and thus its properties, are not known in advance (is the leading car going to keep moving or stop?) so that one cannot easily decide on which controller to use. Switching between various controllers is a possible strategy, which has been studied by some authors and may give satisfactory results in many situations. However, since implementing a predefined switching strategy between two controllers sums up to designing a third controller, this does not solve the core of the problem nor grant any certitude of success.

A third issue, which is not specific to nonholonomic systems, but has seldom been addressed in the nonlinear control literature, concerns the problem of tracking *nonfeasible* trajectories (i.e., trajectories which are not solutions to the system's equations). Since exact tracking is not possible, by the definition of a nonfeasible trajectory, the control objective is then to ensure that the tracking errors shrink to, and ever after never exceed, certain nonzero thresholds. The fact that these thresholds can theoretically be arbitrarily small in the case of nonholonomic systems, if the amplitude of the velocity control inputs is not limited, makes this problem particularly relevant for these systems. This can be termed as a *practical* stabilization objective which, although slightly less ambitious than the objective of asymptotic stabilization considered in previous sections, opens up both the control design problem and the range of applications significantly. For instance, it allows to address the problem of tracking an omnidirectional vehicle with a unicycle-type, or a car-like, vehicle. In the context of planning a trajectory with obstacle avoidance, transforming a nonfeasible trajectory into a feasible approximation for a certain mobile robot can be performed by applying a practical stabilizer to a model of this robot and by numerical integration of the system's closed-loop equations. Also, if one reformulates the former question about the existence of a *universal* stabilizer, with the objective of asymptotic stabilization now replaced by the one of practical stabilization, then the answer becomes positive: such a stabilizer exists and, moreover, the reference trajectories do not even have to be feasible.

34.4.6 Practical Stabilization of Arbitrary Trajectories Based on the Transverse Function Approach

A possible approach for the design of practical stabilizers in the case of controllable driftless systems is described in [34.8]. Some of its basic principles, here adapted to the specific examples of unicycle-type and car-like mobile robots, are recalled next.

Let us introduce some matrix notation that will be used in this section.

$$\begin{aligned} \mathbf{R}(\theta) &= \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}, & S &= \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \\ \bar{\mathbf{R}}(\theta) &= \begin{pmatrix} R(\theta) & 0 \\ 0 & 1 \end{pmatrix}. \end{aligned}$$

Unicycle Case

With the above notation, the kinematic model (34.4) can be written as

$$\dot{\mathbf{g}} = \bar{\mathbf{R}}(\theta) \mathbf{C} \mathbf{u} \quad (34.45)$$

with $\mathbf{g} = (x, y, \theta)'$ and

$$\mathbf{C} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

Let us now consider a smooth function

$$f : \alpha \mapsto f(\alpha) = \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \\ f_\theta(\alpha) \end{pmatrix}$$

with $\alpha \in S^1 = \mathbb{R}/2\pi\mathbb{Z}$ (i.e., α is an angle variable), and define

$$\begin{aligned} \bar{\mathbf{g}} &:= \begin{pmatrix} \bar{x} \\ \bar{y} \\ \bar{\theta} \end{pmatrix} := \mathbf{g} - \bar{\mathbf{R}}(\theta - f_\theta(\alpha)) f(\alpha) \\ &= \begin{pmatrix} (x) \\ (y) \\ \theta - f_\theta(\alpha) \end{pmatrix} - \mathbf{R}(\theta - f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix}. \end{aligned} \quad (34.46)$$

Note that $\bar{\mathbf{g}}$ can be viewed as the situation of a frame $\tilde{\mathcal{F}}_m(\alpha)$ the origin of which has components

$$-\mathbf{R}(-f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix}$$

in the frame \mathcal{F}_m . In term of differential geometry, $\bar{\mathbf{g}}$ is the product of \mathbf{g} by the inverse $f(\alpha)^{-1}$ of $f(\alpha)$, in the sense of the Lie group operations in $SE(2)$. Hence, $\tilde{\mathcal{F}}_m(\alpha)$ is all the closer to \mathcal{F}_m as the components of $f(\alpha)$ are small. For any smooth time function $t \mapsto \alpha(t)$, and along any solution to system (34.45), the time derivative of $\bar{\mathbf{g}}$ is given by

$$\dot{\bar{\mathbf{g}}} = \bar{\mathbf{R}}(\bar{\theta}) \bar{\mathbf{u}} \quad (34.47)$$

with

$$\bar{\mathbf{u}} = A(\alpha) \begin{pmatrix} \bar{\mathbf{R}}(f_\theta(\alpha)) & -\partial f / \partial \alpha(\alpha) \end{pmatrix} \begin{pmatrix} \mathbf{C} \mathbf{u} \\ \dot{\alpha} \end{pmatrix} \quad (34.48)$$

and

$$A(\alpha) = \begin{pmatrix} I_2 & -S \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix} \\ 0 & 1 \end{pmatrix}. \quad (34.49)$$

From (34.47) and (34.48), one can view $\dot{\alpha}$ as a complementary control input that can be used to monitor the motion of the frame $\tilde{\mathcal{F}}_m(\alpha)$. More precisely, $\tilde{\mathcal{F}}_m(\alpha)$ can be viewed as an omnidirectional frame provided that \bar{u} can be rendered equal to any vector of \mathbb{R}^3 , i.e., provided that the mapping $(\mathbf{u}, \dot{\alpha}) \mapsto \bar{u}$ is onto. Let us determine when this condition is satisfied. Equation (34.48) can also be written as

$$\bar{u} = A(\alpha)H(\alpha) \begin{pmatrix} \mathbf{u} \\ \dot{\alpha} \end{pmatrix} \quad (34.50)$$

with

$$H(\alpha) = \begin{pmatrix} \cos f_\theta(\alpha) & 0 & -\partial f_x / \partial \alpha(\alpha) \\ \sin f_\theta(\alpha) & 0 & -\partial f_y / \partial \alpha(\alpha) \\ 0 & 1 & -\partial f_\theta / \partial \alpha(\alpha) \end{pmatrix}. \quad (34.51)$$

Since $A(\alpha)$ is invertible, $\tilde{\mathcal{F}}_m(\alpha)$ is omnidirectional if and only if the matrix $H(\alpha)$ is also invertible. A function f which satisfies this property for any $\alpha \in S^1$ is called a *transverse function* [34.9]. The issue of the existence of such functions has been treated in the much more general context of the transverse function approach [34.8, 9]. In the present case, a family of transverse functions is given by:

$$f(\alpha) = \begin{pmatrix} \varepsilon \sin \alpha \\ \varepsilon^2 \eta \frac{\sin 2\alpha}{4} \\ \arctan(\varepsilon \eta \cos \alpha) \end{pmatrix} \quad \text{with } \varepsilon, \eta > 0. \quad (34.52)$$

Indeed, with this function one can verify that, for any $\alpha \in S^1$, $\det H(\alpha) = -\frac{\varepsilon^2 \eta}{2} \cos(\arctan(\varepsilon \eta \cos \alpha)) < 0$. Note that the components of f uniformly tend to zero as ε tends to zero, so that the associated omnidirectional frame $\tilde{\mathcal{F}}_m(\alpha)$ can be made arbitrarily close to \mathcal{F}_m by choosing ε small (but different from zero).

Now, let $t \mapsto \mathbf{g}_r(t) = [\mathbf{x}_r(t), \mathbf{y}_r(t), \theta_r(t)]^\top$ denote a smooth, but otherwise arbitrary, reference trajectory. It is not difficult to derive from (34.47) a feedback law \bar{u} which asymptotically stabilizes \bar{g} at \mathbf{g}_r . A possible choice is given by

$$\bar{u} = \bar{\mathbf{R}}(-\bar{\theta})[\dot{\mathbf{g}}_r - k(\bar{g} - \mathbf{g}_r)], \quad (34.53)$$

which implies that $(\dot{\bar{g}} - \dot{\mathbf{g}}_r) = -k(\bar{g} - \mathbf{g}_r)$ and therefore that $\bar{g} - \mathbf{g}_r = 0$ is an exponentially stable equilibrium of the above equation for any $k > 0$. Then, it follows from (34.46) that

$$\lim_{t \rightarrow +\infty} \left\{ g(t) - \mathbf{g}_r(t) - \bar{\mathbf{R}}[\theta_r(t)]f[\alpha(t)] \right\} = 0. \quad (34.54)$$

The norm of the tracking error $\|\bar{g} - \mathbf{g}_r\|$ is thus ultimately bounded by the norm of $f(\alpha)$ which, in view of (34.52), can be made arbitrarily small via the choice of ε . It is in this sense that practical stabilization is achieved. The control \mathbf{u} for the unicycle-like robot is then calculated by inverting the relation (34.50) and using the expression (34.53) of \bar{u} .

While it can be tempting to use very small values of ε for the transverse function f in order to obtain a good tracking precision, one must be aware of the limits of this strategy. Indeed, when ε tends to zero, the matrix $H(\alpha)$ defined by (34.51) becomes ill-conditioned, and its determinant tends to zero. This implies, by (34.50), that the robot's velocities u_1 and u_2 may become very large. In particular, when the reference trajectory \mathbf{g}_r is not feasible, many manoeuvres are likely to occur. Note that this difficulty is intrinsic to the robot's nonholonomy and that it cannot be circumvented (think about the problem of parking a car in a very narrow parking place). For this reason, trying to impose very accurate tracking of nonfeasible trajectories is not necessarily a good option in practice. On the other hand, when the trajectory is feasible, manoeuvres are not needed to achieve accurate tracking, so that smaller values of ε can be used in this case. This clearly leads to a dilemma when the reference trajectory is not known in advance and its properties in term of feasibility can vary with time. A control strategy which addresses this issue, based on the use of transverse functions whose magnitude can be adapted online, is proposed in [34.10]. Experimental validations of the present approach on a unicycle-like robot can also be found in [34.11].

Car Case

The control approach presented above can be extended to car-like vehicles (and also to the trailer case). Again, the idea is to associate with the robot's frame \mathcal{F}_m an omnidirectional companion frame $\tilde{\mathcal{F}}_m(\alpha)$ which can be maintained arbitrarily close to \mathcal{F}_m via the choice of some design parameters. Let us show how this can be done for a car-like vehicle. To simplify the forthcoming equations, let us rewrite system (34.5) as

$$\begin{cases} \dot{x} = u_1 \cos \theta, \\ \dot{y} = u_1 \sin \theta, \\ \dot{\theta} = u_1 \xi, \\ \dot{\xi} = u_\xi, \end{cases}$$

with $\xi = (\tan \phi)/L$ and $u_\xi = u_2(1 + \tan^2 \phi)/L$. This system can also be written as (compare with (34.45))

$$\begin{cases} \dot{\mathbf{g}} = \bar{\mathbf{R}}(\theta)\mathbf{C}(\xi)u_1, \\ \dot{\xi} = u_\xi, \end{cases} \quad (34.55)$$

with $\mathbf{g} = (x, y, \theta)^\top$ and $\mathbf{C}(\xi) = (1, 0, \xi)^\top$. Let us now consider a smooth function

$$f : \alpha \mapsto f(\alpha) = \begin{pmatrix} f_g(\alpha) \\ f_y(\alpha) \\ f_\xi(\alpha) \\ f_\theta(\alpha) \\ f_\xi(\alpha) \end{pmatrix} = \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \\ f_\theta(\alpha) \\ f_\xi(\alpha) \end{pmatrix}$$

with $\alpha \in S^1 \times S^1$ (i.e. $\alpha = (\alpha_1, \alpha_2)$), and define (compare with (34.46))

$$\begin{aligned} \bar{\mathbf{g}} &:= \begin{pmatrix} \bar{x} \\ \bar{y} \\ \bar{\theta} \end{pmatrix} := \mathbf{g} - \bar{\mathbf{R}}(\theta - f_\theta(\alpha))f_g(\alpha) \\ &= \left(\begin{pmatrix} x \\ y \\ \theta - f_\theta(\alpha) \end{pmatrix} - \mathbf{R}(\theta - f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \\ f_\theta(\alpha) \end{pmatrix} \right), \end{aligned} \quad (34.56)$$

which, as in the unicycle case, can be viewed as the situation of some *companion frame* $\tilde{\mathcal{F}}_m(\alpha)$. By differentiating $\bar{\mathbf{g}}$ along any smooth time function $t \mapsto \alpha(t)$ and any solution to system (34.55), one can verify that (34.47) is still satisfied, except that $\bar{\mathbf{u}}$ is now given by

$$\begin{aligned} \bar{\mathbf{u}} &= A(\alpha) \left(\bar{\mathbf{R}}[f_\theta(\alpha)] \begin{pmatrix} -\partial f_g / \partial \alpha_1(\alpha) \\ -\partial f_g / \partial \alpha_2(\alpha) \end{pmatrix} \right. \\ &\quad \times \left. \begin{pmatrix} \mathbf{C}(\xi)u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix} \right) \end{aligned} \quad (34.57)$$

rather than by (34.48) (with $A(\alpha)$ still defined by (34.49)). Using the fact that

$$\begin{aligned} \mathbf{C}(\xi)u_1 &= \mathbf{C}(f_\xi(\alpha))u_1 + \{\mathbf{C}(\xi) - \mathbf{C}(f_\xi(\alpha))\}u_1 \\ &= \begin{pmatrix} 1 \\ 0 \\ f_\xi(\alpha) \end{pmatrix}u_1 + \begin{pmatrix} 0 \\ 0 \\ \xi - f_\xi(\alpha) \end{pmatrix}u_1, \end{aligned}$$

(34.57) can also be written as

$$\bar{\mathbf{u}} = A(\alpha)\mathbf{H}(\alpha) \begin{pmatrix} u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix} + A(\alpha) \begin{pmatrix} 0 \\ 0 \\ u_1[\xi - f_\xi(\alpha)] \end{pmatrix} \quad (34.58)$$

with

$$\mathbf{H}(\alpha) = \begin{pmatrix} \cos f_\theta(\alpha) & -\partial f_x / \partial \alpha_1(\alpha) & -\partial f_x / \partial \alpha_2(\alpha) \\ \sin f_\theta(\alpha) & -\partial f_y / \partial \alpha_1(\alpha) & -\partial f_y / \partial \alpha_2(\alpha) \\ f_\xi(\alpha) & -\partial f_\theta / \partial \alpha_1(\alpha) & -\partial f_\theta / \partial \alpha_2(\alpha) \end{pmatrix}. \quad (34.59)$$

By setting

$$u_\xi = \dot{f}_\xi(\alpha) - k(\xi - f_\xi(\alpha)) \quad (34.60)$$

with $k > 0$, it follows from (34.55) that $\xi - f_\xi(\alpha)$ exponentially converges to zero. Hence, after some transient phase whose duration is commensurable with $1/k$, $\xi - f_\xi(\alpha) \approx 0$, and (34.58) reduces to

$$\bar{\mathbf{u}} = A(\alpha)\mathbf{H}(\alpha) \begin{pmatrix} u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix}. \quad (34.61)$$

Provided that the function f is such that $\mathbf{H}(\alpha)$ is always invertible, this latter relation means that the frame $\tilde{\mathcal{F}}_m(\alpha)$ associated with $\bar{\mathbf{g}}$ is omnidirectional. Any function f for which this property is satisfied is called a transverse function. Once it has been determined, one can proceed as in the unicycle case to asymptotically stabilize an arbitrary reference trajectory \mathbf{g}_r for $\bar{\mathbf{g}}$, for example, by defining $\bar{\mathbf{u}}$ as in (34.53). The control u_1 for the car is then obtained by inverting relation (34.61). The following lemma specifies a family of transverse functions for the car case.

Lemma 34.1

For any $\varepsilon > 0$ and any η_1, η_2, η_3 such that $\eta_1, \eta_2, \eta_3 > 0$ and $6\eta_2\eta_3 > 8\eta_3 + \eta_1\eta_2$, the function f defined by

$$f(\alpha) = \begin{pmatrix} \bar{f}_1(\alpha) \\ \bar{f}_4(\alpha) \\ \arctan(\bar{f}_3(\alpha)) \\ \bar{f}_2(\alpha)\cos^3 f_3(\alpha) \end{pmatrix}$$

with $\bar{f} : S^1 \times S^1 \rightarrow \mathbb{R}^4$ given by

$$\begin{aligned} \bar{f}(\alpha) &= \begin{pmatrix} \varepsilon(\sin \alpha_1 + \eta_2 \sin \alpha_2) \\ \varepsilon \eta_1 \cos \alpha_1 \\ \varepsilon^2 \left(\frac{\eta_1 \sin 2\alpha_1}{4} - \eta_3 \cos \alpha_2 \right) \\ \varepsilon^3 \left(\eta_1 \frac{\sin^2 \alpha_1 \cos \alpha_1}{6} - \frac{\eta_2 \eta_3 \sin 2\alpha_2}{4} - \eta_3 \sin \alpha_1 \cos \alpha_2 \right) \end{pmatrix} \end{aligned}$$

satisfies the transversality condition $\det \mathbf{H}(\alpha) \neq 0 \forall \alpha$, with $\mathbf{H}(\alpha)$ defined by (34.59) [34.12].

The simulation results reported in Fig. 34.12 illustrate the application of this control approach for a car-like robot. The reference trajectory is defined by the initial condition $g_r(0) = 0$ and its time derivative

$$\dot{g}_r(t) = \begin{cases} (0, 0, 0)^T & \text{if } t \in [0, 30] \\ (1, 0, 0)^T & \text{if } t \in [30, 38] \\ (0, 0.3, 0)^T & \text{if } t \in [38, 53] \\ (-1, 0, 0)^T & \text{if } t \in [53, 61] \\ (0, 0, 0.2)^T & \text{if } t \in [61, 80] \end{cases}$$

This corresponds to a fixed situation when $t \in [0, 30]$, three sequences of pure translational motion when $t \in [30, 61]$, and a pure rotational motion when $t \in [61, 80]$. Let us remark that this trajectory is not feasible for the car-like robot when $t \in [38, 53]$, since it corresponds to a lateral translation in the direction of the unit vector j_r of the frame \mathcal{F}_r associated with g_r , nor when $t \in [61, 80]$, since a rear-drive car cannot perform pure rotational motion. The initial configuration of the car-like robot, at $t = 0$, is $g(0) = (0, 1.5, 0)$, and the initial steering wheel angle is $\phi(0) = 0$.

In Fig. 34.12a, the robot is drawn with a solid line at several time instants, whereas the chassis of the reference vehicle is shown as a dashed line at the same time instants. The figure also shows the trajectory of the point located at the mid-distance of the robot's rear wheels. Figure 34.12b shows the time evolution of the tracking error expressed in the reference frame (i.e., (x_e, y_e) as defined by (34.20), and $\theta_e = \theta - \theta_r$). It follows from (34.54) that, after the transient phase associated with the exponential convergence of \bar{g} to zero, the ultimate bound for $|x_e|$, $|y_e|$, and $|\theta_e|$ is upper-bounded by the maximum amplitude of the functions f_x , f_y , and f_θ , respectively. For this simulation, the control parameters of the transverse function f of Lemma 34.1 have been chosen as follows: $\varepsilon = 0.17$, $\eta_{1,2,3} = (12, 2, 20)$. With these values, one can verify that $|f_x|$, $|f_y|$, and $|f_\theta|$ are bounded by 0.51, 0.11, and 0.6, respectively. This is consistent with the time evolution of the tracking error in

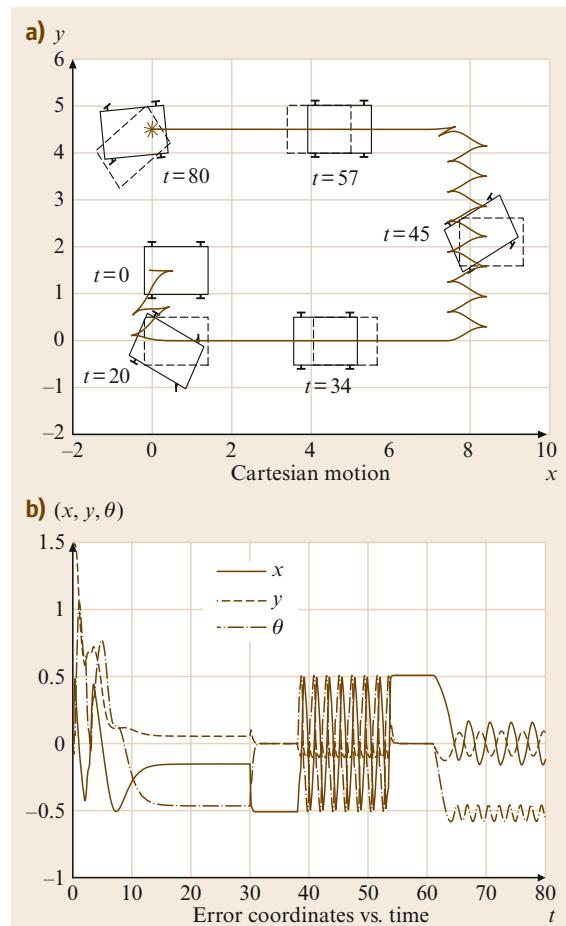

Fig. 34.12a,b Practical stabilization of an arbitrary trajectory by the transverse function approach

the figure. As pointed out for the unicycle case, a greater tracking precision could be obtained by decreasing the value of ε , but this would involve larger values of the control inputs and also more frequent manoeuvres, especially on the time intervals [38, 53] and [61, 80] when the reference trajectory is not feasible.

34.5 Complementary Issues and Bibliographical Guide

General Trailer Systems

Most of the control design approaches here presented and illustrated for unicycle-like and car-like vehicles can be extended to the case of trains of vehicles composed of trailers hitched to a leading vehicle. In particular, the

methods of Sect. 34.4 which are specific to nonholonomic systems can be extended to this case, provided that the kinematic equations of motion of the system can be transformed (at least semiglobally) into a chained system [34.5]. This basically requires that the hitch point

of each trailer is located on the rear-wheel axle of the preceding vehicle [34.13]. For instance, the transformation to the chained form is not possible when there are two (or more) successive trailers with off-axle hitch points [34.14]. So-called *general trailer systems* (with off-axle hitch points) raise difficult control design issues, and the literature devoted to them is sparse. For this reason, and also because these systems are not met in applications as frequently as simpler vehicles, control methods specifically developed for them are not reported here. Nonetheless, a few related references are given next. The path-following problem has been considered in, e.g., [34.15] for a system with two trailers and, more generally, in [34.16, Chap. 3] and [34.17] for an arbitrary number of trailers. To our knowledge, the problem of stabilizing non-stationary reference trajectories has not been addressed for these systems (except in the single trailer case for which the system can be transformed into the chained form [34.14, 18]). In fact, the explicit calculation of feasible trajectories joining a given configuration to another is already a very difficult problem, even in the absence of obstacles. As for the asymptotic stabilization of fixed configurations, the problem can (in theory) be solved by using existing general methods developed for the larger class of controllable driftless systems. However, the calculations associated with these methods quickly become intractable when the number of trailers increases. More specific and simpler ones have been proposed in [34.19], for an arbitrary number of trailers and the asymptotic stabilization of a reduced set of configurations, and in [34.20], in the case of two trailers and arbitrary fixed configurations.

Sensor-Based Motion Control

The control laws described in the present chapter, and their calculation, involve the online measurement, eventually complemented by the online estimation, of variables depending on the position of the vehicles in their environment. Measures can be acquired via the use of various sensors (odometry, GPS, proximetry, vision, . . .). Usually, various treatments are applied to raw sensory data prior to computing the control variables themselves. For instance, noise filtering and state estimation are such basic operations, well documented in the automatic-control literature. Among all sensors, vision sensors play a particularly important role in robotic applications, due to the richness and versatility of the information which they provide. The combination of visual data with feedback control is often referred to as *visual servoing*. In Chap. 24, a certain number of visual servoing tasks are addressed, mostly in the context of

manipulation and/or under the assumption that realizing the robot task is equivalent to controlling the pose of a camera mounted on an omnidirectional manipulator. In a certain number of cases, the concepts and methods described in this chapter can be adapted, without much effort, to the context of mobile robots. These cases basically correspond to the control methods adapted from robotic manipulation which are described in Sect. 34.3 of the present chapter. For instance, automatic driving via the control of the visually estimated lateral distance between a robotic vehicle and the side of a road, or car-platooning by controlling the frontal and lateral distances to a leading vehicle, can be addressed with the control techniques reported in Chap. 24. The reason is that it is possible to simply recast these techniques in the form of the control laws proposed in Sect. 34.3. However, there are also vision-based applications for nonholonomic mobile robots which cannot be solved by applying classical visual-servoing techniques. This is the case, for instance, of the task objectives addressed in Sect. 34.4, an example of which is the stabilization of the complete posture (i.e., position and orientation) of a nonholonomic vehicle at a desired one. Vision-based control problems of this type have been addressed in [34.10, 21].

A few former surveys on the control of WMRs have been published. Let us mention [34.22–24], which contain chapters on the modeling and control issues. A detailed classification of kinematic and dynamic models for the different types of WMR structures, on which Chap. 17 is based, is provided in [34.25]. The use of the chain form to represent WMR equations has been proposed in [34.26], then generalized in [34.13].

Path following may have been the first mobile robot control problem addressed by researchers in robotics. Among the pioneering works, let us cite [34.27, 28]. Several results presented in the present chapter are based on [34.5, 29].

The problem of tracking admissible trajectories for unicycle-type and car-like vehicles is treated in the books [34.22–24], and also in numerous conference and journal papers. Several authors have addressed this problem by applying dynamic feedback linearization techniques. In this respect, one can consult [34.30–32], and [34.22, Chap. 8], for instance.

Numerous papers on the asymptotic stabilization of fixed configurations have been published. Among them, [34.33] provides an early overview of feedback control techniques elaborated for this purpose, and also a list of references. The first result presenting a time-varying feedback solution to this problem, in the case

of a unicycle-type vehicle, is in [34.3]. The conference paper [34.34] provides a survey on time-varying feedback stabilization, in the more general context of nonlinear control systems. More specific results, like Propositions 34.9 and 34.12, are given in [34.1, 5]. Other early results on the design of smooth time-varying feedbacks can be found in [34.35, 36], for example. Concerning continuous (but not Lipschitz-continuous) time-varying feedbacks yielding exponential convergence, one can consult [34.37]. Designs of hybrid discrete/continuous fixed-point stabilizers can be found in [34.38–40], for instance. The control law in Proposition 34.14 is taken from [34.6]. Discontinuous control

design techniques are not addressed in the present chapter, but the interested reader will find examples of such feedbacks in [34.41, 42].

To our knowledge, the control approach presented in Sect. 34.4.6, which is based on the concept of transverse functions [34.8, 9], is the first attempt to address the problem of tracking *arbitrary* trajectories (i.e., not necessarily feasible for the controlled robot). Implementation issues and experimental results for this approach can be found in [34.10, 11]. An overview of trajectory tracking problems for wheeled mobile robots, with a detailed case study of car-like systems, is presented in [34.12].

35. Motion Planning and Obstacle Avoidance

Javier Minguez, Florent Lamiraux, Jean-Paul Laumond

Part E | 35

This chapter describes motion planning and obstacle avoidance for mobile robots. We will see how both areas do not share the same modeling background. From the very beginning of motion planning, the research has been dominated by computer science. Researchers aim at devising well-grounded algorithms with well-understood completeness and exactness properties. The introduction of nonholonomic constraints has forced these algorithms to be revisited via the introduction of differential geometry approaches. Such a combination has been made possible for certain classes of systems, so-called small-time controllable ones. The underlying hypothesis of motion planning algorithms remains the knowledge of a global and accurate map of the environment. More than that, the considered system is a formal system of equations that does not account for the entire physical system: uncertainties in the world or system modeling are not considered. Such hypotheses are too strong in practice. This is why other complementary researchers have adopted a parallel, more pragmatic but realistic approach to deal with obstacle avoidance. The problem here is not to deal with complicated systems like a car with multiple trailers. The considered systems are much simpler with respect to their geometric shape. The problem considers sensor-based motion to face the physical issues of a real system navigating in a real world better than motion planning algorithms: how to *navigate* toward a goal in a cluttered environment when the obstacles to avoid are discovered in real time? This is the question obstacle avoidance addresses.

The appearance of mobile robots in the late 1960s to early 1970s initiated a new research domain: autonomous navigation. It is interesting to notice that the first navigation systems were published in the very first International Joint Conferences on Artificial Intelligence (IJCAI 1969). These systems were based on seminal ideas which have been very fruitful in the development of robot motion planning algorithms. For instance, in 1969, the mobile robot Shakey used a grid-based approach to model and explore the environment [35.1]; in 1977 Jason used a visibility graph built from the corners of the obstacles [35.2]; in 1979 Hilare decomposed the environment into collision-free convex cells [35.3].

In the late 1970s, studies of robot manipulators popularized the notion of configuration space of a mechanical system [35.4]. In the configuration space the *piano* becomes a point. The motion planning problem for a mechanical system was thus reduced to finding a path for a point in the configuration space. The way was open to extend the seminal ideas and to develop new and well-grounded algorithms (see Latombe's book [35.5]).

One decade later, the notion of nonholonomic systems (also borrowed from mechanics) appeared in the

literature [35.6] on robot motion planning through the problem of car parking. This problem had not been solved by the pioneering works on mobile robot navigation. Nonholonomic motion planning then became an attractive research field [35.7].

Besides this research effort in path planning, work was initiated in order to make robots move out of their initially artificial environments where the world was cylindrical and composed of wooden vertical boards. Robots started to move in laboratory buildings, with people walking around. Inaccurate localization, uncertain and incomplete maps of the world, and unexpected moving or static obstacles made roboticists aware of the gap between planning a path and executing a motion. From then on, the domain of obstacle avoidance has been very active.

The challenge of this chapter is to present both nonholonomic motion planning (Sects. 35.1–35.6) and obstacle avoidance (Sects. 35.7–35.10) issues. Section 35.11 reviews recent successful approaches that tend to embrace the whole problem of motion planning and motion control. These approaches benefit from both nonholonomic motion planning and obstacle avoidance methods.

35.1 Nonholonomic Mobile Robots: Where Motion Planning Meets Control Theory

Nonholonomic constraints are nonintegrable linear constraints over the velocity space of a system. For instance, the rolling without slipping constraint of a differentially driven mobile robot (Fig. 35.1) is linear with respect to the velocity vector (vector of linear and angular velocities) of the differentially driven robot and is nonintegrable (it cannot be integrated into a constraint over the configura-

tion variables). As a consequence, a differentially driven mobile robot can go anywhere but not following any trajectory. Other types of nonholonomic constraints arise when considering second-order differential equations such as the conservation of inertial momentum. A number of papers investigate the famous falling cat problem or free-floating robots in space (see [35.7] for an overview). This chapter is devoted

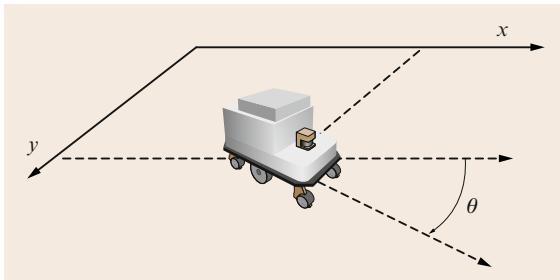

Fig. 35.1 A differentially driven mobile robot is subject to one linear kinematic constraint, due to the rolling without slipping constraint of the wheel axis

to nonholonomic constraints for mobile robots with wheels.

While the constraints due to obstacles are expressed directly in the configuration space, that is a manifold, nonholonomic constraints are expressed in the tangent space. In the presence of a linear kinematic constraint, the first question that naturally arises is: does this constraint reduce the space *reachable* by the system? This question can be answered by studying the structure of

the distribution spanned by the Lie algebra of the control system.

Even in the absence of obstacles, planning admissible motions (i.e., that satisfy the kinematic constraints) for a nonholonomic system between two configurations is not an easy task. Exact solutions have been proposed only for some classes of systems but a lot of systems remain without exact solution. In the general case however, an approximate solution can be used.

The motion planning problem for a nonholonomic system can be stated as follows: given a map of the environment with obstacles in the workspace, a robot subject to nonholonomic constraints, an initial configuration, and a goal configuration, find an admissible collision-free path between the initial and goal configurations. Solving this problem requires to take into account both the configuration space constraints due to obstacles and the nonholonomic constraints. The tools developed to address this issue thus combine motion planning and control theory techniques. Such a combination is possible for the class of so-called small-time controllable systems thanks to topological arguments (Theorem 35.2 in Sect. 35.3).

35.2 Kinematic Constraints and Controllability

In this section, we give the main definition about controllability, using Sussman's terminology [35.8].

35.2.1 Definitions

Let us denote by \mathcal{CS} the configuration space of dimension n of a given mobile robot and by \mathbf{q} the configuration of this robot. If the robot is mounted on wheels, it is subject to kinematic constraints, linear in the velocity vector:

$$\omega_i(\mathbf{q})\dot{\mathbf{q}} = 0, \quad i \in \{1, \dots, k\}.$$

We assume that these constraints are linearly independent for any \mathbf{q} . Equivalently, for each \mathbf{q} , there exist $m = n - k$ linearly independent vectors $f_1(\mathbf{q}), \dots, f_m(\mathbf{q})$ such that the above constraints are equivalent to

$$\exists(u_1, \dots, u_m) \in \mathbb{R}^m, \quad \dot{\mathbf{q}} = \sum_{i=1}^m u_i f_i(\mathbf{q}). \quad (35.1)$$

Let us notice that the choice of vectors $f_i(\mathbf{q})$ is not unique. Fortunately, all the following developments are

valid whatever the choice we make. Moreover, if the linear constraints are smooth, vector fields f_1, \dots, f_m can be chosen smooth with respect to \mathbf{q} . We assume this condition from now on.

Let us define \mathcal{U} , a compact subset of \mathbb{R}^m . We denote by Σ the control system defined by (35.1), with $(u_1, \dots, u_m) \in \mathcal{U}$

Definition 35.1

Local and small-time controllability

1. Σ is *locally controllable about configuration \mathbf{q}* iff the set of configurations reachable from \mathbf{q} by an admissible trajectory contains a neighborhood of \mathbf{q} ,
2. Σ is *small-time controllable about configuration \mathbf{q}* iff the set of configurations reachable from \mathbf{q} by an admissible trajectory in time less than T contains a neighborhood of \mathbf{q} for any T ,

f_1, \dots, f_m are called *control vector fields* of Σ . A system that is small-time controllable about each configuration is said to be *small-time controllable*.

35.2.2 Controllability

Checking the controllability properties of a system requires the analysis of the control Lie algebra associated with the system. Let us illustrate what is the Lie bracket of two vector fields in an informal way. Consider two basic motions: *go along a straight line* and *turn on the spot*, supported by vector fields denoted by f and g , respectively. Now consider the following combination: go forward during a time t , turn clockwise during the same time t , go backward during the same time t , and then turn counterclockwise during the time t . The system reaches a configuration which is not the starting one. Of course when t tends to 0 the goal configuration is very close to the starting one. The direction indicated by such goal configurations when t tends to 0 correspond to a new vector field which is the Lie bracket of f and g . In a more mathematical formulation, the Lie bracket $[f, g]$ of two vector fields f and g is defined as being the vector field $\partial f g - \partial g f$. The k -th coordinate of $[f, g]$ is

$$[f, g][k] = \sum_{i=1}^n (g[i] \frac{\partial}{\partial x_i} f[k] - f[i] \frac{\partial}{\partial x_i} g[k]).$$

The following theorem [35.9] gives a powerful result for symmetric systems (a system is said to be symmetric when \mathcal{U} is symmetric with respect to the origin)

Theorem 35.1

A symmetric system is small-time controllable about configuration \mathbf{q} iff the rank of the vector space spanned by the family of vector fields f_i together with all their brackets is n at \mathbf{q} .

Checking the Lie algebra rank condition (**LARC**) on a control system consists of trying to build a basis of the tangent space from a basis (e.g., a P. Hall family) of the free Lie algebra spanned by the control vector fields. An algorithm is proposed in [35.10, 11].

35.2.3 Example: The Differentially Driven Mobile Robot

To illustrate the notions developed in this section, we consider the differentially driven mobile robot displayed in Fig. 35.1. The configuration space of this robot is $\mathbb{R}^2 \times \mathcal{S}^1$, and a configuration can be represented by $\mathbf{q} = (x, y, \theta)$, where (x, y) is the position in the horizontal plane of the center of the wheel axis of the robot and θ the orientation with respect to the x -axis. The rolling without slipping kinematic constraint:

$$-\dot{x} \sin \theta + \dot{y} \cos \theta = 0$$

is linear with respect to the velocity vector $(\dot{x}, \dot{y}, \dot{\theta})$. Therefore, the subspace of admissible velocities is spanned by two vector fields, for instance:

$$f_1(\mathbf{q}) = \begin{pmatrix} \cos \theta \\ \sin \theta \\ 0 \end{pmatrix} \quad \text{and} \quad f_2(\mathbf{q}) = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}. \quad (35.2)$$

The Lie bracket of these two vector fields is

$$f_3(\mathbf{q}) = \begin{pmatrix} \sin \theta \\ -\cos \theta \\ 0 \end{pmatrix}.$$

This implies that, about any configuration \mathbf{q} , the rank of the vector space spanned by $f_1(\mathbf{q}), f_2(\mathbf{q}), f_3(\mathbf{q})$ is 3 and therefore that the differentially driven mobile robot is small-time controllable.

35.3 Motion Planning and Small-Time Controllability

Motion planning raises two problems: the first one addresses the *existence* of a collision-free admissible path (the decision problem) while the second one addresses the *computation* of such a path (the complete problem).

35.3.1 The Decision Problem

From now on, we assume that the set of collision-free configurations is an open subset. This implies that contact configurations are assumed in collision.

Theorem 35.2

The existence of a collision-free admissible path for a symmetric small-time controllable mobile robot between two configurations is equivalent to the existence of a collision-free (not necessarily admissible) path between these configurations.

Proof: Let us consider a not necessarily admissible, collision-free path between two configurations \mathbf{q}_1 and \mathbf{q}_2 as a continuous mapping Γ from interval $[0, 1]$ into the configuration space $\mathcal{C}S$ such that:

1. $\Gamma(0) = \mathbf{q}_1, \Gamma(1) = \mathbf{q}_2,$
2. for any $t \in [0, 1]$, $\Gamma(t)$ is collision free.

Point 2 implies that, for any t , there exists a neighborhood $U(t)$ of $\Gamma(t)$ included in the collision-free subset of the configuration space.

Let us denote by $\varepsilon(t)$ the bigger lower bound of the time to collision of all the trajectories starting from $\Gamma(t)$. As the control vector (u_1, \dots, u_m) remains in the compact set \mathcal{U} , $\varepsilon(t) > 0$.

As the system is small-time controllable about $\Gamma(t)$, the set reachable from $\Gamma(t)$ in time less than $\varepsilon(t)$ is a neighborhood of $\Gamma(t)$ that we denote by $V(t)$.

The collection $\{V(t), t \in [0, 1]\}$ is an open covering of the compact set $\{\Gamma(t), t \in [0, 1]\}$. Therefore, we can extract a finite covering: $\{V(t_1), \dots, V(t_l)\}$, where $t_1 = 0 < t_2 < \dots < t_{l-1} < t_l = 1$ such that, for any i between 1 and $l-1$, $V(t_i) \cap V(t_{i+1}) \neq \emptyset$. For each i between 1 and $l-1$, we choose one configuration \mathbf{r}_i in $V(t_i) \cap V(t_{i+1})$. As the system is symmetric, there exists an admissible collision-free path between $\mathbf{q}(t_i)$ and \mathbf{r}_i and between \mathbf{r}_i and $\mathbf{q}(t_{i+1})$. The concatenation of these paths is a collision-free admissible path between \mathbf{q}_1 and \mathbf{q}_2 . ■

35.3.2 The Complete Problem

In the former section, we established that the decision problem, i.e., determining whether there exists a collision-free admissible path between two configurations, is equivalent to determining whether the configurations lie in the same connected component of the collision-free configuration space. In this section we present the tools necessary to solve the complete problem. These tools blend ideas from the classical motion planning problem addressed in Chap. 5 and from open-loop control theory, but require specific developments that we are going to present in the next section. Two main approaches have been devised in order to plan admissible collision-free motions for nonholonomic systems. The first one, proposed by [35.12], exploits the idea of the proof of Theorem 35.2 by recursively approximating a not necessarily admissible, collision-free path by a sequence of feasible paths. The second approach replaces the local method of probabilistic roadmap method (PRM) algorithms (Chap. 5) by a local steering method that connects configuration pairs by admissible paths.

Both approaches use a steering method. Before briefly describing them, we give the definition of a local steering method.

Definition 35.2

A local steering method for system Σ is a mapping

$$\begin{aligned} \delta_{\text{loc}} : \mathcal{CS} \times \mathcal{CS} &\rightarrow C_{\text{pw}}^1([0, 1], \mathcal{CS}), \\ (\mathbf{q}_1, \mathbf{q}_2) &\mapsto \delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2), \end{aligned}$$

where $\delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2)$ is a piecewise continuously differentiable curve in \mathcal{CS} satisfying the following properties:

1. $\delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2)$ satisfies the kinematic constraints associated to Σ ,
2. $\delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2)$ connects \mathbf{q}_1 to \mathbf{q}_2 : $\delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2)(0) = \mathbf{q}_1$, $\delta_{\text{loc}}(\mathbf{q}_1, \mathbf{q}_2)(1) = \mathbf{q}_2$.

Approximation

of a Not Necessarily Admissible Path

A not necessarily admissible collision-free path $\Gamma(t)$, $t \in [0, 1]$ connecting two configurations and a local steering method δ_{loc} being given, the approximation algorithm proceeds recursively by calling the function approximation defined by Algorithm 35.1 with inputs Γ , 0, and 1.

Algorithm 35.1

approximation function: inputs are a path Γ and two abscissas t_1 and t_2 along this path

if $\delta_{\text{loc}}(\Gamma(t_1), \Gamma(t_2))$ collision free **then**

return $\delta_{\text{loc}}(\Gamma(t_1), \Gamma(t_2))$

else

return concat(approximation($\Gamma, t_1, (t_1+t_2)/2$),
approximation($\Gamma, (t_1+t_2)/2, t_2$))

endif

Sampling-Based Roadmap Methods

Most sampling-based roadmap methods as described in Chap. 5 can be adapted to nonholonomic systems by replacing the connection method between pairs of configurations by a local steering method. This strategy is rather efficient for PRM algorithms. For the rapid random trees (RRT) method, the efficiency strongly depends on the metric used to choose the nearest neighbor. The distance function between two configurations needs to account for the length of the path returned by the local steering method to connect these configurations [35.13].

35.4 Local Steering Methods and Small-Time Controllability

The approximation algorithm described in the former section is recursive and raises the completeness question: does the algorithm finish in finite time or may it fail to find a solution?

A sufficient condition for the approximation algorithm to find a solution in a finite number of iterations is that the local steering method accounts for small-time controllability.

Definition 35.3

A local steering method δ_{loc} accounts for the small-time controllability of system Σ iff

For any $q \in CS$, for any neighborhood U of q ,
there exists a neighborhood V of q such that
for any $r \in V$, $\delta_{\text{loc}}(q, r)([0, 1]) \subset U$

In other words, a local steering method accounts for the small-time controllability of a system if it produces paths getting closer to the configurations it connects when these configurations get closer to each other.

This property is also sufficient for probabilistic completeness of roadmap sampling-based methods.

35.4.1 Local Steering Methods that Account for Small-Time Controllability

Constructing a local steering method that accounts for small-time controllability is a difficult task that has been achieved only for a few classes of systems. Most mobile robots studied in the domain of motion planning are wheeled mobile robots, towing trailers or not.

Steering Using Optimal Control

The simplest system, namely the differentially driven robot presented in Sect. 35.2.3 with bounded velocities or the so-called *Reeds and Shepp* (RS) [35.14] car with bounded curvature have the same control vector fields (35.2). The difference lies in the domain of the control variables:

- $-1 \leq u_1 \leq 1, |u_2| \leq |u_1|$ for the RS car,
- $|u_1| + b|u_2| \leq 1$ for the differentially driven robot

where b is half of the distance between the right and left wheels. For these systems, a local steering method accounting for small-time controllability can be constructed using optimal control theory. For any admissible path defined over an interval I of one of these systems, we define a length as follows:

$$\int_I |u_1| \quad \text{for RS car ,}$$

$$\int_I |u_1| + b|u_2| \quad \text{for the differentially driven robot .}$$

The length of the shortest path between two configurations defines in both cases a metric over the configuration space. The synthesis of the shortest paths, i.e., the determination of the shortest path between any pair of configurations has been achieved, respectively, by [35.15] for RS car and later by [35.16] for the differentially driven (DD) robot. Figure 35.2 shows a representation of the balls corresponding to these metrics.

Optimal control naturally defines a local steering method that associates to any pair of configurations,

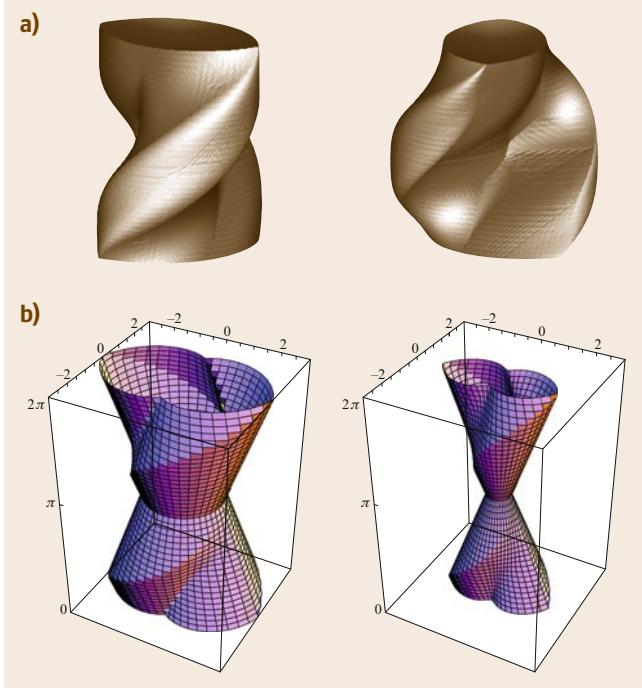

Fig. 35.2 (a) Two perspective views of an RS ball: the set of configurations reachable by a path of length less than a given distance for Reeds and Shepp car. (b) Perspective views of two DD balls: the set of configurations reachable by a path of length less than a given distance for the differentially driven robot. The orientation θ is represented on the z -axis

a shortest path between these configurations. Let us notice that the shortest path is unique between most pairs of configurations. A general result states that the collection of balls of radius $r > 0$ centered about \mathbf{q} induced by nonholonomic metrics constitute an increasing collection of neighborhoods of \mathbf{q} the intersection of which is $\{\mathbf{q}\}$. This property directly implies that local steering methods based on shortest paths account for small-time controllability.

The main advantage of optimal control is that it provides both a local steering method and a distance metric consistent with the steering method. This makes the steering methods well suited for path planning algorithms designed for holonomic systems and using a distance function, such as RRT (Chap. 5) for instance.

Unfortunately, the synthesis of the shortest paths has been realized only for the two simple systems described in this section. For more complex systems, the problem remains open.

The main drawback of the shortest path based steering methods described in this section is that input functions are not continuous. This requires an additional step to compute a time parameterization of the paths before motion execution. Along this time parameterization, input discontinuities force the robot to stop, for instance, to follow two successive arcs of circles of opposite curvature a mobile robot needs to stop between the arcs of circle in order to ensure continuity of the linear and angular velocities u_1 and u_2 .

Steering Chained-Form Systems

Some classes of systems can be put into what is called a *chained-form system* by a change of variable:

$$\dot{z}_1 = u_1, \quad (35.3)$$

$$\dot{z}_2 = u_2, \quad (35.4)$$

$$\dot{z}_3 = z_2 u_1, \quad (35.5)$$

$$\vdots \quad \vdots \quad (35.6)$$

$$\dot{z}_n = z_{n-1} u_1. \quad (35.7)$$

Let us consider the following inputs [35.17]:

$$\begin{cases} u_1(t) = a_0 + a_1 \sin \omega t, \\ u_2(t) = b_0 + b_1 \cos \omega t + \dots + b_{n-2} \cos(n-2)\omega t. \end{cases} \quad (35.8)$$

Let $Z^{\text{start}} \in \mathbb{R}^n$ be a starting configuration. Each $z_i(1)$ can be computed from the coordinates of Z^{start} and parameters $(a_0, a_1, b_0, b_1, \dots, b_{n-2})$. For a given $a_1 \neq 0$ and a given configuration Z^{start} , the mapping from

$(a_0, b_0, b_1, b_2, b_3)$ to $Z(1)$ is a C^1 -diffeomorphism at the origin; the system is then invertible. For n smaller or equal to 5, the parameters $(a_0, b_0, b_1, \dots, b_{n-2})$ can be analytically computed from the coordinates of the two configurations Z^{start} and Z^{goal} . The corresponding sinusoidal inputs steer the system from Z^{start} to Z^{goal} . The shape of the path only depends on the parameter a_1 . Each value of a_1 thus defines a local steering method, denoted by $\mathcal{S}_{\text{sin}}^{a_1}$. None of these steering methods account for small-time controllability since, for any $Z \in \mathbb{R}^n$, $\mathcal{S}_{\text{sin}}^{a_1}(Z, Z)([0, 1])$ is not reduced to $\{Z\}$. To construct a local steering method accounting for small-time controllability from the collection of $\mathcal{S}_{\text{sin}}^{a_1}$, we need to make a_1 depend on the configurations Z_1 and Z_2 that we want to connect:

$$\lim_{Z^2 \rightarrow Z^1} a_1(Z^1, Z^2) = 0,$$

$$\lim_{Z^2 \rightarrow Z^1} a_0(Z^1, Z^2, a_1(Z^1, Z^2)) = 0,$$

$$\lim_{Z^2 \rightarrow Z^1} b_i(Z^1, Z^2, a_1(Z^1, Z^2)) = 0.$$

Such a construction is achieved in [35.18].

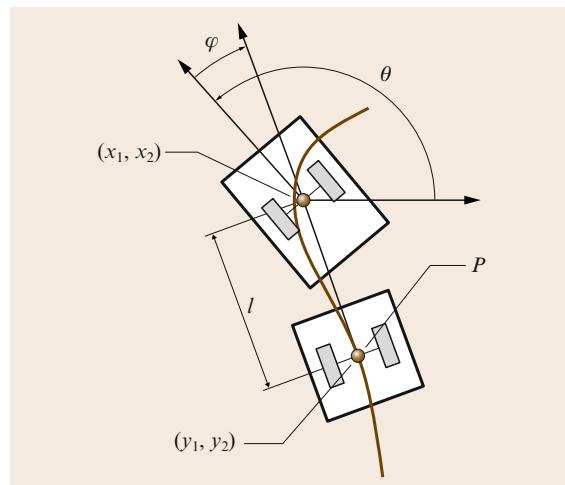

Fig. 35.3 A differentially driven robot towing a trailer hitched on top of the wheel axis of the robot is a feedback-linearizable system. The linearizing output is the center of the wheel axis of the trailer. The configuration of the system can be reconstructed by differentiating the curve $y(s)$, where s is an arc-length parameterization, followed by linearizing the output. The orientation of the trailer is given by $\tau = \arctan(\dot{y}_2 / \dot{y}_1)$. The angle between the robot and the trailer is given by $\varphi = -l \arctan(d\tau/ds)$, where l is the length of the trailer connection

Steering Feedback–Linearizable Systems

The concept of *feedback linearizability* (or differential flatness) was introduced by Fliess et al. [35.19, 20].

A system is said to be *feedback linearizable* if there exists an output (i.e., a function of the state, input, and input derivatives) called the *linearizing output*, such that the state and the input of the system are functions of the linearizing output and its derivatives. The dimension of the linearizing output is the same as the dimension of the input.

Let us illustrate this notion with a simple example. We consider a differentially driven mobile robot towing a trailer hitched on top of the wheel axis of the robot, as displayed in Fig. 35.3. The tangent to the curve followed by the center of the wheel axis of the trailer gives the orientation of the trailer. From the orientation of the trailer along the curve, we can deduce the curve followed by the center of the robot. The tangent to the curve followed by the center of the robot gives the orientation of the robot. Thus the linearizing output of this system is the center of the wheel axis of the trailer. By differentiating the linearizing output twice, we can reconstruct the configuration of the system.

Feedback linearizability is very interesting for steering purposes. Indeed, the linearizing output is not subject to any kinematic constraints. Therefore, if we know the relation between the state and the linearizing output, planning an admissible path between two configurations simply consists of building a curve in \mathbb{R}^m , where m is the dimension of the input with differential constraints at both ends. This problem can be easily solved using, for instance, polynomials.

For two input driftless systems like Σ , the linearizing output only depends on state q , and the state q depends on the linearizing output through the parameterization invariant values, namely, the linearizing output y , the orientation τ of the vector tangent to the curve followed by y , and the successive derivatives of τ with respect to the curvilinear abscissa s .

Thus, the configuration of a two-input feedback-linearizable driftless system of dimension n can be represented by a vector $(y, \tau, \tau^1, \dots, \tau^{n-3})$ representing the geometric properties of the curve followed by the linearizing output along an admissible path passing through the configuration.

Therefore, designing a local steering method for such a system is equivalent to associating to any pair of vectors $(y_1, \tau_1, \tau_1^1, \dots, \tau_1^{n-3}), (y_2, \tau_2, \tau_2^1, \dots, \tau_2^{n-3})$ a curve in the plane starting from y_1 and ending at

y_2 with orientation of the tangent vector and successive derivatives with respect to s , respectively, equal to $\tau_1, \tau_1^1, \dots, \tau_1^{n-3}$ at the beginning and to $\tau_2, \tau_2^1, \dots, \tau_2^{n-3}$ at the end. This exercise is relatively easy using polynomials and transforming the boundary conditions into linear equations over the coefficients of the polynomials. However, taking into account small-time controllability is a little more difficult.

Reference [35.21] propose a flatness-based steering method built on convex combinations of canonical curves.

35.4.2 Equivalence Between Chained–Formed and Feedback–Linearizable Systems

In the previous section, we proposed methods to steer feedback-linearizable control systems or systems that can be put into chained form. We now give a necessary and sufficient condition for feedback linearizability.

Feedback Linearizability: Necessary and Sufficient Condition

In cite [35.22], Rouchon gives conditions to check whether a system is feedback linearizable. For two-input driftless systems a necessary and sufficient condition is the following: let us define as Δ^k , $k > 0$ the collection of distributions (i.e., the set of vector fields) iteratively defined by: $\Delta_0 = \text{span}\{f_1, f_2\}$, $\Delta_1 = \text{span}\{f_1, f_2, [f_1, f_2]\}$ and $\Delta_{i+1} = \Delta_0 + [\Delta_i, \Delta_i]$ with $[\Delta_i, \Delta_i] = \text{span}\{[f, g], f \in \Delta_i, g \in \Delta_i\}$. A system with two-dimensional input is feedback linearizable iff $\text{rank}(\Delta_i) = 2 + i$.

Example 35.1: The chained-form system. Let us consider the chained-form system defined by (35.3–35.7). The control vector fields of this system are:

$$f_1 = (1, 0, z_2, \dots, z_{n-1}) \quad f_2 = (0, 1, \dots, 0)$$

$\text{rank} \Delta_0 = 2$. If we compute $f_3 = [f_1, f_2] = (0, 0, 1, 0, \dots, 0)$, we notice that $\text{rank} \Delta_1 = 3$. By computing $f_i = [f_1, f_{i-1}]$ for i up to n we find a sequence $f_i = (0, \dots, 0, 1, 0, \dots, 0)$ where 1 is at position i . Therefore, $\text{rank} \Delta_i = 2 + i$ for i up to $n - 2$ and the chained-form system is feedback linearizable. This conclusion could have been drawn in a more straightforward way by noticing that the state can be reconstructed from (z_1, z_2) and its derivatives. (z_1, z_2) is thus the linearizing output of the chained-form system.

35.5 Robots and Trailers

Robotics systems studied in motion planning are mainly those composed of a mobile robot alone or towing one or several trailers. The input of these systems is two dimensional.

35.5.1 Differentially Driven Mobile Robots

The simplest mobile robot, namely the differentially driven mobile robot displayed in Fig. 35.1, is obviously feedback linearizable, the trajectory of the center of the wheel axis (the linearizing output) of the robot gives the orientation of the robot. It can thus be steered using a flatness-based local steering method.

35.5.2 Differentially Driven Mobile Robots Towing One Trailer

The differentially driven mobile robot towing a trailer hitched on top of the wheel axis of the robot displayed in Fig. 35.3 is feedback linearizable and the linearizing output is the center of the wheel axis of the trailer. The differentially driven mobile robot towing a trailer with a hitched kingpin (Fig. 35.4) is also feedback linearizable [35.23] but the relation between the linearizing output and configuration variables is more intricate:

$$\begin{cases} y_1 = x_1 - b \cos \theta + L(\phi) \frac{b \sin \theta + a \sin(\theta + \phi)}{\sqrt{a^2 + b^2 + 2ab \cos \phi}} , \\ y_2 = x_2 - b \sin \theta - L(\phi) \frac{a \cos(\theta + \phi) + b \cos \theta}{\sqrt{a^2 + b^2 + 2ab \cos \phi}} , \end{cases}$$

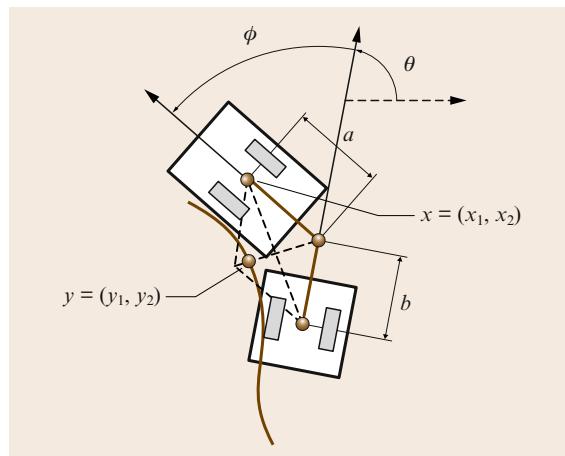

Fig. 35.4 A differentially driven mobile robot towing a trailer with a hitched kingpin is feedback linearizable

where L is defined by the following elliptic integral

$$L(\phi) = ab \int_0^\phi \frac{\cos \sigma}{\sqrt{a^2 + b^2 + 2ab \cos(\sigma)}} d\sigma ,$$

which is the linearizing output of the system. These relations together with the following ones

$$\tan \tau = \frac{a \sin(\theta + \phi) + b \sin \theta}{b \cos \theta + a \cos(\theta + \phi)} ,$$

$$\kappa = \frac{\sin(\phi)}{\cos \phi \sqrt{a^2 + b^2 + 2ab \cos \phi + L(\phi) \sin(\phi)}}$$

make it possible to reconstruct the configuration variables from the linearizing output and its two first derivatives.

35.5.3 Car-Like Mobile Robots

A car-like mobile robot consists of a fixed rear wheel axis and two steerable front wheels, the axes of which intersect at the center of curvature (Fig. 35.5). A car-like mobile robot is kinematically equivalent to a differentially driven mobile robot towing a trailer hitched on top of the wheel axis of the robot (Fig. 35.3): the virtual front wheel corresponds to the differentially driven robot, while the body of the car corresponds to the trailer.

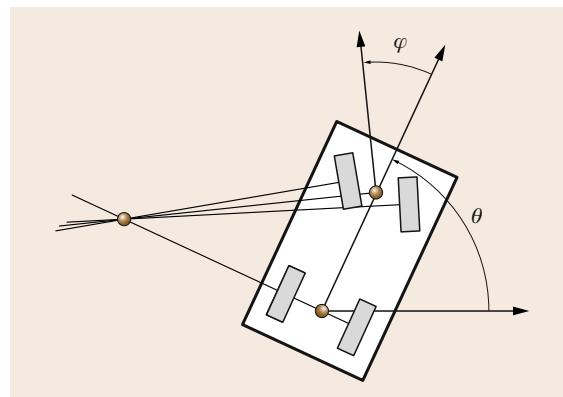

Fig. 35.5 Car-like mobile robot. The axes of the front wheels intersect at the center of curvature. The steering angle φ is the angle between the longitudinal axis of the car and a virtual front wheel in the middle of the two front wheels

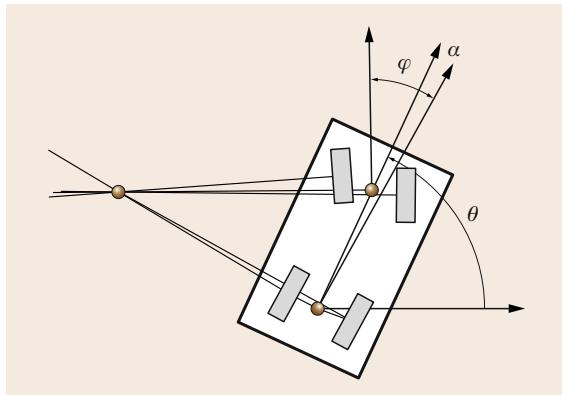

Fig. 35.6 Bi-steerable robot. The front and rear wheels are steerable and there is a relation between the rear steering angle and the front steering angle: $\alpha = f(\varphi)$

35.5.4 Bi-steerable Mobile Robots

The bi-steerable mobile robot (Fig. 35.6) is a car with front and rear steerable wheels and with a relation between the front and rear steering angles. This system has been proven to be feedback linearizable in [35.24]. As for the mobile robot towing a trailer with a hitched kingpin, the linearizing output is a moving point in the robot reference frame.

35.5.5 Differentially Driven Mobile Robots Towing Trailers

Let us consider the differentially driven mobile robot towing a trailer connected on top of the wheel axis of the robot, and let us add an arbitrary number of trailers, each one connected on top of the wheel axis of the previous one. By differentiating the curve followed by the center of the last trailer once, we get the orientation of the last trailer (this orientation coincides with the orientation of the tangent to the curve). If we know the orientation and the position of the center of the last trailer along the path, we can reconstruct the curve followed by the center of the previous trailer; repeating this reasoning, we can reconstruct the trajectory of the whole system by differentiating a sufficient number of times. The system is therefore feedback linearizable and the linearizing output is the center of the last trailer.

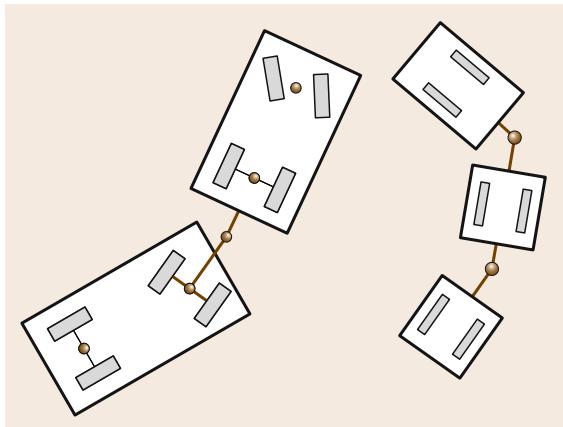

Fig. 35.7 A truck towing a towbar trailer with hitched kingpin and a differentially driven mobile robot towing two trailers with hitched kingpin: two open problems for exact path planning for nonholonomic systems

Combining the above reasoning with systems reviewed in this section, we can build hybrid feedback-linearizable trailer systems. For instance, a differentially driven mobile robot towing an arbitrary number n of trailers each one connected on top of the wheel axis of the previous trailer, except the last trailer with a hitched kingpin, is feedback linearizable. Simply consider the two last trailers as a feedback-linearizable system composed of a mobile robot with one trailer as in Fig. 35.4. The linearizing output of this system enables us to reconstruct the trajectory of the two last trailers. The center of trailer $n - 1$ is a linearizing output for the mobile robot towing the $n - 1$ last trailers.

35.5.6 Open Problems

Eventually all the systems for which we are able to plan exact motions between arbitrary pairs of configurations are included in the large class of feedback-linearizable systems. We have seen indeed that chained-form systems are also part of this class. For other systems, no exact solution has been proposed up to now, for instance, both systems displayed in Fig. 35.7 are not feedback linearizable. They do not satisfy the necessary condition of Sect. 35.4.2.

35.6 Approximate Methods

To deal with nonholonomic systems not belonging to any class of systems for which exact solutions exist, approximate numerical solutions have been developed. We review some of these methods in this section.

35.6.1 Forward Dynamic Programming

Barraquand and Latombe propose in [35.25] a dynamic programming approach to nonholonomic path planning. Admissible paths are generated by a sequence of constant input values, applied over a fixed interval of time δt . Starting from the initial configuration the search generates a tree: the children of a given configuration q are obtained by setting the input to a constant value and integrating the differential system over δt . The configuration space is discretized into an array of cells of equal size (i.e., hyperparallelepipeds). A child q' of a configuration q is inserted in the search tree iff the computed path from q to q' is collision free and q' does not belong to a cell containing an already generated configuration. The algorithm stops when it generates a configuration belonging to the same cell as the goal (i.e., it does not necessarily reach the goal exactly).

The algorithm has been proved to be asymptotically complete with respect to both δt and the size of the cells. As a brute force method, it remains quite time consuming in practice. Its main interest is that the search is based on Dijkstra's algorithm which allows to take into account optimality criteria such as the path length or the number of reversals. Asymptotical optimality to generate the minimum of reversals is proved for the car-like robot alone.

35.6.2 Discretization of the Input Space

Davelbiss and Wen propose in [35.26] a method to produce an admissible collision-free path for a nonholonomic mobile robot in the presence of obstacles. They restrict the set of input functions over the subspace spanned by a Fourier basis over the interval $[0, 1]$. An in-

put function is thus represented by a finite-dimensional vector λ . Reaching a goal configuration thus becomes a nonlinear system of equations, the unknown of which are the coordinates λ_i of λ . The authors use the Newton–Raphson method to find a solution. Obstacles are defined by inequality constraints over the configuration space. The path is discretized into N samples. The noncollision constraint expressed at these sample points yields inequality constraint over the vector λ . These inequality constraints are turned into equality constraints through the function g , defined as:

$$g(c) = \begin{cases} (1 - e^c)^2 & \text{if } c > 0 \\ 0 & \text{if } c \leq 0. \end{cases}$$

Reaching a goal configuration while avoiding obstacles thus becomes a nonlinear system of equations over vector λ again solved using the Newton–Raphson method. The method is rather efficient for short maneuvers. The main difficulty is to tune the order of the Fourier expansion. Long motions in cluttered environments require a higher order while motion in empty space can be solved with a low order. The authors do not mention the problem of numerical instability in the integration of the dynamic system.

35.6.3 Input-Based Rapidly Exploring Random Trees

RRT algorithms, described in Chap. 5, can be used without local steering method to plan paths for nonholonomic systems. New nodes can be generated from existing nodes by applying random input functions over an interval of time [35.27]. The main difficulty consists in finding a distance function that really accounts for the distance the system needs to travel to go from one configuration to another. Moreover, the goal is never exactly reached. This latter drawback can be overcome by postprocessing the path returned by **RRT** using a path deformation method, as described in [35.28].

35.7 From Motion Planning to Obstacle Avoidance

Up to now we have described motion planning techniques. Their objective is to compute a collision-free trajectory to the target configuration that complies with the vehicle constraints. They assume a perfect model

of the robot and scenario. The advantage of these techniques is that they provide complete and global solutions of the problem. Nevertheless, when the surroundings are unknown and unpredictable, these techniques fail.

A complementary way to address the motion problem is obstacle avoidance. The objective is to move a vehicle towards a target location free of collisions with the obstacles detected by the sensors during motion execution. The advantage of reactive obstacle avoidance is to compute motion by introducing the sensor information within the control loop, used to adapt the motion to any contingency incompatible with initial plans.

The main cost of considering the reality of the world during execution is locality. In this instance, if global reasoning is required, a trap situation could occur. De-

spite this limitation, obstacle avoidance techniques are mandatory to deal with mobility problems in unknown and evolving surroundings.

Notice that methods have been developed to combine both the global point of view of motion planning and the local point of view of obstacle avoidance. How to consider robot perception at the planning level? This is the so-called sensor-based motion planning. Several variants exist, such as the BUG algorithms initially introduced in [35.29]. However none of them consider the practical context of nonholonomic mobile robots.

35.8 Definition of Obstacle Avoidance

Let \mathcal{A} be the robot (a rigid object) moving in the workspace \mathcal{W} , whose configuration space is \mathcal{CS} . Let \mathbf{q} be a configuration, \mathbf{q}_t this configuration at time t , and $\mathcal{A}(\mathbf{q}_t) \in \mathcal{W}$ the space occupied by the robot in this configuration. In the vehicle there is a sensor, that in \mathbf{q}_t measures a portion of the space $\mathcal{S}(\mathbf{q}_t) \subset \mathcal{W}$ identifying a set of obstacles $\mathcal{O}(\mathbf{q}_t) \subset \mathcal{W}$.

Let \mathbf{u} be a constant control vector and $\mathbf{u}(\mathbf{q}_t)$ this control vector applied in \mathbf{q}_t during time δt . Given $\mathbf{u}(\mathbf{q}_t)$, the vehicle describes a trajectory $\mathbf{q}_{t+\delta t} = f(\mathbf{u}, \mathbf{q}_t, \delta t)$, with $\delta t \geq 0$. Let $\mathcal{Q}_{t,T}$ be the set of configurations of the trajectory followed from \mathbf{q}_t with $\delta t \in [0, T]$, a given time interval. $T > 0$ is called the *sampling period*.

Let $F : \mathcal{CS} \times \mathcal{CS} \rightarrow \mathbb{R}^+$ be a function that evaluates the progress of one configuration to another.

Obstacle Avoidance Problem

Let $\mathbf{q}_{\text{target}}$ be a target configuration. Then, in time t_i the robot \mathcal{A} is in \mathbf{q}_{t_i} , where a sensor measurement is obtained $\mathcal{S}(\mathbf{q}_{t_i})$, and thus an obstacle description $\mathcal{O}(\mathbf{q}_{t_i})$. The objective is to compute a motion control \mathbf{u}_i such that: (i) the trajectory generated is free of collisions with the obstacles $\mathcal{A}(\mathcal{Q}_{t_i,T}) \cap \mathcal{O}(\mathbf{q}_{t_i}) = \emptyset$; and (ii) it makes the vehicle progress to the target location $F(\mathbf{q}_{t_i}, \mathbf{q}_{\text{target}}) < F(\mathbf{q}_{t_i+T}, \mathbf{q}_{\text{target}})$.

The result of solving this problem at each sample time (Fig. 35.8a) is a sequence of motion controls $\{\mathbf{u}_1 \dots \mathbf{u}_n\}$ computed in execution time that avoids the obstacles gathered by the sensors, while making the vehicle progress towards the target location in each configuration $\{\mathbf{q}_{t_1} \dots \mathbf{q}_{\text{target}}\}$ (Fig. 35.8b). Notice that the motion problem is a global problem. The obstacle avoidance methods are local and iterative techniques to address this problem. The disadvantage of locality (trap situations) is counteract with the advantage of intro-

ducing the sensory information within the control cycle (to take into account the reality of the world during execution).

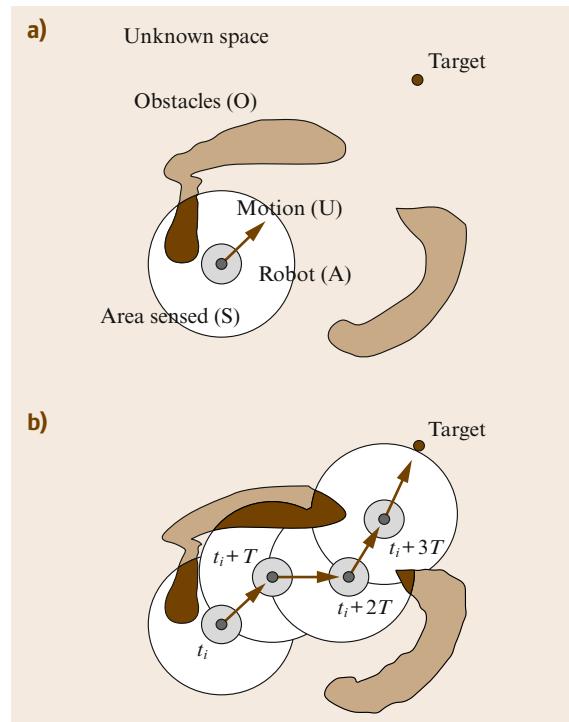

Fig. 35.8 (a) The obstacle avoidance problem consists of computing a motion control that avoid collisions with the obstacles gathered by the sensors, whilst driving the robot towards the target location. (b) The result of applying this technique at each time is a sequence of motions that drive the vehicle free of collisions to the target

There are at least three aspects that affect the development of an obstacle avoidance method: the avoidance technique, the type of robot sensor, and the type of scenario. These subjects correspond to the next three sections. First, we describe the obstacle avoidance techniques (Sect. 35.9). Second, we discuss the techniques to adapt a given obstacle avoidance method to work on a vehicle taking into account the shape, kinematics, and

dynamics (Sect. 35.10). Sensory processing is detailed in Chaps. 4 and 24. Finally, the usage of an obstacle avoidance technique on a vehicle in a given scenario is highly dependent on the scenario nature (static or dynamic, unknown or known, structured or not, or its size for example). Usually, this problem is associated with the integration of planning and obstacle avoidance (Sect. 35.11).

35.9 Obstacle Avoidance Techniques

We describe here a taxonomy of obstacle avoidance techniques and some representative methods. First there are two groups: methods that compute the motion in one step and that do it in more than one. One-step methods directly reduce the sensor information to a motion control. There are two types:

- The *heuristic* methods were the first techniques used to generate motion based on sensors. The majority of these works derived from classic planning methods and will not be described here. See [35.1, 29–32] for some representative works.
- The methods of *physical analogies* assimilate the obstacle avoidance to a known physical problem. We discuss here the potential field methods [35.33, 34]. Other works are variants adapted to uncertain models [35.35] or that use other analogies [35.36–38].

Methods with more than one step compute some intermediate information, which is processed next to obtain the motion.

- The methods of *subset of controls* compute an intermediate set of motion controls, and next choose one of them as a solution. There are two types: (i) methods that compute a subset of motion directions. We describe here the vector field histogram [35.39] and the obstacle restriction method [35.40]. Another method is presented in [35.41]. (ii) Methods that compute a subset of velocity controls. We describe here the dynamic window approach [35.42] and the velocity obstacles [35.43]. Another method based on similar principles but developed independently is the curvature velocity method [35.44].
- Finally, there are methods that compute some *high-level information* as intermediate information, which is translated next in motion. We describe the nearness diagram navigation [35.45, 46].

All the methods outlined here have advantages and disadvantages depending on the navigation context, like uncertain worlds, motion at high speeds, motion in confined or troublesome spaces, etc. Unfortunately there is no metric available to measure the performance of the methods quantitatively. However, for an experimental comparison in terms of their intrinsic problems see [35.45].

35.9.1 Potential Field Methods (PFM)

The potential field method (PFM) uses an analogy in which the robot is a particle that moves in the configuration space under the influence of a force field. While the target location exerts a force that attracts the particle \mathbf{F}_{att} , the obstacles exert repulsive forces \mathbf{F}_{rep} . At each time t_i , the motion is computed to follow the direction of the artificial force induced by the sum of both potentials $\mathbf{F}_{\text{tot}}(\mathbf{q}_{t_i}) = \mathbf{F}_{\text{att}}(\mathbf{q}_{t_i}) + \mathbf{F}_{\text{rep}}(\mathbf{q}_{t_i})$ (the most promising motion direction), Fig. 35.9.

Example 35.2:

$$\mathbf{F}_{\text{att}}(\mathbf{q}_{t_i}) = K_{\text{att}} \mathbf{n}_{q_{\text{target}}} \quad (35.9)$$

$$\mathbf{F}_{\text{rep}}(\mathbf{q}_{t_i}) = \begin{cases} K_{\text{rep}} \sum_j \left(\frac{1}{d(\mathbf{q}_{t_i}, \mathbf{p}_j)} - \frac{1}{d_0} \right) \mathbf{n}_{p_j}, & \text{if } d(\mathbf{q}_{t_i}, \mathbf{p}_j) < d_0 \\ 0, & \text{otherwise} \end{cases} \quad (35.10)$$

where K_{att} and K_{rep} are the constants of the forces, d_0 is the influence distance of the obstacles \mathbf{p}_j , \mathbf{q}_{t_i} is the current vehicle configuration, and $\mathbf{n}_{q_{\text{target}}}$ and \mathbf{n}_{p_j} are the unitary vectors that point from \mathbf{q}_{t_i} to the target and each obstacle \mathbf{p}_j , respectively. From $\mathbf{F}_{\text{tot}}(\mathbf{q}_{t_i})$, the control \mathbf{u}_i can be obtained with a position or force control [35.47].

This is the classic version, where the potentials only depend on the current vehicle configuration. Comple-

mentarily the generalized potentials depend also on the instantaneous robot velocity and vehicle accelerations.

Example 35.3:

$$F_{\text{rep}}(\dot{\mathbf{q}}_{t_i}) = \begin{cases} K_{\text{rep}} \sum_j \left(\frac{a \dot{\mathbf{q}}_{t_i}}{(2ad(\mathbf{q}_{t_i}, \mathbf{p}_j) - \dot{\mathbf{q}}_{t_i}^2)} \right) \mathbf{n}_{p_j} \cdot \mathbf{n}_{\dot{\mathbf{q}}_{t_i}}, & \text{if } \dot{\mathbf{q}}_{t_i} > 0 \\ 0, & \text{otherwise} \end{cases} \quad (35.11)$$

where $\dot{\mathbf{q}}_{t_i}$ is the current robot velocity, $\mathbf{n}_{\dot{\mathbf{q}}_{t_i}}$ the unitary vector pointing in the direction of the robot velocity, and a is the maximum vehicle acceleration. This expression arises when the repulsive potential is defined as the inverse of the difference between the estimated time until a collision takes place and the time needed to stop

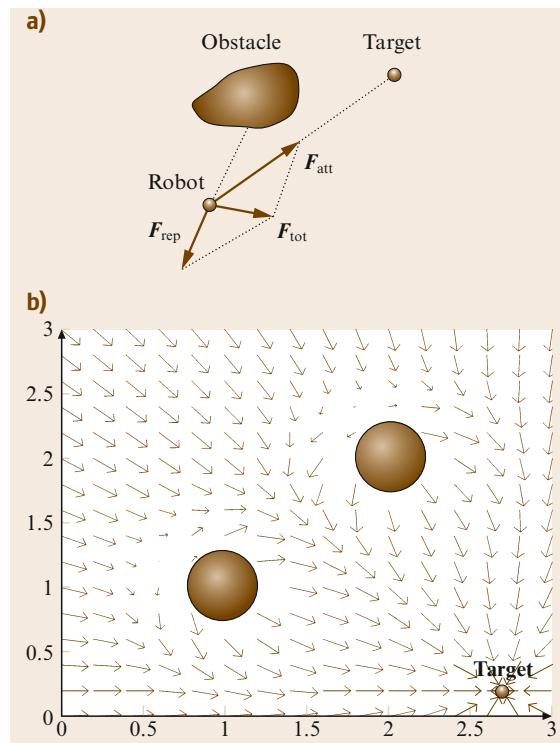

Fig. 35.9 (a) Computation of the motion direction with a potential field method. The target attracts the particle \mathbf{F}_{att} while the obstacle exerts a repulsive force \mathbf{F}_{rep} . The resulting force \mathbf{F}_{tot} is the most promising motion direction. (b) Motion directions computed in each point of the space with the classic method

the robot until full backward acceleration. Notice how the repulsive force only affects in the direction of motion of the vehicle as opposed to the classic potential. For a comparison between the classic and generalized versions, and the relation with the way to compute the motion controls next, see [35.47]. This method is widely used due to its easy understanding and clear mathematical formalism.

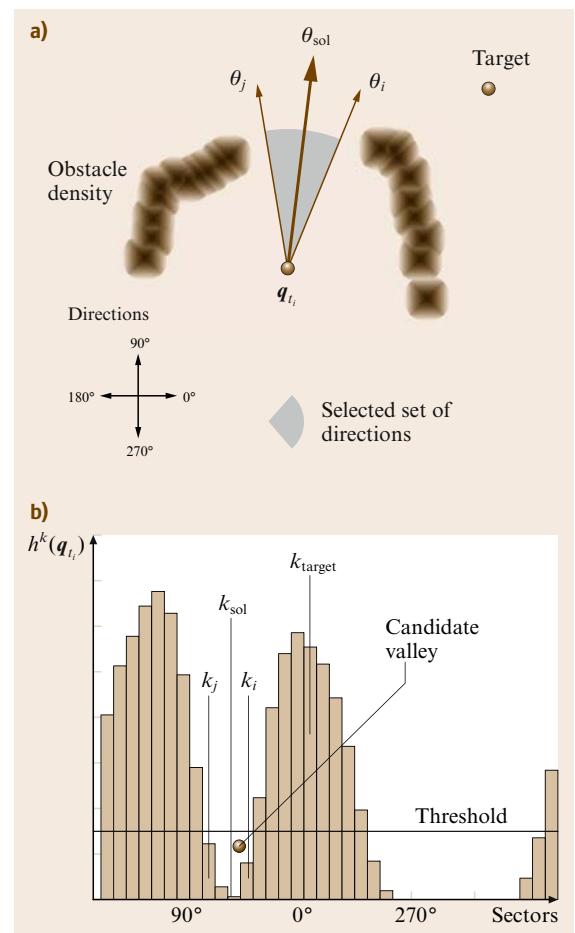

Fig. 35.10a,b Computation of the motion direction θ_{sol} with the VFH. (a) Robot and obstacle occupancy distribution. (b) The candidate valley is the set of adjacent components with lower value than the threshold. The navigation case is case 3 since the sector of the target k_{target} is not in the valley and the number of sectors is lower than a fixed quantity m ($m = 8$, i. e., 45°). Thus the solution is $k_{\text{sol}} = \frac{k_i + k_j}{2}$, whose bisector is θ_{sol} in (a). The bisectors of k_i and k_j are θ_i and θ_j , respectively

35.9.2 Vector Field Histogram (VFH)

The VFH solves the problem in two steps by computing a set of candidate motion directions and then selecting one of them.

Candidate Set of Directions

Firstly the space is divided into sectors from the robot location. The method uses a polar histogram H constructed around the robot, where each component represents the obstacle polar density in the corresponding sector. The function that maps the obstacle distribution in sector k on the corresponding component of the histogram $h^k(\mathbf{q}_{t_i})$ is:

$$h^k(\mathbf{q}_{t_i}) = \int_{\Omega_k} P(\mathbf{p})^n \left(1 - \frac{d(\mathbf{q}_{t_i}, \mathbf{p})}{d_{\max}}\right)^r d\mathbf{p} \quad (35.12)$$

The domain of integration is $\Omega_k = \{\mathbf{p} \in \mathcal{W} \setminus \mathbf{p} \in k \wedge d(\mathbf{q}_{t_i}, \mathbf{p}) < d_0\}$. The density $h^k(\mathbf{q}_{t_i})$ is proportional to the probability $P(\mathbf{r})$ that a point was occupied by an obstacle, and to a factor that increases as the distance to the point decreases (both functions powered by some integers $n, r > 0$).

Typically the resulting histogram has peaks (directions with a high density of obstacles) and valleys (directions with a low density). The set of candidate directions is the set of adjacent components with lower density than a given threshold, and closest to the component that contains the target direction. This set of components (sectors) is called the selected valley, and represents a set of candidate directions (Fig. 35.10).

Motion Computation

The objective of the next step is to choose a direction of this set. The strategy is to apply three heuristics that depend on the component that contains the target or on the size of the selected valley. The cases are checked in sequence:

1. Case 1: goal sector in the selected valley. Solution: $k_{\text{sol}} = k_{\text{target}}$, where k_{target} is the sector that contains the goal location.
2. Case 2: goal sector not in the selected valley and a number of sectors of the valley greater than m . Solution: $k_{\text{sol}} = k_i \pm \frac{m}{2}$, where m is a fixed number of sectors and k_i the sector of the valley closer to the k_{target} .
3. Case 3: goal sector not in the selected valley and number of sectors of the valley lower or equal to m . Solution: $k_{\text{sol}} = \frac{k_i + k_j}{2}$, where k_i and k_j are the extreme sectors of the valley.

The result is a sector k_{sol} whose bisector is the direction solution θ_{sol} . The velocity v_{sol} is inversely proportional to the distance to the closest obstacle. The control is $\mathbf{u}_i = (v_{\text{sol}}, \theta_{\text{sol}})$.

The VFH is a method formulated to work with probability obstacle distributions and thus is well adapted to work with uncertain sensors such as ultrasonic sonars.

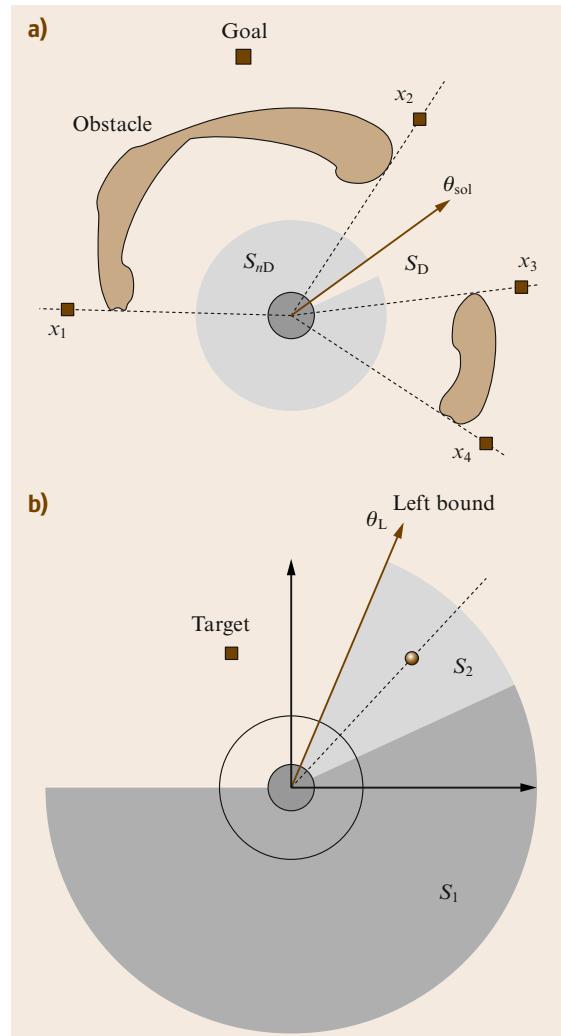

Fig. 35.11 (a) Distribution of the subgoals x_i . The selected instantaneous target location is x_2 . The set of candidate directions is S_{nD} and the solution is θ_{sol} (the second case). **(b)** The two set of undesirable directions S_1 and S_2 for a given obstacle

35.9.3 The Obstacle Restriction Method (ORM)

The **ORM** solves the problem in three steps, where the result of the first two steps is a set of candidate motion directions. The first step is to compute an instantaneous subgoal if necessary. The second step then associates a motion constraint to each obstacle and joins them next to compute the set of desirable directions. The last step is a strategy to compute the motion given this set.

Instantaneous Target Selection

This step computes a subgoal when is better to direct the motion towards a given zone of the space (that ameliorates the situation to reach the goal latter), rather than directly towards the goal itself. The subgoals are located in between obstacles or at the edge of an obstacle (Fig. 35.11a). Next, the process checks by using a local algorithm whether the goal can be reached from the robot location. If it cannot, then the closest reachable subgoal to the goal is selected. To check whether a point can be reached, there is a local algorithm that computes the existence of a local path that joins two locations [35.45]:

Let x_a and x_b be two locations of the space, R the robot radius, and L a list of obstacle points, where p_i is an obstacle of the list. Let \mathcal{A} and \mathcal{B} be the two semiplanes divided by the line that joins x_a and x_b . Then, if for all the points of L , $d(p_j, p_k) > 2R$ (with $p_j \in \mathcal{A}$ and $p_k \in \mathcal{B}$), then there is a collision-free path that joins both locations. If this condition is not satisfied, then there is no local path (although a global one could exist). The interesting result is when the result is positive, since the guarantee that one point can be reached from the other exists.

The result of the process is the goal or an instantaneous subgoal (from now on this location is called the target location). Notice that this process is general and can be used as a preprocessing step by other methods to instantaneously validate the goal location or to compute an instantaneous subgoal to drive the vehicle.

Candidate Set of Directions

For each obstacle i a set of not desirable directions for motion S_{nD}^i is computed (the motion constraint). This set is the union of two subsets: S_1^i and S_2^i . S_1^i represents the side of the obstacle not suitable to achieve avoidance and S_2^i is an exclusion area around the obstacle (Fig. 35.11b). The motion constraint for the obstacle is the union of these two sets $S_{nD}^i = S_1^i \cup S_2^i$. The set of

desired directions of motion is the complementary set $S_D = \{[-\pi, \pi] \setminus dS_{nD}\}$, where $S_{nD} = \bigcup_i S_{nD}^i$.

Motion Computation

The final step is to select a direction of motion. There are three cases, depending on the set of desirable directions S_D and on the target direction θ_{target} . The cases are checked in sequence:

1. Case 1: $S_D \neq \emptyset$ and $\theta_{target} \in S_D$. Solution: $\theta_{sol} = \theta_{target}$.
2. Case 2: $S_D \neq \emptyset$ and $\theta_{target} \notin S_D$. Solution: $\theta_{sol} = \theta_{lim}$, where θ_{lim} is the direction of S_D closest to θ_{target} .
3. Case 3: $S_D = \emptyset$. Solution: $\theta_{sol} = \frac{\phi_{lim}^l + \phi_{lim}^r}{2}$, where ϕ_{lim}^l and ϕ_{lim}^r are the directions of S_{D_l} and S_{D_r} closer to θ_{target} (S_{D_l} and S_{D_r} are the set of desirable directions of obstacles on the left-hand side and right-hand side of the target, respectively).

The result is a solution θ_{sol} for the direction of motion. The velocity v_{sol} is inversely proportional to the distance to the closest obstacle. The control is $u_i = (v_{sol}, \theta_{sol})$.

This is a geometric-based method based on cases. The advantage is that it has been demonstrated to address effective motion in confined spaces.

35.9.4 Dynamic Window Approach (DWA)

The **DWA** is a method that solves the problem in two steps, computing as intermediate information a subset of the control space \mathcal{U} . For simplicity, we consider

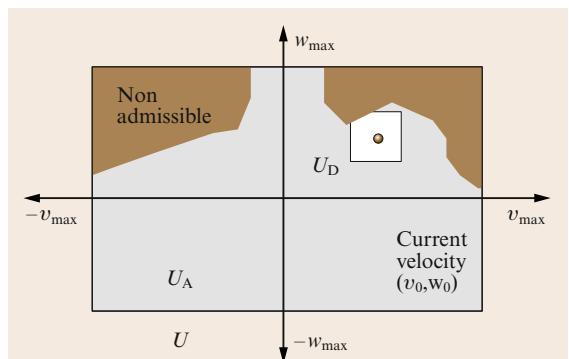

Fig. 35.12 Subset of controls $\mathcal{U}_R = \mathcal{U} \cap \mathcal{U}_A \cap \mathcal{U}_D$, where \mathcal{U} contains the controls within the maximum velocities, \mathcal{U}_A the admissible controls, and \mathcal{U}_D the controls reachable by a short period of time

a motion control as translational and rotational velocity (v, w) . \mathcal{U} is defined by:

$$\begin{aligned} \mathcal{U} = \{(v, w) \in \mathbb{R}^2 \setminus v \in [-v_{\max}, v_{\max}] \\ \wedge w \in [-w_{\max}, w_{\max}]\}. \end{aligned} \quad (35.13)$$

Set of Candidate Controls

The candidate set of controls \mathcal{U}_R contains the controls that (i) are within the maximum velocities of the vehicle \mathcal{U} ; (ii) generate safe trajectories \mathcal{U}_A ; and (iii) can be reached within a short period of time given the vehicle accelerations \mathcal{U}_D . The set \mathcal{U}_A contains the admissible controls. These controls can be canceled before collision by applying the maximum deceleration (a_v, a_w) :

$$\mathcal{U}_A = \{(v, w) \in \mathcal{U} \mid v \leq \sqrt{2d_{\text{obs}}a_v} \wedge w \leq \sqrt{2\theta_{\text{obs}}a_w}\}, \quad (35.14)$$

where d_{obs} and θ_{obs} are the distance to the obstacle and the orientation of the tangent to the trajectory over the obstacle, respectively. The set \mathcal{U}_D contains the reachable controls in a short period:

$$\begin{aligned} \mathcal{U}_D = \{(v, w) \in \mathcal{U} \setminus v \in [v_0 - a_v T, v_0 + a_v T] \\ \wedge w \in [w_0 - a_w T, w_0 + a_w T]\}, \end{aligned} \quad (35.15)$$

where $\dot{\mathbf{q}}_{t_i} = (v_0, w_0)$ is the current velocity.

The resulting subset of controls is (Fig. 35.12):

$$\mathcal{U}_R = \mathcal{U} \cap \mathcal{U}_A \cap \mathcal{U}_D. \quad (35.16)$$

Motion Computation

The next step is to select one control $\mathbf{u}_i \in \mathcal{U}_R$. The problem is set out as the maximization of an objective function:

$$\begin{aligned} G(\mathbf{u}) = \alpha_1 \cdot \text{Goal}(\mathbf{u}) + \alpha_2 \cdot \text{Clearance}(\mathbf{u}) \\ + \alpha_3 \cdot \text{Velocity}(\mathbf{u}). \end{aligned} \quad (35.17)$$

This function is a compromise among $\text{Goal}(\mathbf{u})$, which favors velocities that offer progress to the goal, $\text{Clearance}(\mathbf{u})$, which favors velocities far from the obstacles, and $\text{Velocity}(\mathbf{u})$ that favors high speeds. The solution is the control \mathbf{u}_i that maximizes this function.

The DWA solves the problem in the control space using information of the vehicle dynamics, thus the method is well adapted to work on vehicles with slow dynamic capabilities or that work at high speeds.

35.9.5 Velocity Obstacles (VO)

The velocity obstacles (VO) method solves the problem in two steps, by computing as intermediate information

a subset of the \mathcal{U} . The framework is the same as for the DWA method. The difference is that the computation of the set of safe trajectories \mathcal{U}_A takes into account the velocity of the obstacles, which is described next.

Let \mathbf{v}_i be the velocity of obstacle i (that enlarged with the vehicle radius occupies an area B_i) and \mathbf{u} a given vehicle control. The set of colliding relative velocities is called the *collision cone*:

$$CC_i = \left\{ \mathbf{u}_i \mid \lambda_i \bigcap B_i \neq \emptyset \right\}, \quad (35.18)$$

where λ_i is the direction of the unitary vector $\mathbf{u}_i = \mathbf{u}_i - \mathbf{v}_i$. The *velocity obstacle* is this set in a common absolute system of reference:

$$VO_i = CC_i \oplus \mathbf{v}_i, \quad (35.19)$$

where the \oplus is the Minkowski vector sum. The set of unsafe trajectories is the union of the velocity obstacles for each moving obstacle $\bar{\mathcal{U}}_A = \cup_i VO_i$ (Fig. 35.13).

The advantage of this method is that it takes into account the velocity of the obstacles and thus is well suited to dynamic scenarios.

35.9.6 Nearness Diagram Navigation (ND)

This method is more a methodology to design obstacle avoidance methods rather than a method in itself. The ND is an obstacle avoidance method obtained with a geometric implementation following this methodology. The idea behind this approach is to employ a divide-

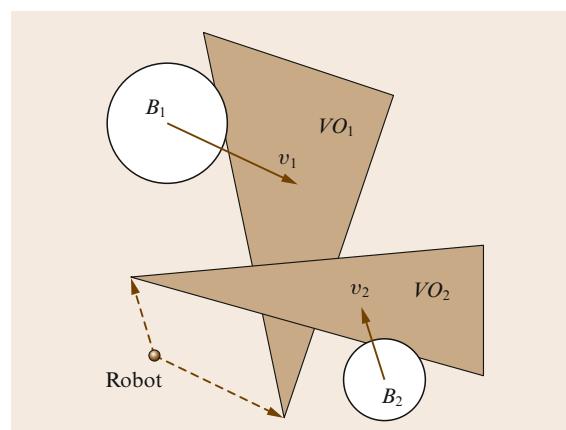

Fig. 35.13 The subset of controls that are not safe $\bar{\mathcal{U}}_A = VO_1 \cup VO_2$. A control vector out of this set generates a collision free-motion with the moving obstacles

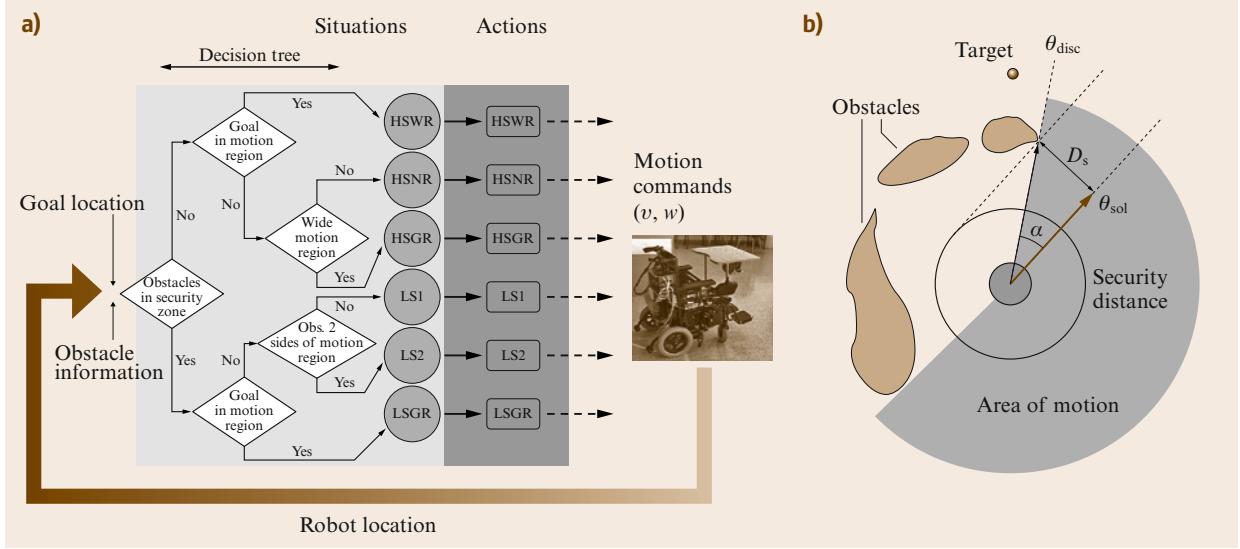

Fig. 35.14 (a) Design diagram of the method. Given the obstacle information and the target location, one situation is identified given some criteria. Next the associated action is executed, computing the motion. (b) Example of computation of the solution of the ND (geometric implementation). The first step is to identify the situation. There are not obstacles closer than the security distance D_s . Next the q_{target} is not within the motion area. Third, the motion area is wide. With these three criteria we identify the current situation, HSWR. In this situation, the associated action computes the control as $u_i = (v_{sol}, \theta_{sol})$, where v_{sol} is the maximum velocity and θ_{sol} is computed as a deviation α from the limit direction θ_{disc} of the motion area closer to the target direction

and-conquer strategy based on situations to simplify the obstacle avoidance problem following the situated-activity paradigm (see [35.48] for a review). First, there is a set of situations that represent all the cases among robot locations, obstacles, and target locations. Also, a motion law is associated with each case. During the execution phase, at time t_i , one situation is identified and the corresponding law is used to compute the motion.

Situations

The situations are represented in a binary decision tree. The selection of a situation depends on the obstacles $\mathcal{O}(q_{t_i})$, on the robot location q_{t_i} , and the target q_{target} . The criteria are based on high-level entities like a security distance around the robot bounds and a motion area (that identifies suitable areas of motion), for example, one criterion is whether there are obstacles within the security zone. Another is whether the motion area is large or narrow. The result is only one situation since, by definition and representation (binary decision tree), the set of situations is complete and exclusive (Fig. 35.14).

Actions

Associated to any situation there is an action that computes the motion to adapt the behavior to the case represented by each situation. At a high level the actions describe the behavior desired in each situation, for example, one situation is when there are no obstacles within a security area and the goal is within the motion area (HSGR). The solution is to *move towards the goal*. Another situation is when there are no obstacles within a security area, and the goal is not within the motion area but is wide (HSWR). The solution is to *move towards the limit of the motion area but clearing the security area of obstacles*.

The interesting aspect of this method is that it employs a *divide-and-conquer* strategy to solve the navigation and thereby simplifies the problem. The first advantage is that the methodology is described at a symbolic level and thus there are many ways to implement the method. Second, a geometric implementation of this methodology (the ND method) has been demonstrated to address difficult navigation cases that translate to achieving safe navigation in dense, complex, and difficult scenarios.

35.10 Robot Shape, Kinematics, and Dynamics in Obstacle Avoidance

There are three aspects of the vehicle that have to be taken into account during the obstacle avoidance process: shape, kinematics, and dynamics. The shape and the kinematics together form a geometric problem that involves the representation of the vehicle configurations in collision given the admissible trajectories $\mathcal{Q}_{t,\infty}$. The

dynamics involves the accelerations and temporal considerations and has two aspects: (i) choosing a control reachable in a short period of time T given the current velocity $\dot{\mathbf{q}}_{t_i}$ and the maximum accelerations; (ii) taking into account the braking distance, so that after a control execution, the vehicle can always stop before collision by applying the maximum deceleration (improving safety).

The problem of the shape, kinematics, and dynamics in obstacle avoidance has been taken into account from three different points of view: (i) designing a way to incorporate the constraints within the method (Sect. 35.9.4), (ii) developing techniques that abstract the vehicle aspects from the application of the method [35.49, 50], and (iii) by techniques that break down the problem into subproblems and incorporate the aspects in sequence [35.51–53] after the method usage.

35.10.1 Techniques that Abstract the Vehicle Aspects

These techniques are based on constructing an abstraction layer between the aspects of the vehicle and the obstacle avoidance method in such a way that, when the method is applied, its solutions already take into account these aspects [35.49, 50]. We consider here vehicles whose elementary paths obtained under the execution of constant controls can be approximated by circular arcs (for example a differential-drive robot, a synchro-drive or a tricycle). To simplify the analysis, a control is a translational and rotational velocity $\mathbf{u} = (v, w)$. The set of reachable controls \mathcal{U}_A given the current velocity $\dot{\mathbf{q}}_{t_i} = (v_0, w_0)$ and the maximum accelerations (a_v, a_w) is obtained by (35.15).

Abstraction Construction

For these vehicles, the configuration space \mathcal{CS} is three dimensional. The idea is to construct, centered at the robot at each time t_i , the manifold of the configuration space $ARM(\mathbf{q}_{t_i}) \equiv ARM$ defined by elementary circular paths. The function that defines the manifold is:

$$\theta = f(x, y) = \begin{cases} \arctan 2\left(x, \frac{x^2-y^2}{2y}\right) & \text{if } y \geq 0, \\ -\arctan 2\left(x, -\frac{x^2-y^2}{2y}\right) & \text{otherwise.} \end{cases} \quad (35.20)$$

It is easy to see that the function f is differentiable in $\mathbb{R}^2 \setminus (0, 0)$. Thus $(x, y, f(x, y))$ de-

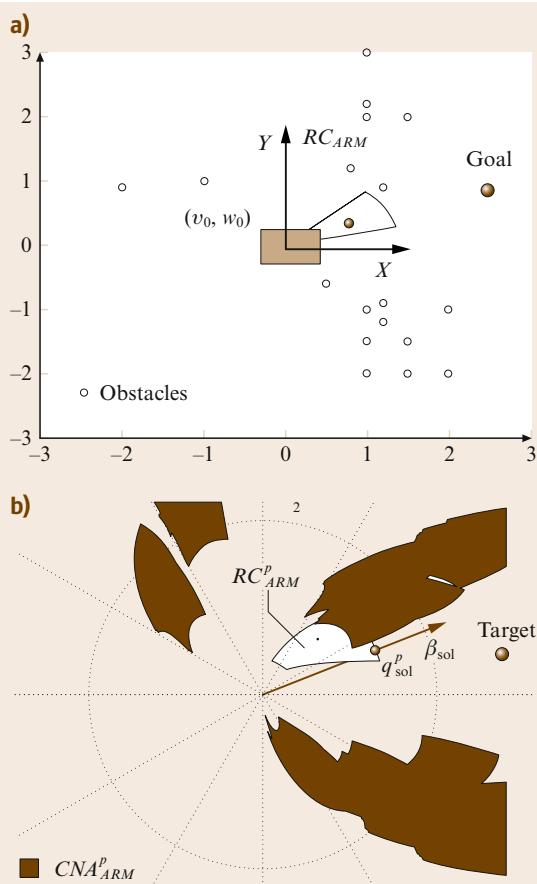

Fig. 35.15 (a) Robot location, obstacle information, and goal location. (b) The abstraction layer in ARM^p . In this representation the obstacles are the no admissible region CNA_{ARM}^p in ARM^p and motion is omnidirectional (applicability conditions of many obstacle avoidance methods). The method is applied to obtain the most promising direction β_{sol} , used to obtain the configuration solution \mathbf{q}_{sol}^p in the set of reachable configurations RC_{ARM}^p . Finally, the solution is the control \mathbf{u}_{sol} that reaches this configuration at time T . This control complies with the kinematics and dynamics and takes into account the exact vehicle shape

fines a two-dimensional manifold in $\mathbb{R}^2 \times \mathcal{S}^1$ when $(x, y) \in \mathbb{R}^2 \setminus (0, 0)$. This manifold ARM contains all the configurations that can be reached at each step of the obstacle avoidance.

Next, in the ARM one computes the exact region of the configurations in collision CO_{ARM} given any shape of the robot (i.e., obstacle representation in the manifold). Given an obstacle point (x_p, y_p) and a point of the robot bounds (x_r, y_r) , a point (x_s, y_s) of the CO_{ARM} boundary is obtained by

$$\begin{aligned} x_s &= (x_f + x_i)a, \\ y_s &= (y_f - y_i)a, \end{aligned} \quad (35.21)$$

with

$$a = \frac{[(y_f^2 - y_i^2) + (x_f^2 - x_i^2)][(y_f - y_i)^2 + (x_f - x_i)^2]}{(y_f - y_i)^4 + 2(x_f^2 + x_i^2)(y_f - y_i)^2 + (x_f^2 - x_i^2)^2}.$$

This result is used to map the robot bounds for all obstacles in the manifold, computing the exact shape of CO_{ARM} . Next, one computes the nonadmissible configurations CNA_{ARM} in the manifold ARM , which correspond to configurations where, once reached at a given velocity in time T , the vehicle cannot be stopped by applying the maximum deceleration without collision (i.e., there is not enough braking distance). These regions CNA_{ARM} are the CO_{ARM} enlarged by a magnitude that depends on the maximum vehicle accelerations. The set of configurations reachable RC_{ARM} by controls reachable in a short period of time \mathcal{U}_A is also computed in the ARM . Finally, a change of coordinates is applied to ARM , leading to ARM^P ; its effect is that elementary circular paths become straight segments in the manifold. As a consequence, the problem is now to move an omnidirectional point in a bidimensional space free of any constraint.

Method Application

The final step is to apply the avoidance method on ARM^P to avoid the CNA_{ARM}^P regions. The method solution β_{sol} is the most promising direction in ARM^P . This direction is used to select an admissible location $q_{sol}^P \notin CNA_{ARM}^P$ in the set of dynamic reachable configurations RC_{ARM}^P . Finally, the control u_{sol} that leads to this location at time T is selected. By construction, this control is kinematic and dynamic admissible, avoids collisions with the exact vehicle shape and takes into account the braking distance (Fig. 35.15).

Notice how with these techniques, the three-dimensional obstacle avoidance problem is converted into the simple problem of moving a point in a two-dimensional space without kinematic and dynamic restrictions (the applicability conditions for many existing methods). Thus, many existing methods can be applied in this abstraction, and as a consequence, the solutions take into account the vehicle constraints.

35.10.2 Techniques of Decomposition in Subproblems

These techniques address the obstacle avoidance problem, taking into account the vehicle constraints by breaking down this problem into subproblems: (i) obstacle avoidance, (ii) kinematics and dynamics, and (iii) shape. Each subproblem is dealt with in sequence (Fig. 35.16).

Obstacle Avoidance

First the obstacle avoidance method is used by assuming a circular and omnidirectional vehicle. The solution is the most promising motion direction and the velocity $u_1 = (v_1, \theta_1)$ to direct the vehicle towards the target.

Kinematics and Dynamics

Second, this control is converted into a control that complies with the kinematics and dynamics, which tends to align the vehicle with the instantaneous motion direction θ_1 of u_1 , for example, [35.52, 53] modify the output of the obstacle avoidance method by a feedback action that aligns the vehicle with the direction solution in a least-squares fashion; or [35.51] use a dynamic controller of the vehicle. This controller models the behavior of the vehicle as if it were pulled by a virtual force, and computes the motion that would result after applying this force during a short period of time. The motion generated is the new control. In order to use the controller, the previous control u_1 is converted into an instantaneous force

| Steps | Step 1 | Step 2 | Step 3 |
|-----------------------|--------------------------|---------------------------------------|------------------------------------------|
| Robot aspects | Circular omnidirectional | Circular with kinematics and dynamics | Rectangular with kinematics and dynamics |
| Subproblem (solution) | Obstacle avoidance | Motion controller | Shape corrector |

Fig. 35.16 Decomposition of the obstacle avoidance problem into subproblems that are addressed in steps, incorporating the vehicle aspects successively

$\mathbf{F} = (\theta_1, F_{\max} \frac{v_1}{v_{\max}})$ input of the controller, that computes a control \mathbf{u}_2 that complies with the kinematic and dynamics.

Shape

The final step is to ensure that the control \mathbf{u}_2 obtained in the previous step avoids collisions with the exact shape

of the vehicle. To do this, a shape corrector is used to check collisions by dynamic simulation of the control. If there is a collision, the set of reachable controls (35.15) is explored until a collision-free control is found. The result of this process is a motion control \mathbf{u}_i that guarantees obstacle avoidance and complies with the kinematics and dynamics of the vehicle.

35.11 Integration Planning – Reaction

In this section we show how the obstacle avoidance methods are integrated into real systems. On the one hand, obstacle avoidance methods are local techniques to address the motion problem. Thus, they are doomed to fall into local minima that translates in trap situations or cyclic motions. This reveals the necessity of more-global reasoning. On the other hand, motion planning techniques compute a geometric path free of collisions that guarantees global convergence. However, when the scenarios are unknown and evolve, these techniques fail, since the precomputed paths will almost surely collide with obstacles. It seems clear that one key aspect to build a motion system is to combine the best of both worlds: the global knowledge given by motion planning and the reactivity of obstacle avoidance methods.

The most extended ways to specify the interaction between the deliberation and reaction are: (i) to precompute a path to the target, which is then deformed during execution as a function of changes in the scenario obtained from sensor information (path deformation systems), for example, [35.54–56]. (ii) To use a planner at a high frequency with a tactical role, leaving the degree of execution to the reactor [35.57–62].

35.11.1 Path Deformation Systems

The *elastic bands* method initially assumes the existence of a geometric path to the target location (computed by a planner). The path is assimilated with a band, subjected to two types of forces: an inner contraction force and an external force. The inner force simulates the tension of a strip and maintains the stress. The external force is exerted by the obstacles and moves the band away from them. During execution, new obstacles produce forces that move the band away from them, guaranteeing their avoidance. These methods are described in Chap. 5 of this book.

An extension of the method of path deformation has been proposed in [35.56] for nonholonomic sys-

tems. Even though the objective is the same as for mobile robots without kinematic constraints (avoiding obstacles while following a trajectory), the concepts are completely different. The trajectory Γ of a nonholonomic system is completely defined by an initial configuration $\Gamma(0)$ and the value of the input function $\mathbf{u} \in C^1(I, \mathbb{R}^m)$, where I is an interval. The trajectory deformation method for a nonholonomic system is thus based on the perturbation of the input function of the current trajectory in order to achieve three objectives:

1. keeping the nonholonomic constraints satisfied
2. getting away from obstacles detected online by on-board sensors
3. keeping unchanged the initial and last configurations of the trajectory after deformation

Perturbing the input function of Γ , by a vector-valued input perturbation $\mathbf{v} \in C^1(I, \mathbb{R}^m)$ yields a trajectory deformation $\eta \in C^1(I, \mathbb{R}^n)$:

$$\mathbf{u} \leftarrow \mathbf{u} + \tau \mathbf{v} \Rightarrow \Gamma \leftarrow \Gamma + \tau \eta, \quad (35.22)$$

where τ is a positive asymptotically small real number. As an approximation of order one, the relation between \mathbf{u} and η is given by the linearized system, which we do not express here.

Obstacle Potential Field

Obstacles are taken into account by defining a potential field over the configuration space, which increases when the robot gets closer to obstacles. This potential field is lifted into the space of trajectories by integration along the trajectory of the configuration potential value.

Discretization of the Input Space

The space $C^1(I, \mathbb{R}^m)$ of input perturbations is an infinite-dimensional vector space. The choice of an input perturbation is restricted to a finite-dimensional sub-

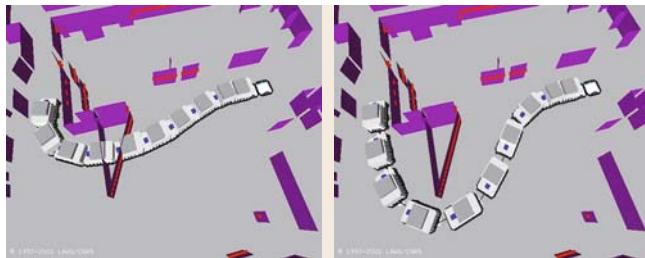

Fig. 35.17 A differentially driven mobile robot towing a trailer, applying the trajectory deformation algorithm to avoid obstacles detected online

space spanned by p arbitrary test functions, e_1, \dots, e_p , where p is a positive integer. An input perturbation: $\mathbf{u} = \sum_{i=1}^p \lambda_i e_i$ is thus defined by a vector $\lambda \in \mathbb{R}^p$. The variation of the trajectory potential is linear with respect to λ .

Boundary Conditions

The boundary conditions consist of applying a trajectory perturbation equal to zero at both ends of the interval I that is linear with respect to λ . It is therefore easy to find a vector λ that makes the potential decrease and that satisfies the boundary conditions.

Nonholonomic Constraint Deviation

The approximation of order one in the relation between the input perturbation and trajectory deformation induces a side effect: after a few iterations, the nonholonomic constraints are not satisfied anymore. This side effect is corrected by considering an augmented system with n control vector fields f_1, \dots, f_n spanning \mathbb{R}^n for each configuration and by keeping the input components

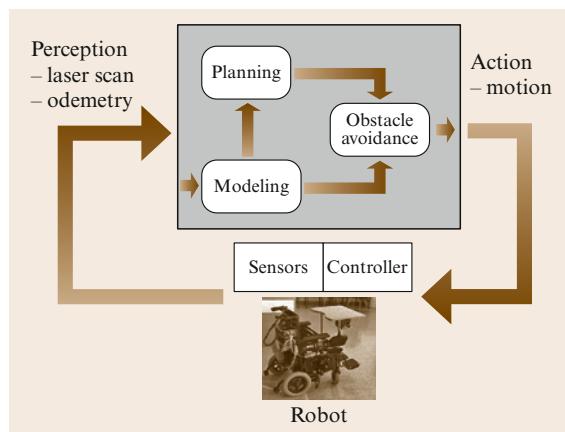

Fig. 35.18 Overview of the motion system

u_{m+1} to u_n along the additional vector fields as close as possible to zero.

Figure 35.17 shows an example of the trajectory deformation algorithm applied to a nonholonomic system.

35.11.2 Tactical Planning Systems

Tactical planning systems recompute a path to the target location at a high frequency, and use the main course to advise the obstacle avoidance module. The design of these motion systems involves the synthesis of (at least) three functionalities: the construction of a model, deliberative planning, and obstacle avoidance. The mod-

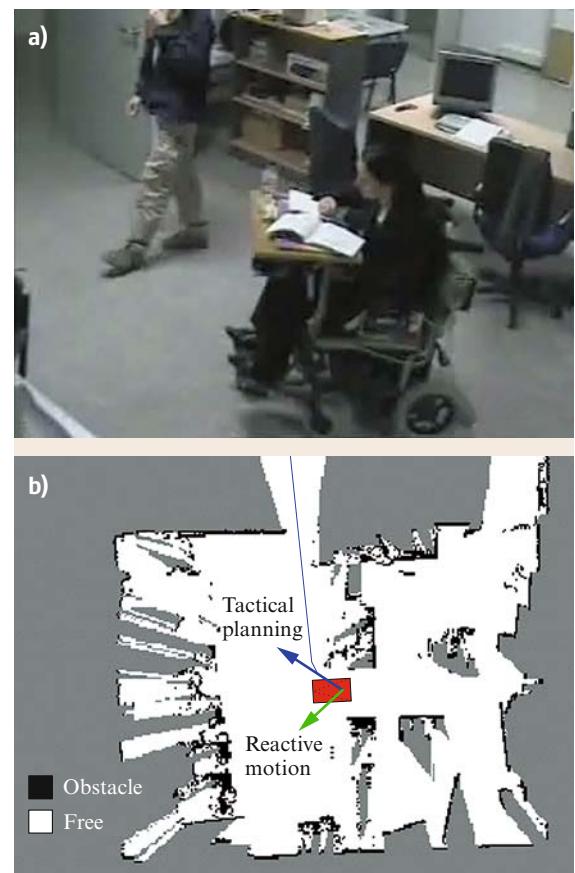

Fig. 35.19 (a) Snapshot of an experiment carried out with the motion system described working on a wheelchair robot equipped with a planar range laser sensor. (b) Information of the motion system at a given time: current accumulated map of the scenario, the path computed with the planner and tactical direction of motion, and the solution of the reactive obstacle avoidance method

eler constructs a representation base for deliberation and memory for the reactive behavior. The planner generates global plans that are used as tactics to guide the obstacle avoidance module, which generates the local motion. Below we give a perspective of the three functionalities and three possible tools to implement them [35.62].

Model Builder Module

The construction of a model of the environment (to increase the spatial domain of the planning and used as a local memory for obstacle avoidance): one possibility is to use a binary occupancy grid that is updated whenever a new sensory measurement is available, and to employ a scan matching technique [35.63, 64] to improve the vehicle odometry before integrating any new measure in the grid.

Planner Module

Extraction of the connectivity of the free space (used to avoid the cyclical motions and trap situations): a good choice is a dynamic navigation function such as D* [35.65, 66]. The idea behind the planner is to focus the search locally in the areas where the changes in the scenario structure have occurred and affect the computation of the path. The planner avoids the local minima and is computationally very efficient for real-time implementations.

Obstacle Avoidance Module

Computation of the collision-free motion: any of the methods described in this chapter could be used. One possibility is the ND method (Sect. 35.9.6) since it has been demonstrated to be very efficient and robust in environments with little space to manoeuvre.

Globally the system works as follows (Fig. 35.18): given a laser scan and the odometry of the vehicle, the model builder incorporates this information into the existing model. Next, the information about changes in obstacle and free space in the model is used by the planner module to compute the course to follow to reach the goal. Finally, the avoidance module uses the information about the obstacles contained in the grid and information from this tactical planner to generate the motion (to drive the vehicle free of collisions towards the goal). The motion is executed by the vehicle controller and the process restarts with a new sensorial measurement. It is important to stress that the three modules should work synchronously within the perception–action cycle for consistency reasons. The advantage of these systems is that the synergy of the modules allows the avoidance of trap situations and cyclic motions (the limitations associated with the local nature of the avoidance methods).

Figure 35.19 shows a snapshot of an experiment carried out with this motion system.

35.12 Conclusions, Future Directions, and Further Reading

The algorithmic tools presented in this chapter show that motion planning and obstacle avoidance research techniques have reached a level of maturity that allow their transfer onto real platforms. Today, several indoor mobile robots use obstacle avoidance techniques on a daily basis to guide visitors in museums. Outdoor applications still require some developments in terms of perception and modeling. For these applications, 3-D sensing capabilities are necessary to model the environment but also to detect obstacles. As an example, several car manufacturer are working on parallel parking assistance. The difficult point of this application is to build a model of a parking spot from 3-D data in a great variety of environments.

The grand challenge of autonomous motion in mobile robots consists today of integrating techniques from different robotics research domains in order to

plan and execute motions for very complex systems such as humanoid robots. Integration in the sense that different software components need to work together on a machine but also in a scientific meaning: the classical motion planning formulation with configuration variables that locate the robot with respect to a global reference frame does not fit partially known environments with imprecise maps. Robotic tasks like motion need to be specified with respect to landmarks of the environment. For instance, grasping an object is by definition a motion specified with respect to the position of the object. Very little has been done to design a general framework in this direction.

Useful complementary readings on motion planning and obstacle avoidance for mobile robots are [35.5, 67–69].

World Model

36. World Modeling

Wolfram Burgard, Martial Hebert

In this chapter we describe popular ways to represent the environment of a mobile robot. For indoor environments, which are often stored using two-dimensional representations, we discuss occupancy grids, line maps, topological maps, and landmark-based representations. Each of these techniques has its own advantages and disadvantages. Whilst occupancy grid maps allow for quick access and can efficiently be updated, line maps are more compact. Also landmark-based maps can efficiently be updated and maintained, however, they do not readily support navigation tasks such as path planning like topological representations do.

Additionally, we discuss approaches suited for outdoor terrain modeling. In outdoor environments, the flat-surface assumption underlying many mapping techniques for indoor environments is no longer valid. A very popular approach in this context are elevation and variants maps, which store the surface of the terrain over a regularly spaced grid. Alternatives to such maps are point clouds, meshes, or three-dimensional grids,

which provide a greater flexibility but have higher storage demands.

The construction of models of the environment is crucial to the development of several applications of mobile robot systems. It is through these environment models that the robot can adapt its decisions to the current state of the world. The models are constructed from sensor data as the robot discovers its environment. There are three challenges in constructing environment models from sensor data. First, the models must be compact so that they can be used efficiently by other components of the system, such as path planners. Second, the models must be adapted to the task and to the type of environment. For example, modeling the environment

as a set of planes is not relevant to a robot operating in natural terrain. In particular, this implies that a *universal* representation for mobile robots is not possible and that we must instead choose from an array of different approaches. Third, the representation must accommodate the uncertainty inherent to both sensor data and to the robot's state estimation system. The latter point is particularly important since environment models typically accumulate sensor readings over substantial distances into a common reference frame. Drift in position estimates are unavoidable and must be accounted for in the model representation and in its construction.

36.1 Historical Overview

Historically, work in this area concentrated first on robots operating in indoor environments. In that case, the models take advantage of the fact that the world can be represented as vertical structures on reference ground planes. This simplification can be used for representing the world as a two-dimensional (2-D) grid. Uncertainty in the measurements and in the robot's pose can then be modeled by using probabilities of occupancy in the grid rather than binary occupied/empty flags. Another feature of indoor environments is that they are highly structured in that they contain primarily linear structures such as lines and planes. This observations led to a second class of representations based on collections of points, lines, and planes to represent the environment. Here again, a lot of attention was paid to representing the uncertainty on the relative poses of these geometric elements, including a considerable amount of work in the 1980s on using Kalman filters and other probabilistic techniques.

With continued progress on sensing (e.g., longer-range image laser scanners and stereo vision), and on mechanical and controls aspects of mobile robots systems, it became possible to develop mobile robot systems for operations in unstructured, natural terrain, motivated in part by planetary exploration and military applications. In these scenarios, it is no longer appropriate to project the data in a 2-D grid, and environments cannot be described adequately by a small vocabulary of geometric elements. Since, in most cases, it is still appropriate to assume (at least locally) that there is a reference ground plane, a natural representation is a 2-1/2-D grid, in which each cell contains the elevation (and possibly other features) of the terrain at that location. Although they have been used extensively, the main challenges with such *elevation maps* are that they are not compact representations and that it is difficult to incorporate uncertainty in the representation. Accordingly, much of the research has focused on designing efficient data structures and algorithms for elevation maps, for example, hierarchical representations. Recently, the uncertainty challenge has been tackled by using probabilistic representation of the elevation maps.

While elevation maps provide a natural representation for many types of natural terrains, they cannot represent environments with vertical or overhanging structures. This limitation has become more evident in

recent years as applications of mobile robots are increasingly demanding operation in urban environment (in which building walls and other structures cannot be represented by elevation maps) and the use of aerial data, which involves overhanging structures such as tree canopies. This has led to the development of representations that are truly three dimensional (3-D), such as point clouds, 3-D grids, and meshes. The two challenges described above apply here as well, except that the situation is more complicated because of the increased complexity introduced by the third dimension. Current research includes efficient computation over 3-D structures and probabilistic representations of 3-D data.

Because of the large volume of data involved in all of these representations, it is important to be able to group the data into larger chunks corresponding to semantically meaningful parts of the environment. This can be done at different levels, depending on the application the environment. At the lowest level, work in this area involves classifying the points into classes that are relevant to navigation tasks (e.g., distinguishing between vegetation and ground, extracting walls, tree surfaces, etc.). At an intermediate level of representation, this part of the work involves extracting parts of the environments that are considered landmarks of interest for the navigation task (e.g., roads). Finally, the highest representation level involves extracting and representing objects in the environments (e.g., natural obstacles, or specific objects such as cars for operation in urban environments).

All of these representations assume a static environment. In fact, many of the current applications of mobile robots call for operation in mixed environments in which the robot shares its environments with other moving agents, including other robots, people, and vehicles. Assuming that perception algorithms are able to detect and track individual moving objects in the environment, the challenge here is to insert this information into a representation that can be used by a planner. In this case, any one of the previous representations can be used as a foundation, but it needs to be extended to handle the temporal dimension by storing a history of the locations and states of the detected objects. Such representations include the detected trajectories of the detected objects and, in some cases, information on the future predicted trajectories of the objects.

36.2 World Models for Indoors and Structured Environments

36.2.1 Occupancy Grids

Occupancy grid maps, which were introduced in the 1980s by *Moravec* and *Elfes* [36.1], are a popular, probabilistic approach to represent the environment. They are an approximative technique in which we calculate for each cell of a discrete grid the posterior probability that the corresponding area in the environment is occupied by an obstacle. The advantage of occupancy grid maps lies in the fact that they do not rely on any predefined features. Additionally, they offer a constant-time access to grid cells and provide the ability to represent unknown (unobserved) areas, which can be important, for example, in exploration tasks. Their disadvantage lies in potential discretization errors and the high memory requirements.

Throughout this section we assume that the map m consists of a discrete, two-dimensional grid of L cells denoted as m_1, \dots, m_L . Given the sensory input $z_{1:t}$ obtained by the robot at the corresponding positions $x_{1:t}$, the occupancy grid mapping approach calculates a posterior probability $p(m | x_{1:t}, z_{1:t})$.

To keep the calculations tractable, the overall approach assumes that the individual cells of the grid are independent, i.e., that the following equation holds:

$$p(m | x_{1:t}, z_{1:t}) = \prod_{l=1}^L p(m_l | x_{1:t}, z_{1:t}). \quad (36.1)$$

Note that this assumption is rather strong. It basically states that any information about the occupancy of one cell does not tell us anything about its neighboring cells. In practice, we often find objects that are larger than the individual grid cells, like doors, cabinets, chairs etc. Thus, if we know that one cell is occupied, for each of its neighboring cells the probability raises that it is occupied. Despite this fact, occupancy grid maps have been successfully applied in numerous installations of mobile robots and have been proven to be a powerful tool that supports various navigation tasks such as localization and path planning.

Because of the independence assumption expressed by (36.1) we can concentrate on the estimation of the occupancy probability of the individual cells m_l in m . Under additional independence assumptions one can finally arrive at the following formula for calculating the occupancy probability $p(m_l | x_{1:t}, z_{1:t})$ that cell m_l is occupied given $p(m_l | x_{1:t-1}, z_{1:t-1})$ and the new obser-

vation z_t observed at position x_t

$$\begin{aligned} p(m_l | x_{1:t}, z_{1:t}) &= \left(1 + \frac{(1 - p(m_l | x_t, z_t))}{p(m_l | x_t, z_t)} \cdot \frac{p(m_l)}{(1 - p(m_l))} \right. \\ &\quad \times \left. \frac{1 - p(m_l | x_{1:t-1}, z_{1:t-1})}{p(m_l | x_{1:t-1}, z_{1:t-1})} \right)^{-1}. \end{aligned} \quad (36.2)$$

In practice, one often assumes that the prior $p(m_l)$ is 0.5 so that the second factor in the product becomes 1 and therefore vanishes from the equation.

Additionally, if we define

$$\text{Odds}(x) = \frac{p(x)}{1 - p(x)}, \quad (36.3)$$

the incremental updates can be computed using the following equation:

$$\begin{aligned} \text{Odds}(m_l | x_{1:t}, z_{1:t}) &= \text{Odds}(m_l | x_t, z_t) \cdot \text{Odds}(m_l)^{-1} \\ &\quad \times \text{Odds}(m_l | x_{1:t-1}, z_{1:t-1}). \end{aligned} \quad (36.4)$$

To recover the occupancy probability from the Odds representation given in (36.4), one can use the following formula, which can easily be derived using (36.3):

$$p(x) = \frac{\text{Odds}(x)}{1 + \text{Odds}(x)}. \quad (36.5)$$

It remains to describe how to compute the occupancy probability $p(m_l | x_t, z_t)$ of a grid cell given a *single* observation z_t and the corresponding pose x_t of the robot. This quantity strongly depends on the sensor of the robot and has to be defined individually for each type of sensor. Additionally, the parameters of these models have to be adapted according to the properties of each sensor. Let us assume that the function $\text{dist}(x_t, m_l)$ refers to the distance between the sensor at pose x_t and the center of the cell m_l . Let us first assume that we only need to consider the optical axis of the sensor cone as is, for example, the case for laser beams sent out by a laser range finder. Then, $p(m_l | x_t, z_t)$ can be formulated as

$$p(m_l | x_t, z_t) = \begin{cases} p_{\text{prior}}, & z_t \text{ is a maximum range reading} \\ p_{\text{prior}}, & m_l \text{ is not covered by } z_t \\ p_{\text{occ}}, & |z_t - \text{dist}(x_t, m_l)| < r/2 \\ p_{\text{free}}, & z_t \geq \text{dist}(x_t, m_l) \end{cases}, \quad (36.6)$$

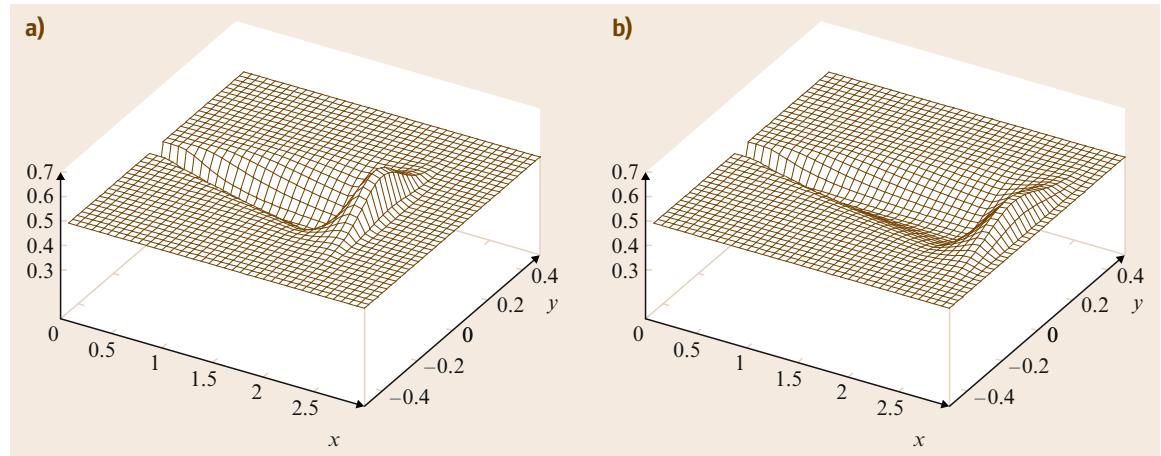

Fig. 36.1a,b Occupancy probability introduced by a single ultrasound measurement of (a) $z = 2.0\text{ m}$ and (b) $z = 2.5\text{ m}$ [36.2]

where r is the resolution of the grid map. Obviously, it must hold $0 \leq p_{\text{free}} < p_{\text{prior}} < p_{\text{occ}} \leq 1$.

If a sonar sensor is used, the sensor model is slightly more complicated, since the sensor is not a beam sensor and the observations are more noisy than the ones of a laser range finder. In practice, one typically uses a mixture of three functions to express the model. First, the influence of an observation (which is represented by the difference between p_{prior} and p_{occ} as well as between p_{prior} and p_{free}) decreases with the measured distance. Second, the proximity information of a sonar is substantially affected by noise. Therefore, one typically uses a piecewise-linear function to model a smooth transition from p_{free} to p_{occ} . Finally, the sonar sensor should not be modeled as a beam sensor, since it sends out a conic signal. The accuracy of an observation decreases with the angular distance between the cell under consideration and the optical axis of the observation. This is expressed by the derivation from the prior and is typically modeled using a Gaussian with zero mean. Therefore, it is maximal along the optical axis and decreases the bigger the angular distance from the optical axis is [36.2].

Two examples for a resulting model are depicted in Fig. 36.1, which shows two three-dimensional plots of the resulting occupancy probabilities for a meas-

Fig. 36.2 Incremental mapping in a corridor environment. The *upper left* image shows the initial map and the lower one shows the resulting map. The maps in between are the local maps built from the individual ultrasound scans perceived by the robot [36.2] ◀

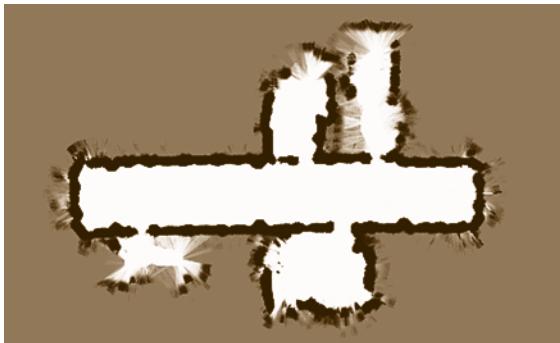

Fig. 36.3 Occupancy grid map obtained from ultrasound data [36.2]

urement of 2 m (Fig. 36.1a) and 2.5 m (Fig. 36.1b). In this figure, the optical axis of the sensor cone was identical with the x -axis and the sensor was placed in the origin of the coordinate frame. As can be seen, the occupancy probability is high for cells whose distance to x_t is close to z_t . It decreases for cells with shorter distance than z_t as well as with increasing values of the angular distance.

Figure 36.2 depicts the mapping process for a sequence of observations recorded with an iRobot B21r robot. The first row shows how a map was built from a sequence of previous ultrasound scans. Afterwards the robot perceived a series of 18 ultrasound scans, each consisting of 24 measurements. The occupancy probabilities for these 18 scans are depicted in rows 2–7. The occupancy probability grid obtained by integrating the individual observations into the map is shown in the last row of this figure. As can be seen, the belief converges to a representation of the corridor structure in which the scans were recorded. A typical resulting map obtained for an indoor environment is depicted in Fig. 36.3.

36.2.2 Line Maps

The representation of the environment by line models is a popular alternative to the grid-based approximations described above. Line models have several advantages over these nonparametric representations. They require substantially less memory than grids and therefore scale better with the size of the environment. They furthermore are more accurate since they do not suffer from discretization problems. In this section, we consider the problem of calculating lines that provide the approximation of a set of range points by a line. If the data points are given by n pairs (x_i, y_i) of Cartesian coordinates, the

line that minimizes the squared distances to all points can be calculated in closed form according to

$$\tan 2\phi = \frac{-2 \sum_i (\bar{x} - x_i)(\bar{y} - y_i)}{\sum_i [(\bar{y} - y_i)^2 - (\bar{x} - x_i)^2]}, \quad (36.7)$$

$$r = \bar{x} \cos \phi + \bar{y} \sin \phi, \quad (36.8)$$

where $\bar{x} = \frac{1}{n} \sum_i x_i$ and $\bar{y} = \frac{1}{n} \sum_i y_i$. In these equations, r is the normal distance of the line from the origin and ϕ is angle of the normal.

Unfortunately, there is no closed-form solution for situations in which the data points are generated by multiple linear structures. In such a situation two problems arise. First one has to answer the question how many lines there are, and second one has to solve a data association problem, which is to find the assignment of the data points to the individual lines. Once the number of lines and the associations are known, we can apply (36.7) and (36.8) to calculate the individual line parameters.

There is a popular approach to solve this problem for range scans with multiple linear structures. This approach, which goes back to the work of *Douglas* and *Peucker* [36.3], is also known as the *split-and-merge* algorithm. Its key idea is to recursively subdivide the point set into subsets that can be more accurately approximated by a line. The approach starts with the line calculated from all data points and determines the data point with maximum distance from this line. If this distance is below a given threshold, the algorithm terminates and provides the fitted line as output. Otherwise,

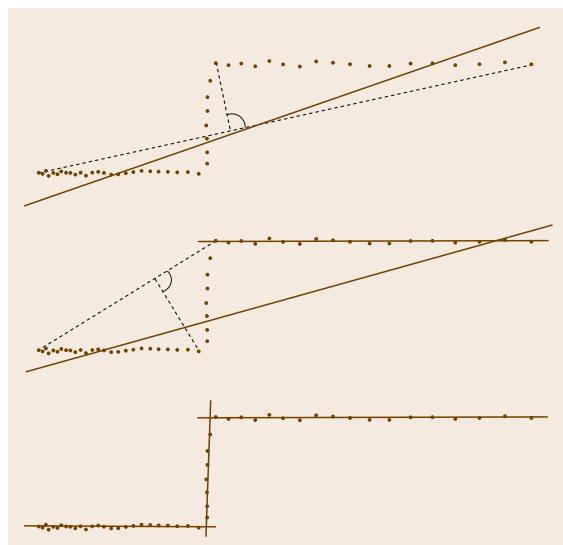

Fig. 36.4 Split-and-merge algorithm applied to a point set

it calculates the point with the largest distance from the line that connects the first and the last point. This point is the so-called splitting point. It then divides the point set into two subsets, one containing all points up to the first to the splitting point and one containing all points after the splitting points. The algorithm is then recursively applied to the two subsets.

Whereas the split-and-merge algorithm is quite effective and efficient, it is not guaranteed that the resulting model is actually optimal, i.e., is the model that minimizes the squared distances of all data points. One approach that is able to find such a model is based on the expectation maximization (EM) algorithm, which in the application described here can be regarded as a variant of the fuzzy k -means clustering algorithm. Let us suppose that the number m of lines in the model θ is known. Let us furthermore suppose that the likelihood of a data point $z = (x, y)$ given the model θ consisting of the line set $\{\theta_1, \dots, \theta_m\}$ is defined as

$$p(z | \theta) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2} \frac{d(z, \theta_j)^2}{\sigma^2}\right), \quad (36.9)$$

where σ is the standard deviation of the measurement noise and θ_j is the line for which Euclidean distance $d(z, \theta_j)$ to z is minimal.

The goal of the EM algorithm is to generate an iterated sequence of models of increased likelihood. To achieve this, one introduces so-called correspondence variables $c_{ij} \in \{0, 1\}$ that specify to which linear component of the model each point belongs. Since the correct values of these assignment variables are unknown, one estimates a posterior about their values. Let θ_j be a component of the model and z_i be a measurement. Then the expectation about c_{ij} , i.e., that measurement i belongs to line j is computed in the E-step as

$$E[c_{ij} | \theta_j, z_i] = p(c_{ij} | \theta_j, z_i) \quad (36.10)$$

$$= \alpha p(z_i | c_{ij}, \theta_j) p(c_{ij} | \theta_j) \quad (36.11)$$

$$= \alpha' p(z_i | \theta_j). \quad (36.12)$$

In the M-step, the algorithm then computes the parameters of the model by taking into account the expectations computed in the E-step:

$$\theta_j^* = \arg \min_{\theta'_j} \sum_i \sum_j E[c_{ij} | \theta_j, z_i] d^2(z_i, \theta'_j). \quad (36.13)$$

Given a fixed variance σ for all data points in z we can determine the most likely model in closed form according to the following equations, which are probabilistic variants of (36.7) and (36.8) that take into account the

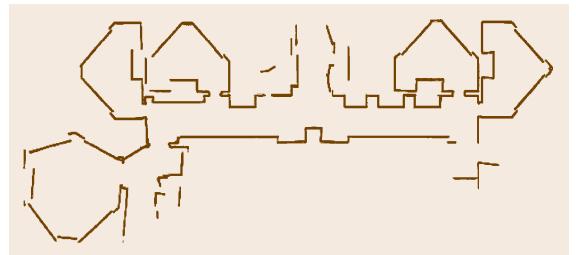

Fig. 36.5 Line map consisting of 94 lines generated for 311 823 range points generated with the EM-based approach [36.4]

data association uncertainty given by the expectations calculated in the E-step:

$$\tan 2\phi_j = \frac{-2 \sum_i E[c_{ij} | \theta_j, z_i] (\bar{x} - x_i)(\bar{y} - y_i)}{\sum_i E[c_{ij} | \theta_j, z_i] [(\bar{y} - y_i)^2 - (\bar{x} - x_i)^2]}, \quad (36.14)$$

$$r_j = \bar{x} \cos \phi_j + \bar{y} \sin \phi_j. \quad (36.15)$$

Here \bar{x} and \bar{y} are computed as

$$\bar{x} = \frac{\sum_i E[c_{ij} | \theta_j, z_i] x_i}{\sum_i E[c_{ij} | \theta_j, z_i]}, \quad \bar{y} = \frac{\sum_i E[c_{ij} | \theta_j, z_i] y_i}{\sum_i E[c_{ij} | \theta_j, z_i]}. \quad (36.16)$$

Figure 36.5 depicts a line map extracted from 311 823 data points using the EM-based approach. In this example, the model consists of 94 lines. One approach to determine the optimal line is to utilize the Bayesian information criterion [36.4].

36.2.3 Topological Maps

In contrast to the previously discussed representations, which mainly focus on the geometric structure of the environment, topological representations have also received significant attraction. One of the pioneering

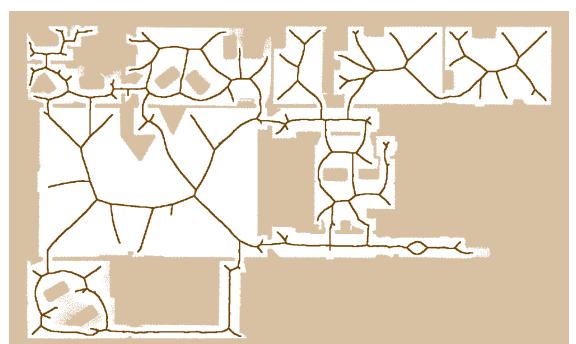

Fig. 36.6 Example of a generalized Voronoi graph [36.5]

Fig. 36.7 (a) Mobile robot mapping a set of stone rocks. The right image (b) depicts the path and the estimated landmark positions. The manually determined positions of the rocks are marked by *circles* [36.8]

approaches to topological mapping have been presented in 1988 is the work by *Kuipers and Byun* [36.6]. In this approach, the environment is represented by a graph-like structure, in which the nodes are locally distinguishable places and the edges are travel edges along which the robot can move between the places. Here, distinctive places are identified according to the distance to nearby objects. The distinctive places were defined by *Choset* and colleagues [36.7] as the meet-points in the generalized Voronoi diagrams, i. e., the points with an out-degree of three or more. A generalized Voronoi diagram is the set of points equidistant from the closest two or more obstacle boundaries. Generalized Voronoi diagrams are a very popular representation as they can be considered as road-maps with a high correspondence to the topological structure of the environment. They have been used extensively for path planning. To plan a path from a starting position to a goal point in the environment, all the robot has to do is to first plan a path to the generalized Voronoi graph, than along the generalized Voronoi graph, and then from the generalized Voronoi graph to the goal point [36.7]. Figure 36.6 shows an example generalized Voronoi graph for an indoor environment. Note that in this figure only those parts of the graph that can be traversed by the robot without colliding with objects are displayed.

36.2.4 Landmark-Based Maps

For environments with locally distinguishable features, landmark-based maps have been extensively used. If we assume that the position of the robot is always known, it simply remains to maintain an estimate about the positions of the individual landmarks over time. In a planar environment, m is represented by K two-dimensional Gaussians with mean μ_k and covariance Σ_k , one for each landmark. If a linearized version of the perception problem is given, the individual Gaussians can be updated using the equations for the extended Kalman filter. Note that, compared to the use of the EKF for landmark-based simultaneous localization and mapping (SLAM), where we needed a $2K + 3$ -dimensional state vector (3 dimensions for the position of the robot and $2K$ dimensions for the positions of the individual landmarks), we only need K two-dimensional Gaussians to represent the entire map since the robot pose is known. This property, for example, has been utilized in the FastSLAM algorithm [36.8].

The left image of Fig. 36.7 shows a robot equipped with a SICK laser range finder that maps the position of rocks. The right image depicts the path of the vehicle as well as the manually determined and automatically estimated landmark positions.

36.3 World and Terrain Models for Natural Environments

From a survey of environment modeling [36.9] with an emphasis on probabilistic techniques for indoor environments, a taxonomy can be created along several axis: metric versus topological versus semantic, robot-centric versus world-centric, or application-based. We choose to first review purely geometric models (elevation grid, 3-D grid, meshes), then geometric models with low-level attributes (cost maps), and then models with

richer semantic attributes, to finish with heterogeneous and hierarchical models.

36.3.1 Elevation Grids

Assuming that the terrain can be represented as a function $h = f(x, y)$, where x and y are the coordinates on a reference place and h is the corresponding eleva-

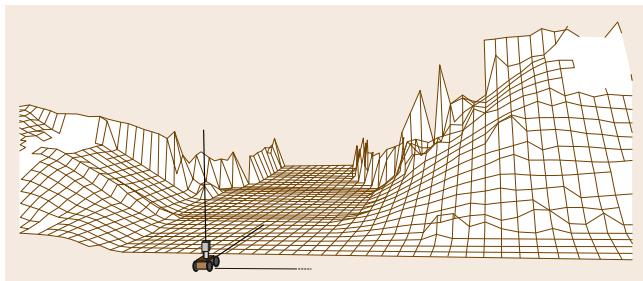

Fig. 36.8 Example elevation map built by accumulating 3-D data from a range sensor

tion. A natural representation is a digital elevation map which stores the value of h at discrete locations (x_i, y_i) . Because they are simple data structures and can be generated from sensor data in a relatively straightforward manner, elevation maps have been used extensively for mobile robots operating in natural environments with no vertical surfaces or overhangs (e.g., for planetary exploration scenarios [36.10]). Several issues need to be addressed when using elevation maps for mobile robots.

A regularly sampled grid is appropriate when the sensor data is roughly uniformly distributed on the reference plane. This is the case, for example, with aerial data. For ground robots, however, the distribution of the data on the reference ground plane varies dramatically because of the small incidence angles with the reference plane. This can be addressed by using variable-size cells instead of regularly sampled cells. In that case, the distribution of the cells on the reference plane is designed to approximate the distribution of points that would be measured by the sensor on this reference plane. Such nonuniform representations are useful primarily in cases in which the map is referenced to the current position

of the robot [36.11] (Fig. 36.9). Frequent resampling is needed if the map is expressed in a global reference frame.

Irrespective of the sampling scheme used to construct the reference grid, the density of data in the grid varies due to local self-occlusions of the terrain surface and to mismatches between the resolution of the projected sensor data and the resolution of the grid. This can be problematic because, from the point of view of a planner, the elevation map would appear as a scattering of cells with elevation data and cells with no evidence. Various schemes have been proposed to remedy this problem. The basic idea is to estimate the elevation values of the empty cells by interpolating across the cells with known elevation values. This has to be done with great care to avoid filling up regions that correspond to parts of the environment occluded by the terrain (*range shadows*) in which elevation data should not be inferred. Such mistakes can be catastrophic since a planner may generate paths through areas that are entirely unknown. One general approach to this problem is to use surface interpolation techniques including a term that allows for discontinuities in the resulting surfaces [36.12]. An alternative approach is to use the visibility constraints induced by the known geometry of the sensor in order to estimate plausible values of elevation at each cell [36.13, 14].

A difficulty in interpolating techniques is to explicitly take into account the sensor uncertainty. In particular, it is difficult to account for the varying resolution of the sensor as a function of range in a fixed-resolution grid. An alternative is to use multiple grids at different resolutions. The appropriate resolution to be used at a particular point (x, y) can be decided based on the range from (x, y) to the closest sensor location to retrieve the value at (x, y) from the appropriate map for that resolution. Generally, the longer the range, the coarser maps that are used. This approach eliminates the gaps in the map due to undersampling at long range from the sensor by using the optimal resolution based on sensor geometry [36.15].

Uncertainty in the sensor measurement is expressed most naturally with respect to the sensor frame, for example, by expressing the uncertainty in the direction of measurement. As a result, converting such uncertainty models to elevation maps is difficult because a distribution in the direction of the measurement maps to a distribution in the reference plane, not a distribution on the elevation value at a particular grid point. When updating a cell based on sensory input, one has to take into account that the uncertainty in a measurement increases

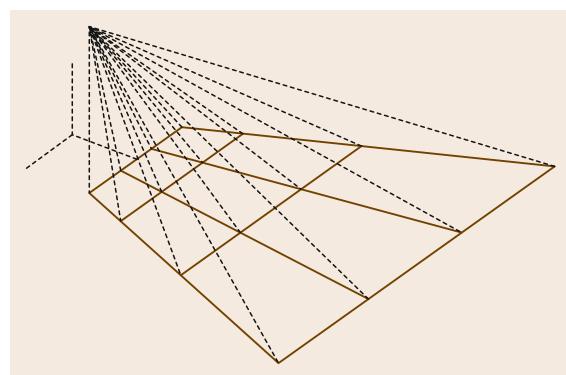

Fig. 36.9 Example of a robot-centric map with variable size (after [36.11])

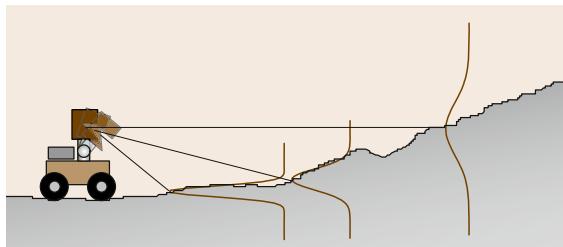

Fig. 36.10 The standard deviation of a height measurement can be modeled to depend linearly on the distance to the grid cell

with the distance measured due to errors in the tilting angle. A popular approach to estimate the height h at location (x, y) is to use a Kalman filter. If we assume that σ is the standard deviation of the current measurement h in the vertical direction in (x, y) and σ_{t-1} is the standard deviation of the current estimate or h_{t-1} , we can apply the following equations to obtain the new estimate h_t with standard deviation σ_t ,

$$h_t = \frac{\sigma^2 h_{t-1} + \sigma_{t-1}^2 h}{\sigma_{t-1}^2 + \sigma^2}, \quad (36.17)$$

$$\sigma_t^2 = \frac{\sigma_{t-1}^2 \sigma^2}{\sigma_{t-1}^2 + \sigma^2}. \quad (36.18)$$

One possible solution to deal with varying uncertainties is to use a model in which the standard deviation of the height of a measurement increases linearly with the length of the range measurement, as indicated in Fig. 36.10.

Vegetation cover is another source of error in the recovery of terrain elevation by totally or partially occluding the ground surface from the vehicle sensors. Online learning techniques can address this issue by predicting ground elevation ahead of the vehicle based on past appearance observations of similar terrain and vehicle state over the terrain [36.17].

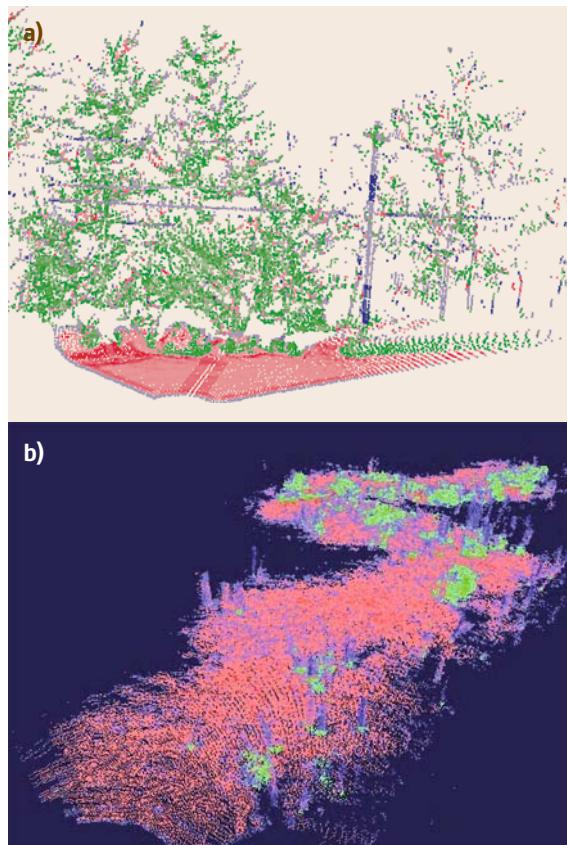

Fig. 36.12a,b Example of mapping and classification of 3-D point sets: (a) 3-D data and classification result (green = vegetation, red = surfaces, blue = lines; the saturation of the color is proportional to the confidence in the classification result); (b) map accumulated over a large number of scans

Intermediate representations between 2-D elevation maps and full 3-D representations, addressed below, are extended elevation maps [36.18] and so-called multilevel surface maps [36.16]. Such approaches are

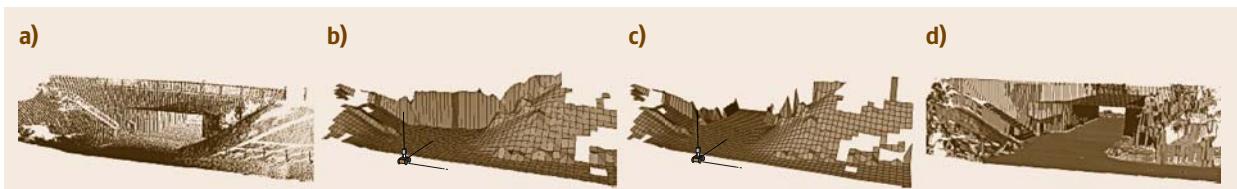

Fig. 36.11a–d Different versions of digital elevation maps [36.16]: (a) scan (point set) of a bridge, (b) a standard elevation map computed from this data set, (c) an extended elevation map, which correctly represents the underpass under the bridge, and (d) a multilevel surface map that correctly represents the height of the vertical objects

specifically useful in structured terrain with vertical objects or overhangs such as bridges (Fig. 36.11).

36.3.2 3-D Grids and Point Sets

Elevation maps as described above assume a reference direction. In many cases, this assumption is violated. An alternative is to represent the data directly in 3-D without projecting it onto a reference 2-D plane. The advantage of doing this is that all the sensor data can be preserved in its original distribution and that there is no restriction on the geometry of the environment. The problem is to be able to manipulate efficiently very large sets of 3-D points. Data structures based on dynamic 3-D grids can be used for this purpose [36.21]. An interesting characteristic of these representations is that they enable the computation of cost evaluated from the true local 3-D distribution of the data (as opposed to costs computed from a local surface). This is important, for example, in environments with vegetation scatter, which cannot be modeled as a surface.

In the past, octree-based 3-D representations have been successfully used to map an underwater cave from several sonars mounted on an underwater vehicle [36.19]. The data structure is designed to maintain efficiently, in terms of memory and access time, hundreds of maps to store particles for localization. However, dense 3-D occupancy grids have also been maintained to model natural environments using a radar [36.20]. An example of each approach is presented in Fig. 36.13.

In the approaches mentioned above, the data sets are accumulated, sometimes probabilistically, into discrete environment volumes. A different approach is to represent the environment with discrete sensor samples

integrated probabilistically into a metric map [36.22]. Such an approach is different from occupancy grids in several aspects: the storage requirement and resolution is adaptive instead of fixed and the potential for extensibility and scalability is higher.

36.3.3 Meshes

As described above, elevation maps are compact and easy to implement but they are restricted to a particular class of terrain; at the other extreme, using 3-D representations directly is more general but it is also more expensive computationally, and it does not represent explicitly surface continuity. A compromise is to represent the map as a mesh. This approach is attractive because it can, in principle, represent any combination of surfaces. It is also a compact representation in that, even though the size of the mesh may be initially very large, efficient mesh simplification algorithms exist in the literature [36.23] and can be used to reduce the map to a small number of vertices.

The key issue with meshes is that extraction of the correct surfaces from raw data can be difficult in complex environments. In particular, the data is corrupted by sensor noise and by random clutter from other sources, such as vegetation, which cannot be represented as a continuous surface. In addition, it is necessary to detect discontinuities in the data precisely so that disconnected pieces of surface do not become accidentally linked in the mesh formation process [36.18]. Figure 36.14 shows typical mesh representations of an urban environment.

In some applications, the objective is to produce terrain models not to support autonomous navigation but to produce a model to be visualized to a human. City planning is a typical application. Examples

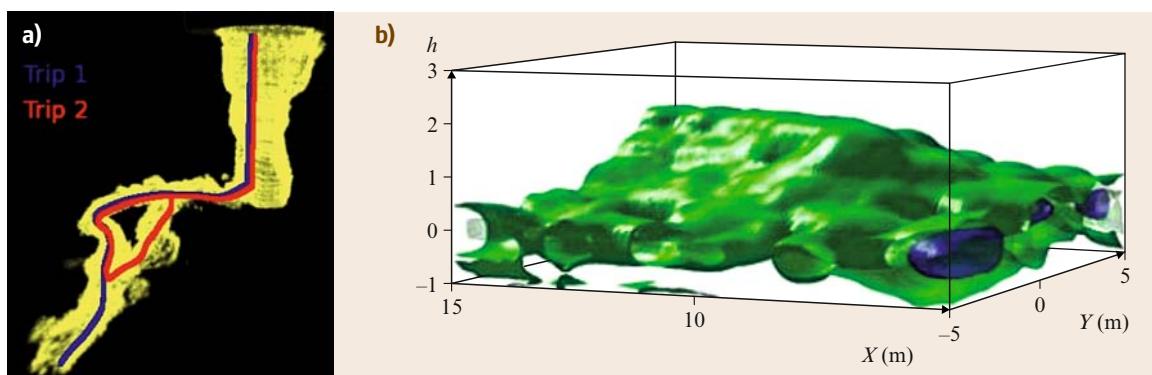

Fig. 36.13a,b Examples of volumetric maps for a natural environment. Whereas (a) shows a map of an underwater cave [36.19], (b) depicts a terrain map obtained from a radar [36.20]

Fig. 36.14a–c Two views (b–c) of the mesh representation of a map (a) obtained by scanning an environment. The meshes are reduced by a factor of 10 from the initial data sampling

Fig. 36.15a–c Examples of urban terrain modeled as a textured mesh (a) from [36.24], (b) from [36.26], and (c) from [36.25])

include producing 3-D texture models of urban environments using videos from a camera mounted on a moving vehicle equipped with an inertial navigation system [36.24], using two laser scanners in push-broom mode, one for mapping and the other for localization [36.25], with a camera coregistered with the mapping laser, and collecting high-resolution laser data and imagery to produce geometric and photometric cor-

rect 3-D models of buildings [36.26]. Figure 36.15 depicts examples of textured meshes representing urban terrain.

36.3.4 Cost Maps

The most direct use of elevation maps is to compute traversability costs at each cell of the grid. The costs

are computed by comparing the local terrain shape with a kinematic model of the robot. Several approaches have been proposed for computing the costs depending on the exact vehicle model; for example, a cost can be computed by considering the local slope and 3-D texture of the terrain [36.27]. More involved models take into account a detailed model of the robot dynamics. In that case, different costs are generated for different possible robot speeds and path curvatures. The cost grid is used in a minimum-cost planner. Since the terrain map is updated continuously as the robot traverses the environment, it is also necessary to update the costs continuously as new data arrives. Consequently, it is important that the planner is able to support changing costs without needing to process the entire grid every time new data is inserted.

An example of such a combination of grid representation and dynamic planner is the D* system, which uses a version of A* that fully supports dynamic grid updates [36.29–31]. Whenever a grid cell (or a group of grid cells) is updated, the planner makes minimal updates to its internal representation so that the optimal path can be updated quickly.

Defining the exact relation between the costs and the elevation values stored in the grid can be quite difficult. In fact, beyond the limiting cases of terrain with large elevation gradient or large slope, there is little guidance as to why a particular part of the terrain may be more traversable than another as it depends critically on the exact configuration of the robot. For this reason, recent work has focused on deriving cost maps directly from observations, rather than by using handcrafted algorithms. One approach involves learning the best weights to combine a set of predefined costs. Another approach uses costs computed from other sources for inferring how to determine the costs on the terrain currently seen

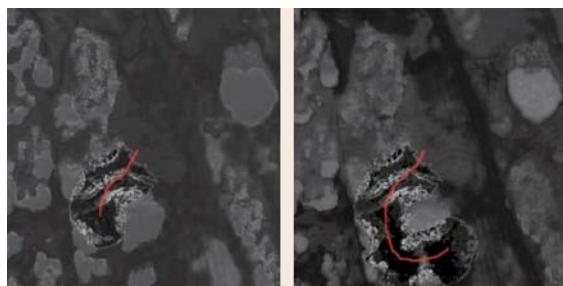

Fig. 36.16 Example of online learning of cost [36.28]. The vehicle trajectory is represented in red. As the vehicle progresses, note the change in cost over all the map. The *darker* the appearance, the lower the cost

by the robot; for example, data from overhead imagery can be used to predict the traversability costs that should be used for a ground robot [36.28] or for learning to map local elevation distributions to costs values by analyzing actual robot trajectories through the terrain. Similar online learning approaches are used to predict terrain roughness [36.32], terrain slippage [36.33], or traversability in general [36.34, 35] to be used in a cost map.

36.3.5 Semantic Attributes

The representations described above are concerned only with storing the data in a way that is compact and that can be used to estimate drivability costs. Often it is necessary to reason with high-level knowledge about the environment, e.g., the location and types of objects around the robot or the type of terrain (vegetation, mud, wall) in the environment. For convenience we will refer to this type of information as *semantic attributes* attached to different parts of the environment. There are several different ways to approach the problem of generating and representing semantic attributes. One possible direction is to approach the problem as one of extracting *landmarks* from the environment. As for their indoor counterparts, outdoor environments can also be modeled using landmarks. Landmarks are defined broadly as scene elements easy to detect, salient in their surroundings, and easy to recognize. They can be specific objects, such as rocks [36.36], tree trunks in forest [36.37], or locations with a distinct appearance signature in 2-D or 3-D, for urban terrain [36.38, 39] or natural environments [36.40]. Landmarks can be used to produce topological representations of the environment or used in conjunction with metric maps. Recent efforts involve learning a compact representation of environments without defining a priori what a landmark should be [36.41, 42] or using statistical learning techniques [36.43] to extract new features from images. Nonlinear dimension-reduction techniques are used to obtain the representation and the results were demonstrated onboard ground and aerial vehicles.

Another view of the problem is as a *classification and grouping* problem. Indeed, the map representations described in the earlier sections are low-level representations in that they do not attempt to group the data points into larger structures that are coherent with respect to geometry, terrain type, or semantic content. In practice, one would like to abstract the data into larger units that can be used by a planner or transmitted to another robot or an operator; for example, in an urban environment, one would like to group the parts of the data that belong

to planes corresponding to pieces of walls. One such example is presented in Fig. 36.18.

One approach is to group 3-D points into components based on low-level classification and feature detection [36.45]. The shape of these component is analyzed further to discriminate between various natural object components (tree trunks, branches) and manmade obstacle (wires). Geometric primitives are then fitted to the components (mesh for the ground surface, ball tree for the vegetation, and cylinder to branches) to produce a compact high-level geometric description of the terrain.

Local terrain classification can be achieved by computing local features from the map and classifying each element of the map in different classes of terrain. This can be done from an elevation map, in which case the *elements* are the cells of the elevation map, or from a point cloud representation in which case the elements are 3-D locations. Given a location in the map x , a feature vector is $V(x)$ is computed in a neighborhood $N(x)$ of x and a classifier $f(V)$ returns the type of terrain at x . Features that have been used in the past are statistics of the distribution of the map data around each element, such as the slope and distribution of elevation [36.46], and the second-order moment of the distribution of the 3-D points in a neighborhood [36.45]. The terrain classes depend on the application. The most direct classification approach uses a binary classifier that separates the terrain into obstacle regions and traversable regions. More involved classifiers segment the map into more classes such as vegetation, solid surfaces, and linear structures [36.13, 45, 47]; an example is shown in Fig. 36.12. In some cases, it is possible to store, with each data element x in the map, the direction in which a measurement was taken for this element. In this case, it is possible to refine the classification by reasoning about the intersection of the measurement ray $d(x)$ with the rest of map; for example, this type of geometric reasoning [36.48] has been exploited to recover the load-bearing surface obscured by vegetation [36.40, 49, 50] and for extracting *negative* obstacles (such as ditches) [36.51]. In all of these cases, the classification information cannot be recovered directly from local statistics and must be inferred from longer-range geometric reasoning.

This class of approaches to local feature classification is similar to approaches for extracting features from images and it suffers from similar limitations. Specifically, these representations are sensitive to the choice of neighborhood used for computing the features. If it is too large, information over a large area is aver-

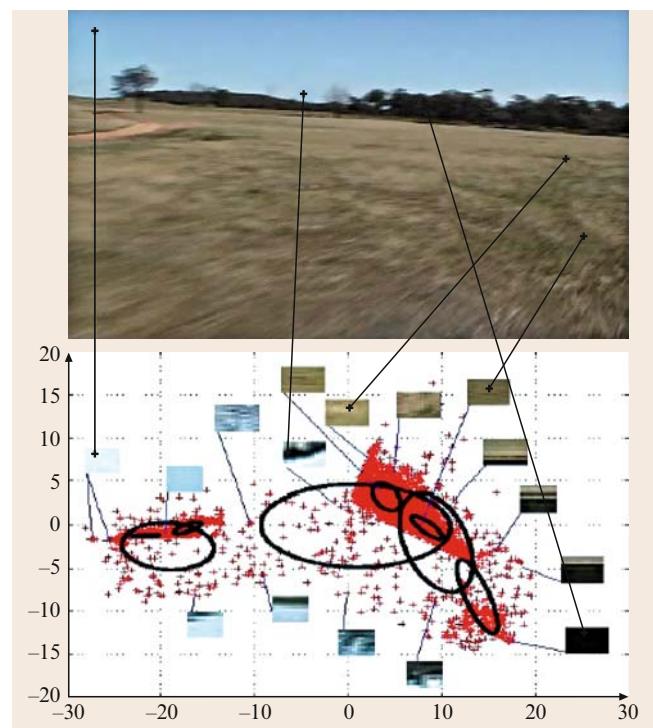

Fig. 36.17 Sample image and low-dimensional embedding of randomly sampled high-dimensional image patches [36.42]

aged out, leading to poor classification performance. If it is too small, there is not enough information in the neighborhood for reliable classification. The situation is complicated by the fact that the resolution of the map, or more precisely the density of data points in the map, may vary drastically as the distance from the sensor changes. This problem is addressed by using different neighbor-

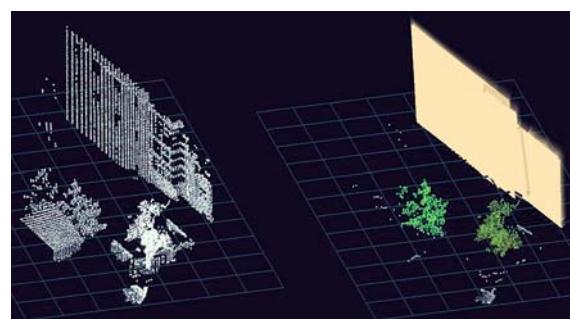

Fig. 36.18 Terrain classification and extraction of geometric features. Whereas the 3-D data is shown on the *left*, the feature map with extracted planes and vegetation regions is shown on the *right* [36.44]

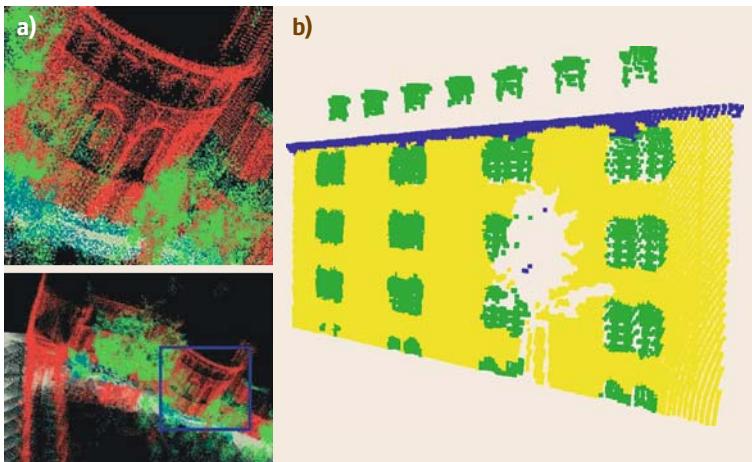

Fig. 36.19 (a) Structure learning for terrain classification [36.54] and (b) building features extraction [36.55]

hood sizes at different locations in the map, or by tuning the classifier differently depending on the map location, typically based on distance from the sensor [36.15, 52]. A second problem is to generate the classifier f . This can be done by using a physical model that predicts the statistics of the local data distribution in the map assuming different terrain types [36.53]. This is generally difficult and a preferred approach is to train the classifier on training data.

This level of classification provides information about the local type of terrain, which can be used in planning, but it does not extract the extended geometric structures that may exist in the environment (Fig. 36.18). Geometric structures such as planar patches can in principle be extracted by using techniques similar to the ones described in the context of indoor environments, such as EM, with the added difficulty that there is a larger amount of clutter that complicates the extraction of the patches. Robust techniques that can handle this level of clutter are typically used for extracting the planes [36.56, 57].

Classification based on local attributes can be improved significantly by taking into account contextual information; for example, hidden Markov models have been successfully used for laser data analysis to determine terrain traversability [36.58]. Another structure learning approach based on Markov random fields in conjunction with margin-maximization

criterion has been demonstrated for a wide class of applications, including 3-D terrain classification and object segmentation [36.54] or building structures extraction [36.55] (Fig. 36.19). Finally there are approaches to detect, select, model, and recognize natural landmarks automatically for robot localization and environment mapping [36.36].

36.3.6 Heterogeneous and Hierarchical Models

For long-range navigation, an autonomous vehicle must perform numerous tasks, including absolute and relative localization, path planning, and reactive obstacle avoidance. In addition, it must perform some tasks to fulfill the mission requirements, detecting and modeling objects, for example. To achieve this, a hierarchical framework has been presented that accounts for the different scales and granularities of the representation needed [36.46]. Furthermore, models build from heterogeneous imagery sources (overhead, descent, and ground) have been used to produce 3-D multiresolution terrain models that support Mars exploration [36.59]. The hybrid metric map [36.60], enhances feature maps with metric maps to provide a dense but compact environment representation. Another representation extracts landmarks based on laser/imagery appearance as well as a metric map [36.61].

36.4 Dynamic Environments

The majority of techniques for mapping have been developed for static environments. Certain approaches

like occupancy grids or elevation maps can in principle deal with dynamic environments in which objects

Fig. 36.20 (a) A mobile robot acquiring a three-dimensional scan of an urban scene. (b) The people in the scene cause spurious data points in the resulting meshes. (c) The same scene after filtering people

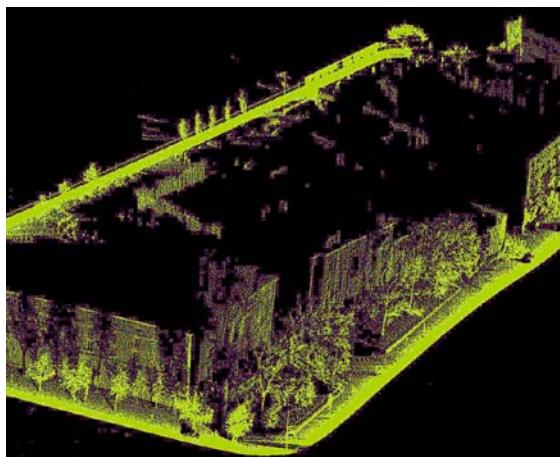

Fig. 36.21 Complex three-dimensional scene acquired with a mobile robot after filtering dynamic objects 36.63

move. Their drawback lies in the fact that the time to unlearn that a cell is free or that the elevation has changed can require as many observations as the robot received with the same area being occupied or with a different elevation. To resolve this

problem, several alternative approaches have been proposed in the past. One very popular technique is to track moving objects using feature-based tracking algorithms [36.62, 63]. Such approaches are especially useful when the type of the dynamic objects is known in advance. They have been successfully applied in the context of learning three-dimensional city maps from range data. Figures 36.20 and 36.21 show applications in which dynamic objects were removed from the 3-D data acquired with mobile robots in urban scenes. Alternative approaches to such tracking techniques include those that learn maps on different time scales [36.64], that explicitly learn different states of dynamic environments [36.65], or that only map the static aspects [36.66].

36.4.1 Conclusion and Further Reading

Further reading about typical representations and how they can be utilized for mobile robot navigation can be found in recent textbooks on mobile robotics [36.2, 67, 68]. A comprehensive survey of the fundamentals of spatial data structures and their applications is available in *Samet* [36.69].

Simultaneou

Sebastian Thrun, John J. Leonard

This chapter provides a comprehensive introduction in to the *simultaneous localization and mapping problem*, better known in its abbreviated form as **SLAM**. **SLAM** addresses the problem of a robot navigating an unknown environment. While navigating the environment, the robot seeks to acquire a map thereof, and at the same time it wishes to localize itself using its map. The use of **SLAM** problems can be motivated in two different ways: one might be interested in detailed environment models, or one might seek to maintain an accurate sense of a mobile robot's location. **SLAM** serves both of these purposes.

We review three major paradigms of algorithms from which a huge number of recently published methods are derived. First comes the traditional approach, which relies on the extended Kalman filter (**EKF**) for representing the robot's best estimate. The second paradigm draws its intuition from the fact that the **SLAM** problem can be viewed as a sparse graph of constraints, and it applies nonlinear optimization for recovering the map and the robot's locations. Finally, we survey the particle filter paradigm, which applies nonparametric

density estimation and efficient factorization methods to the **SLAM** problem. This chapter discusses extensions of these basic methods. It elucidates variants of the **SLAM** problem and proposes a taxonomy for the field. Relevant research is referenced extensively, and open research problems are discussed.

37.1 Overview

This chapter provides a comprehensive introduction into one of the key enabling technologies of mobile robot navigation: *simultaneous localization and mapping* (**SLAM**). **SLAM** addresses the problem of acquiring a spatial map of a mobile robot environment while simultaneously localizing the robot relative to this model. The **SLAM** problem is generally regarded as one of the most important problems in the pursuit of building truly autonomous mobile robots. Despite significant progress in this area, it still poses great challenges. At present, we have robust methods for

mapping environments that are static, structured, and of limited size. Mapping unstructured, dynamic, or large-scale environments remains largely an open research problem.

The historical roots of **SLAM** can be traced back to *Gauss* [37.1], who is largely credited with inventing the least-squares method, for calculating planetary orbits. In the 20th century, a number of fields outside robotics have studied the making of environment models from a moving sensor platform, most notably in *photogrammetry* [37.2] and *computer vision* [37.3, 4]. **SLAM** builds

on this work, often extending the basic paradigms into more scalable algorithms.

This chapter begins with a definition of the **SLAM** problem, which shall include a brief taxonomy of different versions of the problem. The centerpiece of this chapter is a layman's introduction into the three major paradigms in this field, and the various extensions that exist. As the reader will quickly recognize, there is no single best solution to the **SLAM** problem. The method

chosen by the practitioner will depend on a number of factors, such as the desired map resolution, the update time, the nature of the features in the map, and so on. Nevertheless, the three methods discussed in this chapter cover the major paradigms in this field. For an in-depth study of **SLAM** algorithms, we refer the reader to a recent textbook on probabilistic robotics, which dedicates a number of chapters to the topic of **SLAM** [37.5]. Also see [37.6, 7] for a recent in-depth tutorial for **SLAM**.

37.2 SLAM: Problem Definition

37.2.1 Mathematical Basis

The **SLAM** problem is defined as follows. A mobile robot roams an unknown environment, starting at a location with known coordinates. Its motion is uncertain, making it gradually more difficult to determine its global coordinates. As it roams, the robot can sense its environment. The **SLAM** problem is the problem of building a map of the environment while simultaneously determining the robot's position relative to this map.

Formally, **SLAM** is best described in probabilistic terminology. Let us denote time by t , and the robot location by x_t . For mobile robots on a flat ground, x_t is usually a three-dimensional vector, consisting of its two-dimensional coordinate in the plane plus a single rotational value for its orientation. The sequence of locations, or *path*, is then given as

$$X_T = \{x_0, x_1, x_2, \dots, x_T\}. \quad (37.1)$$

Here T is some terminal time (T might be ∞). The initial location x_0 is known; other positions cannot be sensed.

Odometry provides relative information between two consecutive locations. Let u_t denote the odometry that characterized the motion between time $t - 1$ and time t ; such data might be obtained from the robot's wheel encoders or from the controls given to those motors. Then the sequence

$$U_T = \{u_1, u_2, u_3, \dots, u_T\} \quad (37.2)$$

characterizes the relative motion of the robot. For noise-free motion, U_T would be sufficient to recover the past X_T from the initial location x_0 . However, odometry measurements are noisy, and path-integration techniques inevitably diverge from the truth.

Finally, the robot senses objects in the environment. Let m denote the *true* map of the environment. The

environment may be comprised of landmarks, objects, surfaces, etc., and m describes their locations. The environment map m is typically assumed to be time invariant (i.e., static).

The robot measurements establish information between features in m and the robot location x_t . If we, without loss of generality, assume that the robot takes exactly one measurement at each point in time, the sequence of measurements is given as

$$Z_T = \{z_1, z_2, z_3, \dots, z_T\}. \quad (37.3)$$

Figure 37.1 illustrates the variables involved in the **SLAM** problem. It shows the sequence of locations and sensor measurements, and the causal relationships between these variables. Such a diagram is known as a *graphical model*. It is useful in understanding the dependencies in the **SLAM** problem.

The **SLAM** problem is now the problem of recovering a model of the world m and the sequence of robot locations X_T from the odometry and measure-

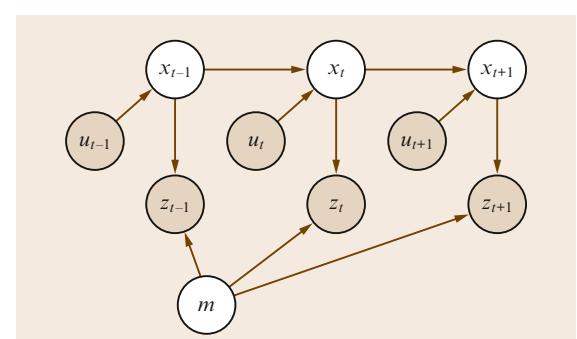

Fig. 37.1 Graphical model of the **SLAM** problem. Arcs indicate causal relationships, and shaded nodes are directly observable to the robot. In **SLAM**, the robot seeks to recover the unobservable variables

ment data. The literature distinguishes two main forms of the **SLAM** problem, which are both of equal practical importance. One is known as the *full SLAM problem*: it involves estimating the posterior over the entire robot path together with the map:

$$p(X_T, m | Z_T, U_T). \quad (37.4)$$

Written in this way, the full **SLAM** problem is the problem of calculating the joint posterior probability over X_T and m from the available data. Notice that the variables right of the conditioning bar are all directly observable to the robot, whereas those on the left are the ones that we want. As we shall see, algorithms for the offline **SLAM** problem are often batch, that is, they process all data at the same time.

The second, equally important **SLAM** problem is the *online SLAM problem*. This problem is defined via

$$p(x_t, m | Z_T, U_T). \quad (37.5)$$

Online **SLAM** seeks to recover the present robot location, instead of the entire path. Algorithms that address the online problem are usually incremental and can process one data item at a time. In the literature such algorithms are typically called *filters*.

To solve either **SLAM** problem, the robot needs to be endowed with two more models: a mathematical model that relates odometry measurements u_t to robot locations x_{t-1} and x_t and a model that relates measurements z_t to the environment m and the robot location x_t . These models correspond to the arcs in Fig. 37.1.

In **SLAM**, it is common to think of those mathematical models as probability distributions: $p(x_t | x_{t-1}, u_t)$ characterizes the probability distribution of the location x_t assuming that a robot started at a known location x_{t-1} and measured odometry data u_t , and likewise $p(z_t | x_t, m)$ is the probability for measuring z_t if this measurement is taken at a known location x_t in a known environment m . Of course, in the **SLAM** problem we do *not* know the robot location, and neither do we know the environment. As we shall see, Bayes rule takes care of this, by transforming these mathematical relationships into a form where we can *recover* probability distributions over those latent variables from the measured data.

37.2.2 Example: SLAM in Landmark Worlds

One common setting of **SLAM** involves the assumption that the environment is populated by point landmarks. When building two-dimensional (2-D) maps, point landmarks may correspond to door posts and corners of

rooms, which, when projected into a 2-D map are characterized by a point coordinate. In a 2-D world, each point landmark is characterized by two coordinate values. Hence the world is a vector of size $2N$, where N is the number of point landmarks in the world.

In a commonly studied setting, the robot can sense three things: the relative range to nearby landmarks, their relative bearing, and the identity of these landmarks. The range and bearing may be noisy, but in the most simple case the identity of the sensed landmarks is known perfectly.

To model such a setup, one begins with defining the *exact*, noise-free measurement function. The measurement function h describes the workings of the sensors: it accepts as input a description of the environment m and a robot location x_t , and it computes the measurement:

$$h(x_t, m). \quad (37.6)$$

Computing h is straightforward in our simplified landmark setting; it is a simple exercise in trigonometry.

The probabilistic measurement model is derived from this measurement function by adding a noise term; it is a probability distribution that peaks at the noise-free value $h(x_t, m)$ but allows for measurement noise:

$$p(z_t | x_t, m) \sim \mathcal{N}(h(x_t, m), Q_t). \quad (37.7)$$

Here \mathcal{N} denotes the two-dimensional normal distribution, which is centered at $h(x_t, m)$. The 2-by-2 matrix Q_t is the noise covariance, indexed by time.

The motion model is derived from a kinematic model of robot motion. Given the location vector x_{t-1} and the motion u_t , textbook kinematics tells us how to calculate x_t . Let this function be denoted by g :

$$g(x_{t-1}, u_t). \quad (37.8)$$

The motion model is then defined by a normal distribution centered at $g(x_{t-1}, u_t)$ but subject to Gaussian noise:

$$p(x_t | x_{t-1}, u_t) = \mathcal{N}(g(x_{t-1}, u_t), R_t). \quad (37.9)$$

Here QR_t is a covariance; it is of size 3-by-3, since the location is a three-dimensional vector.

With these definitions, we have all we need to develop a **SLAM** algorithm. While in the literature, point landmark problems with range-bearing sensing are by far the most widely studied, **SLAM** algorithms are not confined to landmark worlds. However, no matter what the map representation and the sensor modality, any **SLAM** algorithm needs a similarly crisp definition of

the features in m , the measurement model $p(z_t | x_t, m)$, and the motion model $p(x_t | x_{t-1}, u_t)$.

37.2.3 Taxonomy of the SLAM Problem

SLAM problems are distinguished along a number of different dimensions. Most important research papers identify the type of problems addressed by making the underlying assumptions explicit. We already encountered one such distinction: full versus online. Other common distinctions are as follows.

Volumetric Versus Feature-Based

In volumetric **SLAM**, the map is sampled at a resolution high enough to allow for photorealistic reconstruction of the environment. The map m in volumetric **SLAM** is usually quite high dimensional, with the result that the computation can be quite involved. Feature-based **SLAM** extracts sparse features from the sensor stream. The map is then only comprised of features. Our point-landmark example is an instance of feature-based **SLAM**. Feature-based **SLAM** techniques tend to be more efficient, but their results may be inferior to volumetric **SLAM** due to the fact that the extraction of features discards information in the sensor measurements.

Topological Versus Metric

Some mapping techniques recover only a qualitative description of the environment, which characterizes the relation of basic locations. Such methods are known as topological. A topological map might be defined over a set of distinct places and a set of qualitative relations between these places (e.g., place A is adjacent to place B). Metric **SLAM** methods provide metric information between the relation of such places. In recent years, topological methods have fallen out of fashion, despite ample evidence that humans often use topological information for navigation.

Known Versus Unknown Correspondence

The correspondence problem is the problem of relating the identity of sensed things to other sensed things. In the landmark example above, we assumed that the identity of landmarks is known. Some **SLAM** algorithms make such an assumption, while others do not. The algorithms that do not make this assumption provide special mechanisms for estimating the correspondence of measured features to previously observed landmarks in the map. The problem of estimating the correspondence is known as the *data association problem*, and is one of the most difficult problems in **SLAM**.

Static Versus Dynamic

Static **SLAM** algorithms assume that the environment does not change over time. Dynamic methods allow for changes in the environment. The vast majority of the literature on **SLAM** assumes static environments; dynamic effects are often treated just as measurement outliers. Methods that reason about motion in the environment are more involved, but they tend to be more robust in most applications.

Small Versus Large Uncertainty

SLAM problems are distinguished by the degree of location uncertainty that they can handle. The most simple **SLAM** algorithms allow only for small errors in the location estimate. They are good for situations in which a robot goes down a path that does not intersect itself, and then returns along the same path. In many environments it is possible to reach the same location from multiple directions. Here the robot may accrue a large amount of uncertainty. This problem is known as the *loop-closing problem*. When closing a loop, the uncertainty may be large. The ability to close loops is a key characteristic of modern-day **SLAM** algorithms. The uncertainty can be reduced if the robot can sense information about its position in some absolute coordinate frame, e.g., through the use of a satellite-based global positioning system (**GPS**) receiver.

Active Versus Passive

In passive **SLAM** algorithms, some other entity controls the robot, and the **SLAM** algorithm is purely observing. The vast majority of algorithms are of this type; they give the robot designer the freedom to implement arbitrary motion controllers, and pursue arbitrary motion objectives. In active **SLAM**, the robot actively explores its environment in the pursuit of an accurate map. Active **SLAM** methods tend to yield more accurate maps in less time, but they constrain the robot motion. There exist hybrid techniques in which the **SLAM** algorithm controls only the pointing direction of the robot's sensors, but not the motion direction.

Single-Robot Versus Multirobot SLAM

Most **SLAM** problems are defined for a single-robot platform, although recently the problem of multirobot exploration has gained in popularity. Multirobot **SLAM** problems come in many flavors. In some, robots are able to observe each other, while in others robots are told their relative initial locations. Multirobot **SLAM** problems are also distinguished by the type of communication allowed between the different robots. In some, the robots can

communicate with no latency and infinite bandwidth. More realistic are setups in which only nearby robots can communicate, and the communication is subject to latency and bandwidth limitations.

As this taxonomy suggests, there exists a flurry of **SLAM** algorithms. Most modern-day conferences

dedicate multiple sessions to **SLAM**. This chapter focuses on the very basic **SLAM** setup. In particular it assumes a static environment with a single robot. Extensions are discussed towards the end of this chapter, in which the relevant literature is also discussed.

37.3 The Three Main SLAM Paradigms

This section reviews three basic **SLAM** paradigms, from which most others are derived. The first, known as extended Kalman filter (**EKF**) **SLAM**, is historically the earliest but has recently become slightly unpopular due to its limiting computational properties. The second, which is based on graphical representations, successfully applies sparse nonlinear optimization methods to the **SLAM** problem, and has become the main paradigm for solving the full **SLAM** problem. The third and final method uses nonparametric statistical filtering techniques known as particle filters. It is a popular method for online **SLAM**, and provides a fresh new solution to the data association problem in **SLAM**.

37.3.1 Extended Kalman Filters

Historically, the **EKF** formulation of **SLAM** is the earliest, and perhaps the most influential. **EKF SLAM** was introduced in [37.8–10] and [37.11, 12], which were the first papers to propose the use of a single state vector to estimate the locations of the robot and a set of features in the environment, with an associated error covariance matrix representing the uncertainty in these estimates, including the correlations between the vehicle and feature state estimates. As the robot moves through its environment taking measurements, the system state vector and covariance matrix are updated using the the extended Kalman filter [37.13–15]. As new features are observed, new states are added to the system state vector; the size of the system covariance matrix grows quadratically.

This approach assumes a metrical, feature-based environmental representation, in which objects can be effectively represented as points in an appropriate parameter space. The position of the robot and the locations of features form a network of uncertain spatial relationships. The development of appropriate representations is a critical issue in **SLAM**, and intimately related to the topics of sensing and world modeling discussed in Chap. 36 and in Part C in this handbook.

The **EKF** algorithm represents the robot estimate by a multivariate Gaussian:

$$p(x_t, m \mid Z_T, U_T) \sim \mathcal{N}(\mu_t, \Sigma_t). \quad (37.10)$$

The high-dimensional vector μ_t contains the robot's best estimate of its own location and the location of the features in the environment. In our point-landmark example, the dimension of μ_t would be $3 + 2N$, since we need three variables to represent the robot location and $2N$ variables for the N landmarks in the map.

The matrix Σ_t is the covariance of the robot's assessment of its expected error in the guess μ_t . As a quadratic matrix, Σ_t is of size $(3 + 2N) \times (3 + 2N)$. In **SLAM**, this matrix is usually distinctly non-sparse. The off-diagonal elements capture the correlations in the estimates of different variables. Nonzero correlations come along because the robot's location is uncertain, and as a result the locations of the landmarks in the maps are uncertain. The importance of maintaining those off-diagonal elements is one of the key properties of **EKF SLAM** [37.16].

The **EKF SLAM** algorithm is easily derived for our point-landmark example. Suppose, for a moment that the motion function g and the measurement function h were *linear* in their arguments. Then the vanilla Kalman filter, as described in any textbook on Kalman filtering, would be applicable. **EKF SLAM** linearizes the functions g and h using Taylor-series expansion – again, this is standard textbook material. Thus, in its most basic form (and in the absence of any data association problems), **EKF SLAM** is nothing but the application of the vanilla **EKF** to the online **SLAM** problem.

Figure 37.2 illustrates the **EKF SLAM** algorithm for an artificial example. The robot navigates from a start pose that serves as the origin of its coordinate system. As it moves, its own pose uncertainty increases, as indicated by uncertainty ellipses of growing diameter. It also senses nearby landmarks and maps them with an uncertainty that combines the fixed measurement uncertainty with the increasing pose uncertainty. As a result, the uncertainty in the landmark locations grows over time. The

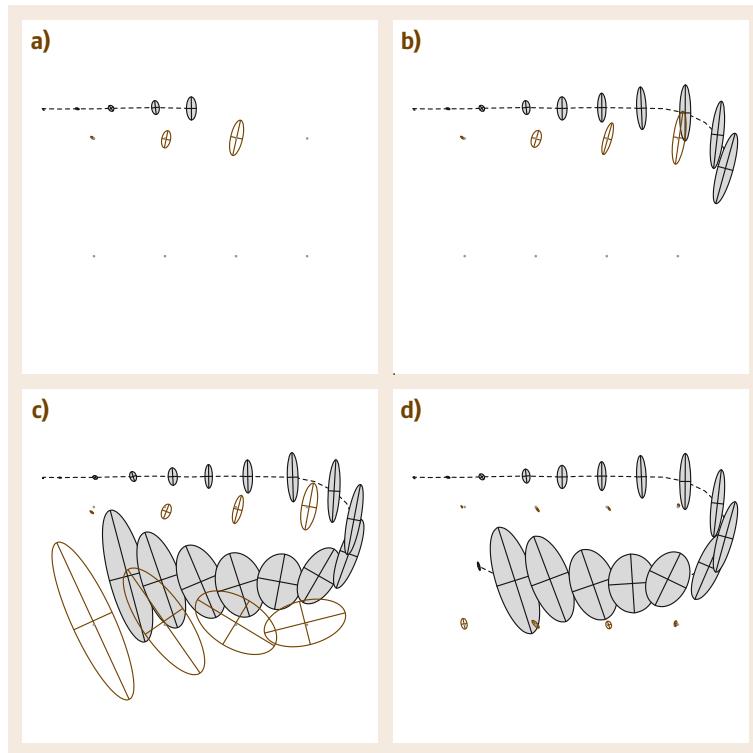

Fig. 37.2a–d EKF applied to the online SLAM problem. The robot’s path is a *dotted line*, and its estimates of its own position are *shaded ellipses*. Eight distinguishable landmarks of unknown location are shown as *small dots*, and their location estimates are shown as *white ellipses*. In (a–c) the robot’s positional uncertainty is increasing, as is its uncertainty about the landmarks it encounters. In (d) the robot senses the first landmark again, and the uncertainty of *all* landmarks decreases, as does the uncertainty of its current pose. (Image courtesy of Michael Montemerlo, Stanford University)

interesting transition is illustrated in Fig. 37.2d: Here the robot observes the landmark it saw in the very beginning of mapping, and whose location is relatively well known. Through this observation, the robot’s pose error is reduced, as indicated in Fig. 37.2d – notice the very small error ellipse for the final robot pose. This observation also reduces the uncertainty for other landmarks in the map. This phenomenon arises from a correlation that is expressed in the covariance matrix of the Gaussian posterior. Since most of the uncertainty in earlier landmark estimates is caused by the robot pose, and since this very uncertainty persists over time, the location estimates of those landmarks are correlated. When gaining information on the robot’s pose, this information spreads to previously observed landmarks. This effect is probably the most important characteristic of the SLAM posterior [37.16]. Information that helps localize the robot is propagated through the map, and as a result improves the localization of other landmarks in the map.

EKF SLAM also addresses the *data association problem*. If the identity of observed features is unknown, the basic EKF idea becomes inapplicable. The solution here is to reason about the most likely data association

when a landmark is observed. This is usually done based on proximity: *which of the landmarks in the map most likely corresponds to the landmark just observed?* The proximity calculation considers the measurement noise and the actual uncertainty in the poster estimate, and the metric used in this calculation is known as a Mahalanobis distance, which is a weighted quadratic distance. To minimize the chances of false data associations, many implementations use visible features to distinguish individual landmarks and associate groups of landmarks observed simultaneously [37.17, 18]. Modern-day implementations also maintain a *provisional landmark list* and only add landmarks to the internal map when they have been observed sufficiently frequently [37.19–22]. With an appropriate landmark definition and careful implementation of the data association step, EKF SLAM becomes a powerful method for feature-based SLAM.

EKF SLAM has been applied successfully to a large range of navigation problems, involving airborne, underwater, indoor, and various other vehicles. Figure 37.3a shows an example result obtained with a state-of-the-art implementation of EKF SLAM. Shown there is an underwater map obtained with the underwater robot Oberon, developed at the University of Sydney, Aus-

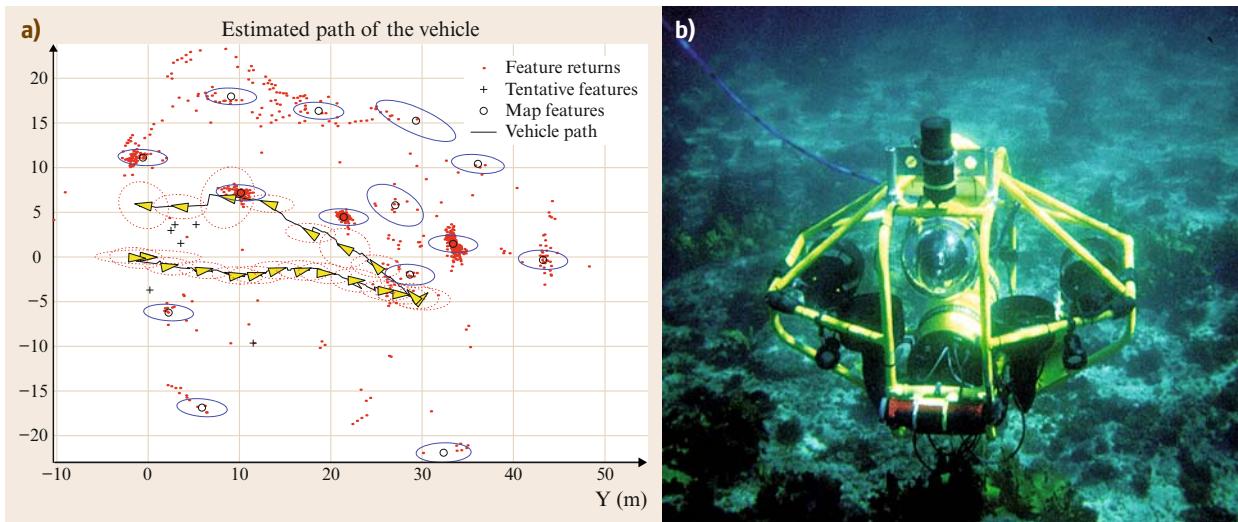

Fig. 37.3 (a) Example of Kalman filter estimation of the map and the vehicle pose. (b) The underwater vehicle Oberon, developed at the University of Sydney. (Images courtesy of Stefan Williams and Hugh Durrant-Whyte, Australian Centre for Field Robotics)

tralia, and shown in Fig. 37.3b. This vehicle is equipped with a pencil-beam, mechanically scanned sonar that can produce high-resolution range and bearing measurements of objects up to 50 m away. To facilitate the mapping problem, researchers have deposited long, small vertical objects in the water, which can be extracted from the sonar scans with relative ease. In this specific experiment, there is a row of such objects, spaced approximately 10 m apart. In addition, a more distant cliff offers additional point features that can be detected using the scanning sonar.

The map shown in Fig. 37.3a depicts the robot path, marked by the triangles connected by a line. Around each triangle one can see an ellipse, which corresponds to the covariance matrix of the Kalman filter estimate projected into the robot location. The ellipse shows the variance; the larger it is, the less certain the robot is about its current pose. Various small dots in Fig. 37.3a show landmark sightings, obtained by searching the sonar scan for small and highly reflective objects. The majority of these sightings is rejected using statistical outlier rejection techniques [37.20]. However, some are believed to correspond to a landmark and are added to the map. At the end of the run, the robot has classified 14 such objects as landmarks, each of which is plotted with the projected uncertainty ellipse in Fig. 37.3a. These landmarks include the artificial landmarks put out by the researchers, but they also include various other terrain features in the vicinity of the robot. The residual pose uncertainty is small.

The basic formulation of **EKF SLAM** assumes that the location of features in the map is fully observable from a single position of the robot. The method has been extended to situations with partial observability, with range-only [37.23] or angle-only [37.24, 25] measurements. The technique has also been utilized using a featureless representation, in which the state consists of current and past robot poses, and measurements take the form of constraints between the poses (derived, for example, from laser scan matching or from camera measurements) [37.26, 27].

A key concern of the **EKF** approach to **SLAM** lies in the quadratic nature of the covariance matrix. A number of researchers have proposed extensions to the **EKF SLAM** algorithms that gain remarkable scalability by decomposing the map into submaps, for which covariances are maintained separately. Relevant literature can be found in [37.19, 28–32]. Other researchers have developed hybrid **SLAM** techniques, which combine **EKF**-style **SLAM** techniques with volumetric map representation; see [37.33–36]. Finally, researchers have developed data association techniques for **SLAM** [37.37–39] based on advanced statistical techniques such as Dempster’s **EM** algorithm [37.40].

37.3.2 Graph-Based Optimization Techniques

A second family of algorithms solves the **SLAM** problem through nonlinear sparse optimization. They draw

their intuition from a graphical representation of the **SLAM** problem. Graph-based techniques were first mentioned in [37.8, 41], but a seminal paper [37.42] provided a first working solution. The representation in this section is closely related to a series of recent papers [37.43–52]. We note that most contemporary techniques are offline and address the full **SLAM** problem, although some online versions exist and will be discussed below.

The basic intuition of graph-based **SLAM** is as follows. Landmarks and robot locations can be thought of as nodes in a graph. Every consecutive pair of locations x_{t-1}, x_t is tied together by an arc that represents the information conveyed by the odometry reading u_t . Other arcs exist between locations x_t and landmarks m_i , assuming that at time t the robot sensed landmark i . Arcs in this graph are soft constraints. Relaxing these constraints yields the robot's best estimate for the map and the full path.

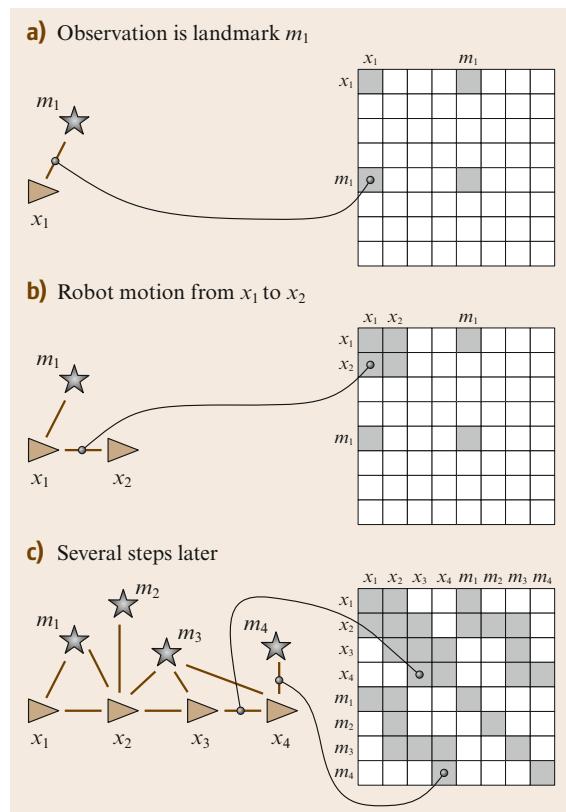

Fig. 37.4a–c Illustration of the graph construction. The *left* diagram shows the graph, the *right* the constraints in matrix form

The construction of the graph is illustrated in Fig. 37.4. Suppose that at time $t = 1$ the robot senses landmark m_1 . This adds an arc in the (yet highly incomplete) graph between x_1 and m_1 . When caching the edges in a matrix format (which happens to correspond to a quadratic equation defining the resulting constraints), a value is added to the elements between x_1 and m_1 , as shown on the right-hand side of Fig. 37.4a.

Now suppose the robot moves. The odometry reading u_2 leads to an arc between nodes x_1 and x_2 , as shown in Fig. 37.4b. Consecutive application of these two basic steps leads to an graph of increasing size, as illustrated in Fig. 37.4c. Nevertheless this graph is *sparse*, in that each node is only connected to a small number of other nodes. The number of constraints in the graph is (at worst) *linear* in the time elapsed and in the number of nodes in the graph.

If we think of the graph as a spring–mass model [37.50], computing the **SLAM** solution is equivalent to computing the state of minimal energy of this model. To see this, note that the graph corresponds to the log-posterior of the full **SLAM** problem (cf. (37.4)):

$$\log p(X_T, m \mid Z_T, U_T). \quad (37.11)$$

Without derivation, we state that this logarithm is of the form

$$\begin{aligned} \log p(X_T, m \mid Z_T, U_T) &= \text{const} \\ &+ \sum_t \log p(x_t \mid x_{t-1}, u_t) \\ &+ \sum_t \log p(z_t \mid x_t, m). \end{aligned} \quad (37.12)$$

Each constraint of the form $\log p(x_t \mid x_{t-1}, u_t)$ is the result of exactly one robot motion event, and it corresponds to an arc in the graph. Likewise, each constraint of the form $\log p(z_t \mid x_t, m)$ is the result of one sensor measurement, to which we can also find a corresponding arc in the graph. The **SLAM** problem is then simply to find the mode of this equation.

$$X_t^*, m^* = \operatorname{argmax}_{X_T, m} \log p(X_T, m \mid Z_T, U_T). \quad (37.13)$$

Without derivation, we note that, under the Gaussian noise assumption that was made in the point-landmark example, this expression resolves to the following

quadratic form:

$$\begin{aligned} \log p(X_T, m | Z_T, U_T) \\ = \text{const} \\ + \sum_t [x_t - g(x_{t-1}, u_t)]^T R_t^{-1} [x_t - g(x_{t-1}, u_t)] \\ + \sum_t [z_t - h(x_t, m)]^T Q_t^{-1} [z_t - h(x_t, m)]. \end{aligned} \quad (37.14)$$

This is a sparse function. A number of efficient optimization techniques can be applied. Common choices include gradient descent, conjugate gradient, and others. Most SLAM implementations rely on some sort of iterative linearizing the functions g and h , in which case the objective in (37.14) becomes quadratic in all of its variables.

The graphical paradigm is easily extended to handle the data association problems. This is because (37.14) is easily extended to integrate additional knowledge on data association. Suppose some oracle informed us that landmarks m_i and m_j in the map corresponded to one and the same physical landmark in the world. Then we can either remove m_j from the graph and attach all adjacent arcs to m_i , or we can add a *soft correspondence constraint* [37.53] of the form

$$[m_j - m_i]^T \Gamma [m_j - m_i]. \quad (37.15)$$

Here Γ is a 2-by-2 diagonal matrix whose coefficients determine the penalty for *not* assigning identical locations to two landmarks (hence we want Γ to be large). Since graphical methods are usually used for the full SLAM problem, the optimization can be interleaved

with the search for the optimal data association. State-of-the-art implementations rely on RANSAC [37.54] or branch-and-bound methods [37.55, 56].

Graphical SLAM methods have the advantage that they scale to much higher-dimensional maps than EKF SLAM. The key limiting factor in EKF SLAM is the covariance matrix, which takes space (and update time) quadratic in the size of the map. No such constraint exists in graphical methods. The update time of the graph is constant, and the amount of memory required is linear (under some mild assumptions). Performing the optimization can be expensive, however. Technically, finding the optimal data association is suspected to be an NP -hard problem, although in practice the number of plausible assignments is usually small. The continuous optimization of the log-likelihood function in (37.14) depends among other things on the number and size of loops in the map.

Figure 37.5 shows the result of a state-of-the-art SLAM algorithm based on analyzing the constraint graph and a nested search of the best data association. The data for this map was acquired by CMU's Groundhog robot [37.57], built to explore and map abandoned underground mines. Groundhog is equipped with a laser range finder which measures the range to obstacles along a horizontal slice of the world. The specific map shown here covers an area of $250\text{ m} \times 150\text{ m}$. The form of the map is known as a *occupancy grid map*, which is due to Elfes and Moravec [37.58, 59]. Occupancy grid maps use Bayesian reasoning to estimate the posterior probability that a cell is free, thereby accommodating noise in range finders.

As a baseline for comparison, Fig. 37.5a shows a map constructed in a much simpler way: here scans

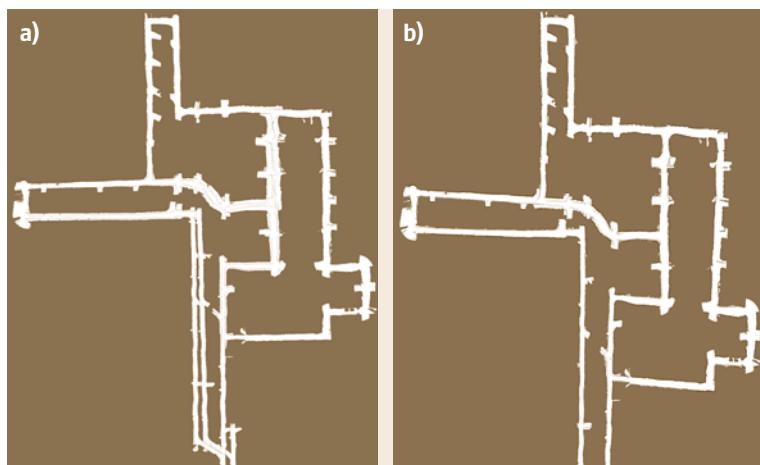

Fig. 37.5a,b An occupancy grid map of an abandoned mine: (a) estimates the data association incrementally, and only in reference to the most recent sensor measurement. The right map (b) is the result of a global data association search and a graphical optimization (Images courtesy of Dirk Hähnel, University of Freiburg)

are localized relative to slightly older scans and, once localized, are added to the map under the assumption that the estimated location is correct. Such a technique is called *scan matching* [37.42]. Scan matching is a **SLAM** method, but it can only accommodate very small amounts of location uncertainties. The failure to close loops is obvious from Fig. 37.5a. In fact, pairwise scan matching can be thought of as a version of a graphical **SLAM** algorithm, but correspondence is only established (and constraints inserted in the graph) between immediately consecutive scans.

To map this data into a graph of manageable size, the algorithm decomposes the map into small local submaps, one for each 5 m of robot travel. Within these 5 m, the maps are sufficiently accurate, as general drift is small and hence scan matching performs essentially flawlessly. Each submap coordinates become a pose node in the GraphSLAM. Adjacent submaps are linked through the relative motion constraints between them. The resulting structure is shown in Fig. 37.5b.

On this graph, we can now perform a branch-and-bound recursive search for correspondences. For finding

good submaps that might correspond, this algorithm uses a correlation analysis for two overlaying maps. Once two suitable maps are found, a soft constraint of the type stated in (37.15) is added to the graph, followed by an optimization step of the resulting set of constraints. Figure 37.6 illustrates the process of data association: each circle corresponds to a new constraint that would be found in the search. The figure illustrates the iterative nature of the search: certain correspondences are only discovered when others have been propagated, and others are dissolved in the process of the search. The final model is stable, in that additional search for new data association induces no further changes. The resulting grid map is shown in Fig. 37.5b.

Other graph-based techniques for **SLAM** have produced similar results. Figure 37.7 shows a map of the same data set generated by [37.26], using an algorithm called *Atlas*. This algorithm decomposes maps into submaps whose relation is maintained through information-theoretic relative link.

We note that the graph-based paradigm is very closely linked to information theory, in that the soft con-

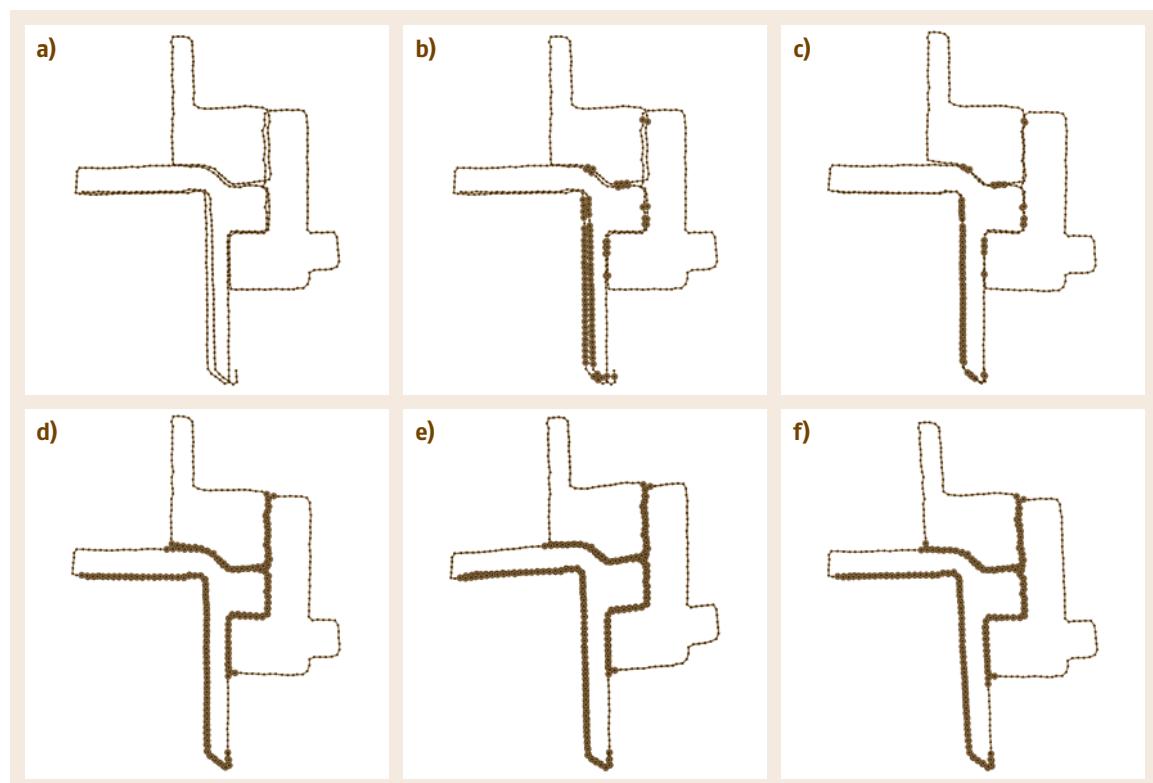

Fig. 37.6a–f Data association search. See text

straints constitute the information the robot has on the world (in an information-theoretic sense [37.60]). Most methods in the field are inherently offline, that is, they optimize for the entire robot path. If the robot path is long, the optimization may become cumbersome. This is one of the disadvantages of the graph-based paradigm. There exists a number of crossovers that manipulate the graph online so as to factor our past robot location variables. The resulting algorithms are filters [37.26, 61–63] and they tend to be intimately related to information filter methods [37.16, 63–67]. Many of the original attempts to decompose **EKF SLAM** representations into smaller submaps to scale up are based on motivations that are not dissimilar to the graphical approach; see [37.29, 30, 68].

As this chapter is being written, graphical and optimization-based **SLAM** algorithm are the subject of intense research. Recent results show that the paradigm scales to maps with 10^8 features [37.26, 43–49, 51, 52, 57]. Arguably, the graph-based paradigm has generated some the largest **SLAM** maps ever built, but usually in an offline fashion.

37.3.3 Particle Methods

The third principal **SLAM** paradigm is based on particle filters. Particle filters can be traced back to [37.69], but they have become popular only in recent years. Particle filter represent a posterior through a set of *particles*. For the novice in **SLAM**, each particle is best thought as a concrete guess as to what the true value of the state may be. By collecting many such guesses into a set of guesses, or set of particles, the particle filters captures a representative sample from the posterior distribution. The particle filter has been shown under mild conditions to approach the true posterior as the particle set size goes to infinity. It is also a nonparametric representation that represents multimodal distributions with ease. In recent years, the advent of extremely efficient microprocessors has made particle filters a popular algorithm [37.70–74].

The key problem with the particle filter in the context of **SLAM** is that the space of maps and robot paths is huge. Suppose we have a map with 1000 features. How many particles would it take to populate that space? In fact, particle filters scale exponentially with the dimension of the underlying state space. Three or four dimensions are thus acceptable, but 100 dimensions are generally not.

The trick to make particle filters amenable to the **SLAM** problem goes back to [37.75, 76]. The trick was introduced into the **SLAM** literature in [37.77], followed by [37.78], who coined the name FastSLAM. Let us

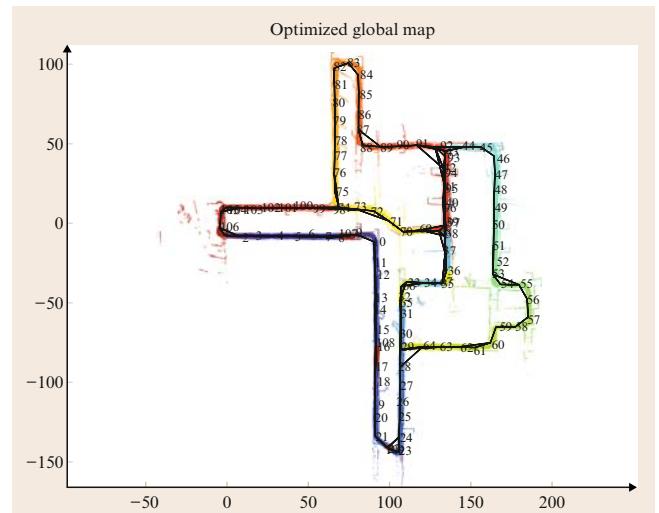

Fig. 37.7 Mine map generated by the *Atlas SLAM* algorithm by [37.26] (after Bosse et al. [37.26])

first explain the basic FastSLAM algorithm on the simplified point-landmark example, and then discuss the justification for this approach.

At any point in time, FastSLAM maintains K particles of the type:

$$X_t^{[k]}, \quad \mu_{t,1}^{[k]}, \dots, \mu_{t,N}^{[k]}, \quad \Sigma_{t,1}^{[k]}, \dots, \Sigma_{t,N}^{[k]}. \quad (37.16)$$

Here $[k]$ is the index of the sample. This expression states that a particle contains

- a sample path $X_t^{[k]}$
- a set of N two-dimensional Gaussians with means $\mu_{t,n}^{[k]}$ and variances $\Sigma_{t,n}^{[k]}$, one for each landmark in the environment

Here n ($1 \leq n \leq N$) is the index of the landmark. From this it follows that K particles possess K path samples. It also possesses KN Gaussians, each of which models exactly one landmark for one of the particles.

Initializing FastSLAM is simple: just set each particle's robot location to its known starting coordinates, and zero the map. The particle update then proceeds as follows.

- When an odometry reading is received, new location variables are generated stochastically, one for each of the particles. The distribution for generating those location particles is based on the motion model

$$x_t^{[k]} \sim p(x_t | x_{t-1}^{[k]}, u^t). \quad (37.17)$$

Here $x_{t-1}^{[k]}$ is the previous location, which is part of the particle. This probabilistic sampling step is easily implemented for any robot whose kinematics can be computed.

- When a measurement z_t is received, two things happen: first, FastSLAM computes for each particle the probability of the new measurement z_t . Let the index of the sensed landmark be n . Then the desired probability is defined as

$$w_t^{[k]} := \mathcal{N}(z_t | x_t^{[k]}, \mu_{t,n}^{[k]}, \Sigma_{t,n}^{[k]}). \quad (37.18)$$

The factor $w_t^{[k]}$ is called the *importance weight*, since it measures how *important* the particle is in the light of the new sensor measurement. As before, \mathcal{N} denotes the normal distribution, but this time it is calculated for a specific value, z_t . The importance weights of all particles are then normalized so that they sum to 1.

Next, FastSLAM draws with replacement from the set of existing particles a set of new particles. The probability of drawing a particle is its normalized importance weight. This step is called *resampling*. The intuition behind resampling is simple: particles for which the measurement is more plausible have a higher chance of surviving the resampling process. Finally, FastSLAM updates for the new particle set the mean $\mu_{t,n}^{[k]}$ and covariance $\Sigma_{t,n}^{[k]}$, based on the

measurement z_t . This update follows the standard **EKF** update rules.

This all sounds complex, but FastSLAM is quite easy to implement. Sampling from the motion model is usually straightforward, since it involves a simple kinematic calculation. Computing the importance of a measurement is, too, straightforward, especially for Gaussian measurement noise. And updating a low-dimensional particle filter is also straightforward. This makes FastSLAM one of the easiest-to-implement algorithms presently available.

FastSLAM has been shown to approximate the full **SLAM** posterior. The derivation of FastSLAM exploits three techniques: Rao–Blackwellization, conditional independence, and resampling. Rao–Blackwellization is the following concept. Suppose we would like to compute a probability distribution $p(a, b)$, where a and b are arbitrary random variables. The vanilla particle filter would draw particles from the joint distributions, that is, each particle would have a value for a and one for b . However, if the conditional $p(b | a)$ can be described in closed form, it is equally legitimate to just draw particles from $p(a)$, and attach to each particle a closed-form description of $p(b | a)$. This trick is known as Rao–Blackwellization, and it yields better results than sampling from the joint distribution. FastSLAM applies this technique, in that it samples from the path posterior $p(X_t^{[k]} | U_t, Z_t)$ and represents the map $p(m | X_t^{[k]}, U_t, Z_t)$ in Gaussian form.

FastSLAM also breaks down the posterior over maps (conditioned on paths) into sequences of low-dimensional Gaussians. The justification for this decomposition is subtle. It arises from a specific conditional independence assumption that is native to **SLAM**. Figure 37.8 illustrates the concept graphically. In **SLAM**, knowledge of the robot path renders all landmark estimates independent. This is easily shown for the graphical network in Fig. 37.8: we find that if we remove the path variables from Fig. 37.8 then the landmark variables are all disconnected [37.79]. Thus, in **SLAM** any dependence between multiple landmark estimates is mediated through the robot path. This subtle but important observation implies that, even if we used a large, monolithic Gaussian for the entire map (one per particle, of course), the off-diagonal element between different landmarks would simply remain zero. It is therefore legitimate to implement the map more efficiently, using N small Gaussians, one for each landmark. This explains the efficient map representation in FastSLAM.

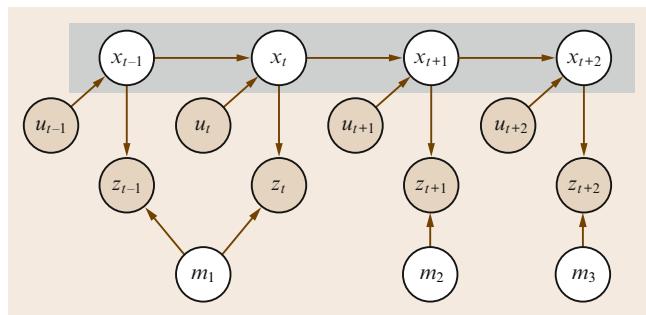

Fig. 37.8 The **SLAM** problem depicted as a Bayes network graph. The robot moves from location x_{t-1} to location x_{t+2} , driven by a sequence of controls. At each location x_t it observes a nearby feature in the map $m = \{m_1, m_2, m_3\}$. This graphical network illustrates that the location variables *separate* the individual features in the map from each other. If the locations are known, there remains no other path involving variables whose value is not known, between any two features in the map. This lack of a path renders the posterior of any two features in the map conditionally independent (given the locations).

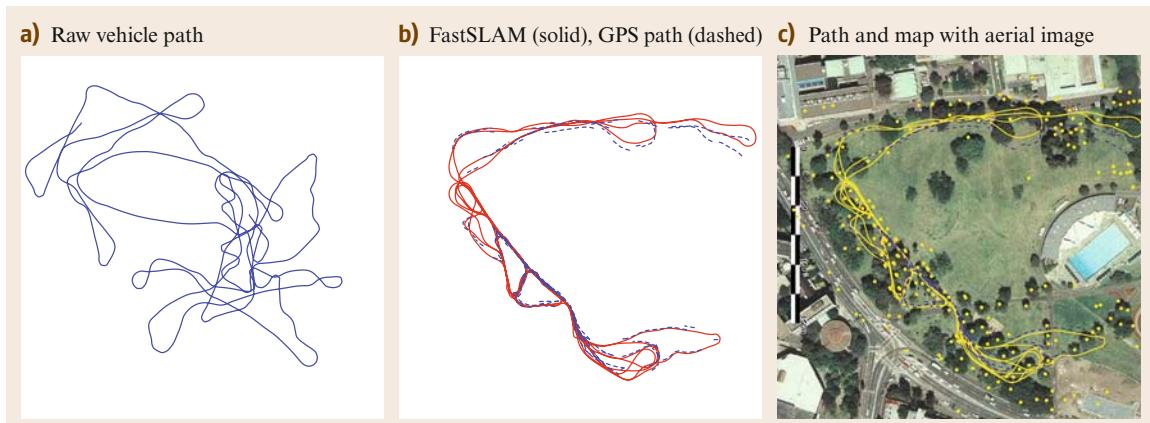

Fig. 37.9 (a) Vehicle path predicted by the odometry; (b) True path (dashed line) and FastSLAM 1.0 path (solid line); (c) Victoria Park results overlaid on aerial imagery with the GPS path in blue (dashed), average FastSLAM 1.0 path in yellow (solid), and estimated features as yellow dots (Data and aerial image courtesy of José Guivant and Eduardo Nebot, Australian Center for Field Robotics)

We also note that FastSLAM uses a particle filter. Derivations of the particle filter can be found in the literature referenced above. Here we note that both steps – the motion and the measurement steps – retain the property that (asymptotically) samples are drawn from the full **SLAM** posterior. This is quite easy to see for the motion update step. For the measurement step, the property is retained through resampling, which adjusts the particle population in response to the new information added by the measurement.

Figure 37.9 shows results for a point-feature problem; here the point features are the centers of tree trunks as observed by an outdoor robot. The dataset used here is known as the Victoria Park dataset [37.80]. Figure 37.9a shows that the path of the vehicle obtained by integrating the vehicle controls, without perception controls, are a poor predictor of location for this vehicle; after 30 min of driving, the estimated position of the vehicle is well over 100 m away from its **GPS** position.

The FastSLAM algorithm has a number of remarkable properties, which may not be intuitive to the untrained eye. First, it solves both the full and the online **SLAM** problems. Each particle has a sample of an entire path (and in fact, conditioning on the entire path is required for its mathematical derivation), but the actual update equation only uses the most recent pose. This makes FastSLAM a filter, similar to the **EKF**. Second, FastSLAM makes it easy to pursue multiple data association hypotheses. It is straightforward to make data association decisions on a per-particle basis, in-

stead of having to adopt the same hypothesis for the entire filter. While we will not give any mathematical justification, we note that the resulting FastSLAM algorithm samples the correct posteriors even for **SLAM** problems with unknown data association – something that neither of the previous two algorithms can claim. And third, FastSLAM can be implemented very efficiently: using advanced tree methods to represent the map estimates, the update can be performed in time logarithmic in the size of the map N , and linear in the number of particles M . These properties, along with the relative ease of implementation, has made FastSLAM a popular choice.

FastSLAM has been extended in great many ways. One important variant is a grid-based version of FastSLAM, in which the Gaussians are replaced by an occupancy grid map [37.81]. This variant is illustrated in Figs. 37.10 and 37.11. Figure 37.10 shows the situation just before closing a large loop. The three different particles each stand for different paths, and they also possess their own local maps. When the loop is closed, importance resampling selects those particles whose maps are most consistent with the measurement. A resulting large-scale map is shown in Fig. 37.11.

Significant extensions of the FastSLAM method can be found in [37.82, 83], whose methods **DP-SLAM** and **ancestry trees** provide efficient tree update methods for grid-based maps. The work in [37.84] provides a way to incorporate new observations into the location sampling process, based on prior work in [37.85].

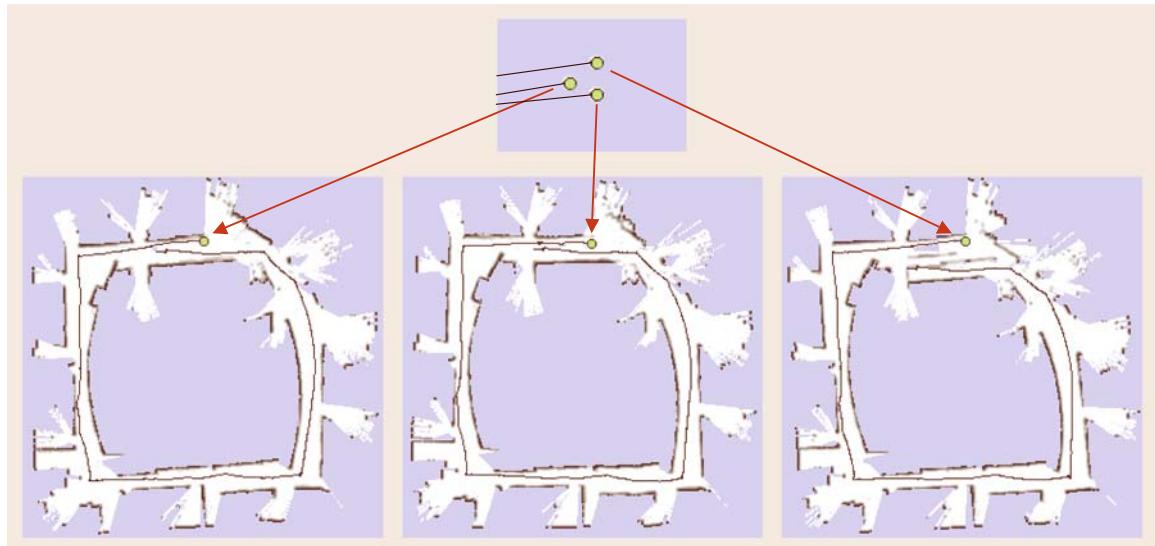

Fig. 37.10 Application of the grid-based variant of the FastSLAM algorithm. Each particle carries its own map, and the importance weights of the particles are computed based on the likelihood of the measurements given the particle's own map

37.3.4 Relation of Paradigms

The three paradigms just discussed cover the vast majority of work in the field of **SLAM**. As discussed, **EKF SLAM** comes with a computational hurdle that poses serious scaling limitations. The most promising extensions of **EKF SLAM** are based on

building local submaps; however, in many ways the resulting algorithms resemble the graph-based approach.

Graph-based methods address the full **SLAM** problem, and hence are by nature not online. They draw their intuition from the observation that **SLAM** can be modeled by a sparse graph of soft constraints,

where each constraint either corresponds to a motion or a measurement event. Due to the availability of highly efficient optimization methods for sparse nonlinear optimization problems, graph-based **SLAM** has become the method of choice for building large-scale maps offline. Data association search is quite easily incorporated into the basic mathematical framework, and a number of search techniques exist for finding suitable correspondences. There are also extensions of the graph-based **SLAM** for the online **SLAM** problem. Those tend to remove old robot locations from the graph.

Particle filter methods sidestep some of the issues arising from the natural interfeature correlations in the map, which plagued the **EKF**. By sampling from robot poses, the individual landmarks in the map become

independent, and hence are decorrelated. As a result, FastSLAM can represent the posterior by a sampled robot pose, and many local, independent Gaussians for its landmarks. The particle representation of FastSLAM has a number of advantages. Computationally, FastSLAM can be used as a filter, and its update requires linear-logarithmic time where **EKF** needed quadratic time. Further, FastSLAM can sample over data association, which makes it a prime method for **SLAM** with unknown data association. On the negative side, the number of necessary particles can grow very large, especially for robots seeking to map multiple nested loops. We discussed extensions of FastSLAM that use occupancy grid maps instead of Gaussian landmarks, and showed state-of-the-art examples in large map building.

37.4 Conclusion and Future Challenges

This chapter provided a comprehensive introduction to the **SLAM** problem and its primary solutions. The **SLAM** problem was defined as the problem faced by a mobile platform roaming an unknown environment, and seeking to localize and map its environment at the same time. The chapter discussed three main paradigms in **SLAM**, which are based on the extended Kalman filter, graph-based sparse optimization techniques, and particle filters. It pointed out some of the advantages and disadvantages of those methods. For a more in-depth discussion, the interested reader should refer to a recent textbook covering **SLAM** [37.5].

Interestingly, the field of **SLAM** is still relatively young, and it has made enormous progress within just the past decade. In fact, nearly every method described here has been developed within the past few years. Despite all this progress, there remains a great number of open research issues that warrant future research.

In particular, **SLAM** techniques mostly deal with static environments, yet nearly every actual robot environment is dynamic. Early applications of **SLAM** methods to dynamic environments can be found in [37.86–88]. More work is needed to understand the interaction of moving and nonmoving objects in **SLAM**.

Most **SLAM** work addresses single-robot mapping, yet sometimes one is given a team of robots. Early and highly restrictive work on multirobot **SLAM** can be found in [37.89, 90]. More recent methods

include those in [37.91–93]. Multirobot **SLAM** has benefited greatly from substantial recent interest; nevertheless, the existing methods have not yet matured to a level where they can be used by nonexperts in the field.

One of the primary challenges in **SLAM** is to pursue significant implementations. While the theory of **SLAM** is now quite well developed, **SLAM** has not yet been used extensively in industrial or commercial applications. There exist promising prototypes, including methods for building large-scale three-dimensional (3-D) volumetric maps [37.94–97], detailed underwater reconstruction [37.31, 98, 99], and mapping of abandoned underground mines [37.57]. Nevertheless, the authors feel that more work is needed to mature the technology into industrial-strength applications.

An ultimate goal is to realize the challenge of *persistent* navigation and mapping – the capability for a robot to perform **SLAM** robustly for days, weeks, or months at a time with minimal human supervision, in complex, dynamic environments. Taking the limit as $t \rightarrow \infty$ poses difficult challenges to most current algorithms; in fact, most robot mapping and navigation algorithms are doomed to fail with the passage of time, as errors inevitably accrue. Research is needed to develop techniques that can recover from mistakes and enable robots to deal with changes in the environment and to recover from mistakes, enabling a long-term autonomous existence.

Behavior-Based Systems

Maja J. Matarić, François Michaud

Nature is filled with examples of autonomous creatures capable of dealing with the diversity, unpredictability, and rapidly changing conditions of the real world. Such creatures must make decisions and take actions based on incomplete perception, time constraints, limited knowledge about the world, cognition, reasoning and physical capabilities, in uncontrolled conditions and with very limited cues about the intent of others. Consequently, one way of evaluating intelligence is based on the creature's ability to make the most of what it has available to handle the complexities of the real world. The main objective of this chapter is to clarify *behavior-based systems* and their use in single- and multi-robot autonomous control problems and applications. The chapter is organized as follows. Section 38.1 overviews robot control, introducing behavior-based systems in relation to other established approaches to robot control. Section 38.2 follows by outlining the basic principles of behavior-based systems that make them distinct from other types of robot control architectures. The concept of basis behaviors, the means of modularizing behavior-based systems, is presented in Sect. 38.3. Section 38.4 describes how behaviors are used as building blocks for creating representations for use by behavior-based systems, enabling the robot to reason about the world and about itself in that world. Section 38.5 presents several different classes of learning methods for behavior-based systems, validated on single-robot and multi-robot sys-

tems. Section 38.6 provides an overview of various robotics problems and application domains that have successfully been addressed with behavior-based control. Finally, Sect. 38.7 concludes the chapter.

38.1 Robot Control Approaches

Situated robotics deals with embodied machines in complex, challenging, often dynamically changing environments. *Situatedness* thus refers to existing in

a complex, challenging environment, and having one's behavior strongly affected by it. In contrast, robots that exist in static, unchanging environments are usu-

ally not thought to be situated. These include assembly robots operating in complex but highly structured, fixed, and strongly predictable environments, specifically engineered and controlled to enable the robot accomplish very specific tasks. The predictability and stability of the environment has a direct impact on the complexity of the robot that must operate in it; situated robots therefore present a significant challenge for the designer.

Robot control, also referred to as robot decision-making or robot computational architecture, is the process of taking information about the environment through the robot's sensors, processing it as necessary in order to make decisions about how to act, and executing actions in the environment. The complexity of the environment, i.e., the level of situatedness, has a direct impact on the complexity of control, which is, in turn, directly related to the robot's task. Control architectures are covered in Part I, Chap. 8, of the Handbook.

While there are infinitely many possible ways to program a robot, there are fundamentally four classes of robot control methods, described below.

38.1.1 Deliberative – Think, Then Act

In deliberative control, the robot uses all of the available sensory information, and all of the internally stored knowledge, to reason about what actions to take next. The control system is usually organized using a functional decomposition of the decision-making processes, consisting of a sensory processing module, a modeling module, a planning module, a value judgment module, and an execution module [38.1]. Such functional decomposition allows complex operations to be performed, but implies strong sequential interdependencies between the decision-making modules.

Reasoning in deliberative systems is typically in the form of planning, requiring a search of possible state-action sequences and their outcomes. *Planning*, a major component of artificial intelligence, is known to be a computationally complex process. The process requires the robot to perform a sequence of sense–plan–act steps (e.g., *combine the sensory data into a map of the world, then use the planner to find a path in the map, then send steps of the plan to the robot's wheels*) [38.2–4]. The robot must construct and then potentially evaluate all possible plans until it finds one that enables it to reach its goal, solve the task, or decide on a trajectory to execute. Shakey, an early mobile robot that used Strips, a general planner, is an example of such a system applied to the problem of avoiding obstacles and navigating based on vision data [38.5].

Planning requires the existence of an internal, symbolic representation of the world, which allows the robot to look ahead into the future and predict the outcomes of possible actions in various states, so as to generate plans. The internal model, thus, must be kept accurate and up to date. When there is sufficient time to generate a plan and the world model is accurate, this approach allows the robot to act strategically, selecting the best course of action for a given situation. However, being situated in a noisy, dynamic world usually makes this impossible [38.6, 7]. Today, no situated robots are purely deliberative. The advent of alternative architectures was driven by the need for faster yet appropriate action in response to the demands of complex and dynamically changing real-world environments.

38.1.2 Reactive – Don't Think, (Re)Act

Reactive control is a technique for tightly coupling sensory inputs and effector outputs, typically involving no intervening reasoning [38.8] to allow the robot to respond very quickly to changing and unstructured environments [38.9]. Reactive control is inspired by the biological notion of *stimulus–response*; it does not require the acquisition or maintenance of world models, as it does not rely on the types of complex reasoning processes utilized in deliberative control. Rather, rule-based methods involving a minimal amount of computation, and no internal representations or knowledge of the world are typically used. Reactive systems achieve rapid real-time responses by embedding the robot's controller in a collection of preprogrammed, concurrent condition-action rules with minimal internal state (e.g., *if bumped, stop; if stopped, back up*) [38.8, 10]. This makes reactive control especially well suited to dynamic and unstructured worlds where having access to a world model is not a realistic option. Furthermore, the minimal amount of computation involved means that reactive systems are able to respond in a timely manner to rapidly changing environments.

Reactive control is a powerful and effective control method that abounds in nature; insects, which vastly outnumber vertebrates, are largely reactive. However, limitations to pure reactivity include the inability to store (much if any) information or have memory or internal representations of the world [38.11], and therefore the inability to learn and improve over time. Reactive control trades off complexity of reasoning for fast reaction time. Formal analysis has shown that, for environments and tasks that can be characterized a priori, reactive controllers can be very powerful, and if properly structured,

capable of optimal performance in particular classes of problems [38.12,13]. In other types of environments and tasks, where internal models, memory, and learning are required, reactive control is not sufficient.

38.1.3 Hybrid – Think and Act Concurrently

Hybrid control aims to combine the best aspects of reactive and deliberative control: the real-time response of reactivity and the rationality and optimality of deliberation. As a result, hybrid control systems contain two different components, the reactive/concurrent condition–action rules and the deliberative ones, which must interact in order to produce a coherent output. This is challenging because the reactive component deals with the robot’s immediate needs, such as moving while avoiding obstacles, and thus operates on a very fast time scale and uses direct external sensory data and signals. In contrast, the deliberative component uses highly abstracted, symbolic, internal representations of the world, and operates on them on a longer time scale, for example to perform global path planning or plan for high-level decision-making. As long as the outputs of the two components are not in conflict, the system requires no further coordination. However, the two parts of the system must interact if they are to benefit from each other. Consequently, the reactive system must override the deliberative one if the world presents some unexpected and immediate challenge. Analogously, the deliberative component must inform the reactive one in order to guide the robot toward more efficient and optimal trajectories and goals. The interaction of the two parts of the system requires an intermediate component, which reconciles the different representations used by the other two and any conflicts between their outputs. The construction of this intermediate component is typically the greatest challenge of hybrid system design.

Hybrid systems are referred to as using *three-layer architectures*, because of their structure, which consists of the reactive (execution) layer, intermediate (coordination) layer, and deliberative (organization/planning) layer, and which is organized according to the principle of increasing precision of control in the lower layers with decreasing intelligence [38.14]. A great deal of research has been invested into the design these components and their interactions [38.2,15–21].

Three-layer architectures aim to harness the best of reactive control in the form of dynamic, concurrent, and time-responsive control, and the best of deliberative control, in the form of globally efficient actions over a long time scale. However, there are complex issues involved

in interfacing these fundamentally differing components and the manner in which their functionality should be partitioned is not yet well understood [38.22].

38.1.4 Behavior-Based Control – Think the Way You Act

Behavior-based control employs a set of distributed, interacting modules, called *behaviors*, that collectively achieve the desired system-level behavior. To an external observer, behaviors are patterns of the robot’s activity emerging from interactions between the robot and its environment. To a programmer, behaviors are control modules that cluster sets of constraints in order to achieve and maintain a goal [38.22,23]. Each behavior receives inputs from sensors and/or other behaviors in the system, and provides outputs to the robot’s actuators or to other behaviors. Thus, a behavior-based controller is a structured network of interacting behaviors, with no centralized world representation or focus of control. Instead, individual behaviors and networks of behaviors maintain any state information and models.

Well-designed behavior-based systems take advantage of the dynamics of interaction among the behaviors themselves, and between the behaviors and the environment. The functionality of behavior-based systems can be said to emerge from those interactions and is thus neither a property of the robot or the environment in isolation, but rather a result of the interplay between them [38.22]. Unlike reactive control, which utilizes collections of reactive rules with little if any state and no representation, behavior-based control utilizes collections of behaviors, which have no such constraints; behaviors do have state and can be used to construct representations, thereby enabling reasoning, planning, and learning.

Each of the above approaches to robot control has its strengths and weaknesses, and all play important and successful roles in certain robot control problems and applications. Each offers interesting but different insights, and no single approach should be seen as ideal or otherwise in the absolute; rather, the choice of robot control methodology should be based on the particular task, environment, and robot.

For example, reactive control is the best choice for environments demanding immediate response, but such speed of reaction comes at the price of being myopic, not looking into the past or the future. Reactive systems are also a popular choice in highly stochastic environments, and environments that can be properly characterized so as to be encoded in a reactive input–

output mapping. Deliberative systems, on the other hand, are the only choice for domains that require a great deal of strategy and optimization, and in turn search and planning. Such domains, however, are not typical of situated robotics, but more so of scheduling, game playing, and system configuration, among others. Hybrid systems are well suited for environments and tasks where internal models and planning are needed, and the real-time demands are few, or sufficiently independent of the higher-level reasoning. Behavior-based systems, in contrast, are best suited for environments with significant dynamic changes, where fast response and adaptivity are crucial, but the ability to do some looking ahead and avoid past mistakes is required. Those capabilities are spread over the active behaviors, using active representations if necessary [38.23], as discussed later in this Chapter.

Characterizing a given robot computational architecture based on these four classes of control is often a matter of degree, as architectures attempt to combine the advantages of these paradigms, especially the responsiveness, robustness, and flexibility of the behavior-based approach with the use of abstract repre-

sentational knowledge for reasoning and planning about the world [38.22] or for managing multiple conflicting goals. For example, AuRA uses a planner to select behaviors [38.22] and 3T uses behaviors in the execution layer of a three-level hierarchical architecture [38.24]; both of these architectures dynamically reconfigure behaviors according to reasoning based on available world knowledge [38.22].

Robot control presents fundamental tradeoffs having to do with time scale of response, system organization, and modularity: thinking allows looking ahead to avoid mistakes, but only as long as sufficient, accurate, up-to-date information is available, otherwise reacting may be the best way to handle the world. As a consequence of these inherent tradeoffs, it is important to have different methodologies at our disposal rather than having to fit all controller needs into a single methodology. Selecting an appropriate control methodology and designing an architecture within it is best determined by the situatedness properties of the problem, the nature of the task, the level of efficiency or optimality needed, and the capabilities of the robot, both in terms of hardware, world modeling, and computation.

38.2 Basic Principles of Behavior-Based Systems

The basic principles of behavior-based control can be summarized briefly as follows:

- Behaviors are implemented as control laws (sometimes similar to those used in control theory), either in software or hardware, as a processing element or as a procedure.
- Each behavior can take inputs from the robot's sensors (e.g., proximity sensors, range detectors, contact sensors, camera) and/or from other modules in the system, and send outputs to the robot's effectors (e.g., wheels, grippers, arm, speech) and/or to other modules.
- Many different behaviors may independently receive input from the same sensors and output action commands to the same actuators.
- Behaviors are encoded to be relatively simple, and are added to the system incrementally.
- Behaviors (or subsets thereof) are executed concurrently, not sequentially, in order to exploit parallelism and speed of computation, as well as the interaction dynamics among behaviors and between behaviors and the environment.

Behavior-based robotics was developed for situated robots, allowing them to adapt to the dynamics of real-world environments without operating upon abstract representations of reality [38.11], but also giving them more computational capability and expressivity than are available to reactive robots. Behavior-based systems maintain a tight coupling of sensing and action through behaviors, and use the behavior structure for representation and learning. Therefore, it is uncommon for a behavior to perform extensive computation or reasoning relying on a traditional world model, unless such computation can be done in a timely manner in response to dynamic and fast-changing environment and task demands.

Behaviors are designed at a variety of abstraction levels, facilitating bottom-up construction of behavior-based systems. New behaviors are introduced into the system incrementally, from the simple to the more complex, until their interaction results in the desired overall capabilities of the robot. In general, behaviors encode time-extended processes, not atomic actions that are typical of feedback control (e.g., *go-forward-by-a-small-increment* or *turn-by-a-small-angle*). As a first

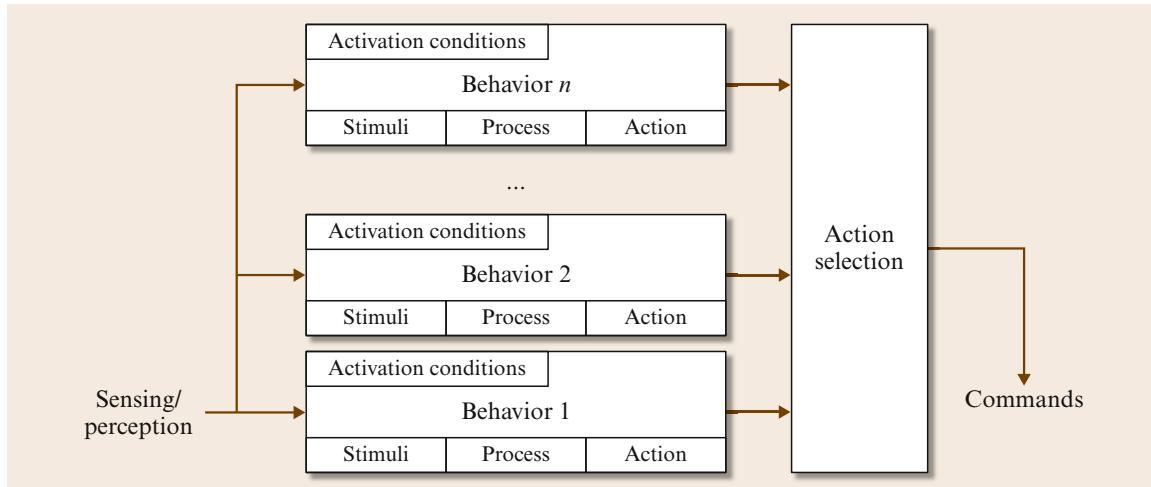

Fig. 38.1 A general schematic of one type of behavior-based systems

step, survival behaviors, such as *collision-avoidance*, are implemented. These behaviors are often reactive in nature, since reactive rules can and often do form components of simple behaviors. Figure 38.1 summarizes the general components of low-level behavior-based systems. Note that there is a distinction between *activation conditions*, which allow the behavior to generate actions, and *stimuli*, from which actions are generated.

Next, behaviors are added that provide more complex capabilities, such as *wall-following*, *target-chasing*, *homing*, *find-object*, *get-recharged*, *avoid-the-light*, *aggregate-with-group*, *pick-up-object*, *find-landmark*. Depending on the system being designed, behaviors implementing distributed representations may be added, as may be behaviors capable of learning about the world and/or the robot itself, and operating on those representations and learned information. Representation and learning are addressed in more detail in Sect. 38.4.

The interaction and integration of temporal and spatial effects is of key importance in behavior-based systems. Merely having one process controlling an actuator for predetermined intervals of time, or using as many processes as there are effectors to control them, does not suffice as the basis for behavior-based control. It is the combined effect of concurrent processes over time and driven by perception and internal states that creates the relevant behavior-based dynamics in a control system.

Behavior-based systems are typically designed so the effects of the behaviors interact largely in the en-

vironment rather than internally through the system, taking advantage of the richness of the interaction dynamics by exploiting the properties of situatedness. These dynamics are sometimes called *emergent* behaviors because they *emerge* from the interactions and are not internally specified by the robot's program. Therefore, the internal behavior structure of a behavior-based system need not necessarily mirror its externally manifested behavior. For example, a robot that flocks with other robots may not have a specific *flocking* behavior; instead, its interaction with the environment and other robots may result in flocking, although its only behaviors may be *avoid-collisions*, *stay-close-to-the-group*, and *keep-going*.

For such an approach to work, a behavior-based system must resolve the issue of choosing a particular action or behavior from multiple options, a process known as *action selection* or the *behavior coordination* problem [38.25]. This is one of the central design challenges of behavior-based systems. One approach to action selection is the use of a predefined behavior hierarchy, in which commands from the highest-ranking active behavior are sent to the actuator and all others are ignored. Numerous approaches based on other principles as well as ad hoc methods for addressing the action selection problem have been developed and demonstrated on robotic systems. These methods aim to provide increased flexibility but, in some cases, may do so at the cost of reducing the efficiency or the analyzability of the resulting control systems. Developed methods include varieties of motor schemas [38.16], command

fusion [38.26], spreading of activation through a behavior network [38.27, 28], and fuzzy logic [38.29, 30], among many others. For a survey of action selection mechanisms, see [38.31].

38.2.1 Misconceptions

Because behavior-based systems are not always simple to describe or implement, they are also often misunderstood. The most common misconception equates reactive and behavior-based systems. Historically, the advent of behavior-based systems was inspired by reactive systems, and both maintain real-time couplings between sensing and action [38.18, 32], and are structured and developed bottom-up, consisting of distributed modules. However, behavior-based systems are fundamentally *more powerful* than reactive systems, because they can store representations [38.33], while reactive systems cannot. Reactive systems are limited by their lack of internal state; they are incapable of using internal representations and learning. Behavior-based systems overcome this limitation because their underlying unit of representation, the *behavior*, can store state internally, in a distributed fashion.

The means by which state and representation are distributed in behavior-based systems is one of the sources of the flexibility of the control methodology. Representations in behavior-based systems are distributed, so as to best match and utilize the underlying behavior structure that causes the robot to act. This is how *thinking* can be organized in much the same way as *acting*. Thus if a robot needs to plan ahead, it does so in a network of communicating behaviors, rather than a single centralized planner. If a robot needs to store a large map, the map might be distributed over multiple behavior modules representing its components, such as a network of landmarks, as in [38.34], or a network of parameterized navigation behaviors, as in [38.35, 36], so that reasoning about the map/environment/task can be done in an active fashion, through using message passing within the behavior network. The planning and reasoning components of the behavior-based system use the same mechanisms as the sensing- and action-oriented behaviors, and as a result do not operate on a fundamentally different time scale and representation relative to one another. Various forms of distributed representations are used, ranging from static table structures and networks, to active procedural processes implemented within the behavior networks.

Another area of common misconception relates to the comparison between behavior-based systems and hybrid systems. Because the two use such different modularization strategies, it is often assumed that one approach (usually hybrid) has improved expressive capabilities. In fact, behavior-based and hybrid systems have the same expressive and computational capabilities: both can exploit representations and look ahead, but they do so in very different ways. This has resulted in different application domains being best suited to behavior-based versus hybrid systems. Specifically, hybrid systems dominate the domain of single-robot control, unless the task is so time-demanding that a reactive system must be used. Behavior-based systems dominate the domain of multi-robot control because the notion of collections of behaviors within the system scales well to collections of such robots, resulting in robust, adaptive group behavior [38.37, 38]. See Chap. 40 on multiple mobile robot systems for more details.

Like hybrid systems, behavior-based systems may be organized in layers, but unlike hybrid systems, the layers do not differ from each other drastically in terms of time scale and representation used. Behavior-based systems typically do not employ the hierarchical/sequential division favored by hybrid approaches. Behavior-based systems do provide both low-level control and high-level deliberation; the latter can be performed by one or more distributed representations that compute(s) over the other behaviors or modules, often directly utilizing low-level behaviors and their outputs. The resulting systems, built from the bottom up, do not divide into differently represented and independent components and consist of elements directly tied in some ways to behaviors. The power, elegance, and complexity of behavior-based systems all stem from the ways in which their constituent behaviors are designed, coordinated, and used.

To summarize briefly, behavior-based systems:

1. use behaviors as the building block of both decision-making and action execution processes;
2. use distributed parallel evaluation and concurrent control over behaviors, which take real-time inputs from sensory data and send real-time commands to effectors; and
3. have no centralized components, each module carrying out its own responsibilities. The following sections describe and illustrate in more detail how behavior-based basic principles can be used to control robots.

38.3 Basis Behaviors

The process of designing a set of behaviors for a robot is referred to as *behavior synthesis*, and is typically performed by hand, although some methods for automated synthesis behaviors have been developed and successfully demonstrated [38,39,40]. In all cases, behaviors perform a particular activity, attain a goal, or maintain some state. The notion of defining an *optimal* behavior set for a given robot or task has been considered, but it is generally accepted that such a notion is not realistic as it is dependent on too many specifics of a given system and environment that cannot currently be effectively formalized.

Mataric et al. [38,38,41] describe *basis behaviors*, also referred to as *primitive behaviors*, as a tool for structuring and thus simplifying behavior synthesis. Basis behaviors are a set of behaviors such that each is *necessary*, in the sense that each either achieves, or helps to achieve, a relevant goal that cannot be achieved without it by other members of that set. Furthermore, the basis behavior set is *sufficient* for achieving the goals mandated for the controller. The term *basis* was chosen to be indicative of the similar notion within linear algebra.

The property of necessity or parsimony is analogous to the idea of linear independence; the idea of sufficiency is similar to the linear algebraic concept of span. Basis behaviors should be simple, stable, robust, and scalable.

Another organizational principle of basis behaviors is *orthogonality*. Two behaviors are orthogonal if they do not interfere with one another, each inducing no side-effects in the other. This is often achieved by having behaviors take mutually exclusive sensory inputs. Another method is to have different behaviors control separate effectors. This form of factorization is only feasible when the robot's dynamics do not inhibit their separability. In contrast, autonomous helicopter control is an example of a highly coupled system; *Saripalli* et al. [38,42] demonstrated how behavior-based control can be effectively applied to robust autonomous helicopter flight.

Basis behavior design principles have been applied to single-robot as well as multi-robot behavior-based systems in a variety of applications, ranging from navigation to foraging, coordinated group movement, box pushing, and others.

38.4 Representation in Behavior-Based Systems

Embedding representation into behavior-based systems involves the challenge of conserving the basic principles of the approach at all levels of system decision-making. Combining abstract reasoning processes with behaviors must be done in a way that exploits interaction dynamics and desirable emergent system properties.

Mataric et al. [38,33,43] describe work with a robot named *Toto*, which introduced the use of distributed representation into behavior-based systems. *Toto*'s capabilities included safe navigation, landmark detection, map learning, and path planning in the learned map representation, all within the behavior-based framework. To exploit the principles underlying behavior-based control, *Toto*'s representation was not a centralized map. Instead, any newly discovered landmark in the environment was assigned to a new map representation behavior, which stored the landmark descriptor (type, estimated Cartesian location, and compass orientation). Whenever sensory inputs matched the landmark descriptor, the robot localized to that particular landmark and the behavior became active. The following is pseudo-code for each landmark behavior:

Algorithm 38.1

```

my-behavior-type: C
my-compass-direction: 0
my-approximate-location: (x,y)
my-approximate-length: 6.5
whenever received (input)
if input(behavior-type) = my-behavior-type
    AND
        input(compass-direction) =
            my-compass-direction
    then
        active <- true

```

As new landmarks are discovered, they are added to the map representation behavior network. In this way, the topology of the resulting map network is isomorphic to the topology of the network graph in the physical environment *Toto* has explored. The edges in the network graph are also communication links in the behavior network, allowing landmark behaviors to communicate through local message passing. Consequently, a cur-

rently active map behavior can send a message to its topological neighbor(s), thereby indicating expectation of it being the next recognized landmark and facilitating Toto's localization. Planning in the network takes place through the use of the same message-passing mechanism. The goal landmark (which could be selected by the user as part of the task, such as *go to this particular corridor* or *go to the nearest north-facing wall*), sends messages (i.e., spreads activation) from itself to its neighbors, which pass it on throughout the network. As messages are passed, the length of each landmark in the graph is accrued, thereby estimating the length of each path. The shortest path arriving at the currently active network behavior indicates the best direction to pursue toward the goal. This is equivalent to a distributed Dijkstra search. Importantly, because this search is not a static process as it would be in a centralized map representation, but an active ongoing process within a behavior map, if the robot is picked up and moved to another location, as soon as it localizes, it will continue on the optimal path to the goal; because each landmark makes a local decision as to where to go next toward the goal, no unique global path is stored in any central

location/representation. Thus, the path is constantly refreshed and updated; if any route is blocked, the link in the graph is disconnected and the shortest path is updated dynamically.

Toto exemplifies how, in behavior-based systems, representations can be stored in a distributed fashion, so as to best match the underlying behavior structure that produces the robot's external goal-driven activity. If a robot needs to make high-level decisions (such as planning ahead to a distant goal), it does so in a network of communicating behaviors, rather than a single centralized component. This results in scalable and efficient computation for the system as a whole, since the typically slower decision-making processes such as planning are distributed and modularized in a way that makes them more consistent with the time scale and representation of the rest of the system. Note the fundamental difference between this general attempt of behavior-based systems to homogenize their representation through the use of behaviors as universal modules, compared to hybrid systems, which rely on inherently different representations and time scales at different levels of the system.

38.5 Learning in Behavior-Based Systems

The ability to improve performance over time and to reason about the world, in the context of a changing and dynamic environment, is an important area of research in situated robotics. Unlike in classical machine learning, where the goal is typically to optimize performance over a long period of time, in situated learning the aim is to adapt relatively quickly, toward attaining efficiency in the light of uncertainty. Models from biology are often considered, given its properties of learning directly from environmental feedback. Variations and adaptations of machine learning, and in particular reinforcement learning, have been effectively applied to behavior-based robots, which have demonstrated learning to walk [38.44], communicate [38.45], navigate and create topological maps [38.33, 46], divide tasks [38.23, 47], behave socially [38.48], and even identify opponents and score goals in robot soccer [38.49]. Methods from artificial life, evolutionary computation/genetic algorithms, fuzzy logic, vision and learning, multi-agent systems, and many other research areas continue to be actively explored and applied to behavior-based robots as their role in animal modeling and practical applications continues to develop.

When operating in unpredictable and partially observable environments, an autonomous robot must examine the evolution of its general states, and try to capture what emerges from the interaction dynamics with its environment. Temporal integration of different types of observations is an important aspect of that capability [38.50, 51]. Work on motivational systems [38.52–56] has shown that a balance between planning and reactivity for goal management can be achieved using internal variables activated or inhibited by different factors [38.37, 57–59]. Motivations can be cyclic (e.g., circadian rhythms) or change in various temporally dependent ways [38.55]. In general, the notion of motivations is used to efficiently balance the need to adapt to the contingencies of the world and to accomplish the robot's goals.

In the following subsections, we discuss three successfully validated classes of learning approaches in behavior-based systems:

1. reinforcement learning over behaviors
2. learning behavior networks for task planning
3. learning from history of behavior use

The approaches differ in what is learned and where learning algorithms are applied, but in all cases behaviors are used as the underlying building blocks for the learning process.

38.5.1 Reinforcement Learning in Behavior-Based Systems

Behaviors are recognized as excellent substrates for speeding up reinforcement learning (RL), which is known to suffer from the curse of dimensionality. The earliest examples of RL in behavior-based systems demonstrated hexapod walking [38.44] and box-pushing [38.60]. Both decomposed the control system into a small set of behaviors, and used generalized input states, thereby effectively reducing the size of the state space. In the box-pushing example, the learning problem was broken up into modularized policies for learning separate mutually exclusive behaviors: for getting out when stuck, for finding the box when lost and not stuck, and for pushing the box when in contact with one and not stuck. The modularization into behaviors resulted in greatly accelerated as well as more robust learning.

Scaling up reinforcement learning to multi-robot behavior-based systems was explored by [38.23] and [38.61]. In multi-robot systems, the environment presents further challenges of nonstationarity and credit assignment, due to the presence of other agents and concurrent learners. The problem was studied in the context of a foraging task with four robots, each initially equipped with a small set of basis behaviors (*searching, homing, picking-up, dropping, following, avoiding*) and learning individual behavior selection policies, i. e., which behavior to execute under which conditions. Due to interference among concurrent learners, this problem could not be solved directly by standard RL. *Shaping*, a concept from psychology [38.62], was introduced; it was subsequently adopted in robot RL [38.63]. Shaping pushes the reward closer to the subgoals of the behavior, and thus encourages the learner to incrementally improve its behaviors by searching the behavior space more effectively. Matarić [38.61] introduced shaping through *progress estimators*, measures of progress toward the goal of a given behavior during its execution. This form of reward shaping addresses two issues associated with delayed reward: behavior termination and fortuitous reward. Behavior termination is event-driven; the duration of any given behavior is determined by the interaction dynamics with the environment, and can vary greatly. Progress estimators provide a principled

means for deciding when a behavior may be terminated even if its goal is not reached and an externally generated event has not occurred. Fortuitous reward refers to reward ascribed to a particular situation–behavior (or state–action) pair which is actually a result of previous behaviors/actions. It manifests as follows: previous behaviors lead the system near the goal, but some event induced a behavior switch, and subsequent achievement of the goal is ascribed most strongly to the final behavior, rather than the previous ones. Shaped reward in the form of progress estimators effectively eliminates this effect. Because it provides feedback during behavior execution, it rewards the previous beneficial behaviors more strongly than the final one, thus more appropriately assigning credit.

In summary, reinforcement learning has been successfully applied to behavior-based robotics, in particular at the level of behavior selection. The learning process is accelerated by the behavior structure, which provides a higher-level representation of actions and time-extended dynamics.

38.5.2 Learning Behavior Networks

The modularization of behavior-based systems as networks of behaviors allows for learning to be applied at the network level as well. Niculescu et al. [38.35, 36] developed the notion of *abstract behaviors*, which separate the activation conditions of a behavior from its output actions (so-called *primitive behaviors*, which share the same principles as basis behaviors described Sect. 38.3); this allows for a more general set of activation conditions to be associated with the primitive behaviors. While this is not necessary for any single task, it is what provides generality to the representation. An abstract behavior is a pairing of a given behavior's activation conditions (i. e., preconditions) and its effects (i. e., postconditions); the result is an abstract and general operator much like those used in classical deliberative systems (Fig. 38.2). Primitive behaviors, which typically consist of a small basis set, may involve one or an entire collection of sequential or concurrently executing behaviors.

Networks of such behaviors are then used to specify strategies or general *plans* in a way that merges the advantages of both abstract representations and behavior-based systems. The nodes in the networks are abstract behaviors, and the links between them represent precondition and postcondition dependencies. The task plan or strategy is represented as a network of such behaviors. As in any behavior-based system, when the conditions of a behavior are met, the behavior is acti-

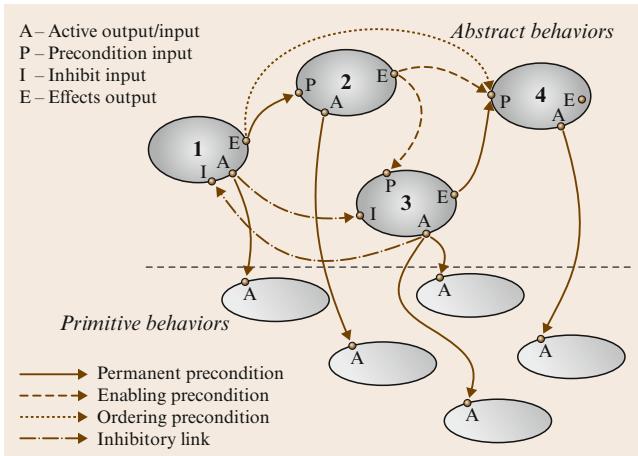

Fig. 38.2 Behavior network

vated. Analogously, when the conditions of an abstract behavior are met, the behavior activates one or more primitive behaviors which achieve the effects specified in its postconditions. The network topology at the abstract behavior level encodes any task-specific behavior sequences, freeing up the primitive behaviors to be reused for a variety of tasks. Thus, since abstract behavior networks are computationally lightweight, solutions for multiple tasks can be encoded within a single system and dynamically switched.

Nicolescu et al. [38.35, 36] introduced a means for automatically generating such networks offline as well as at runtime. The latter enables a learning robot to acquire task descriptions dynamically, while observing its environment, which can include other robots and/or a teacher. The methodology was validated on a mobile robot following a human and acquiring a representation of the human-demonstrated task by observing the activation of its own abstract behavior pre- and postconditions, thus resulting in a new abstract behavior network representing the demonstrated task [38.64]. The robot was able to acquire novel behavior sequences and combinations (i.e., concurrently executing behaviors), resulting in successful learning of tasks involving visiting various targets in particular order, picking up, transporting, and delivering objects, dealing with barriers, and maneuvering obstacle courses in specific ways.

38.5.3 Learning from History of Behavior Use

Most deliberative approaches derive knowledge for reasoning about the world from sensor inputs and actions

taken by the robot. This results in complex state-space representations of the world and does not take into consideration the context in which these sensations/actions are taken. As already discussed, behaviors, which are readily used as low-level control blocks driven by what is experienced from the interactions with the environment, can also serve as an abstract representation to model those interactions. One approach is to use history information [38.65], i.e., to explicitly take into consideration the time sequence of observations in order to make a decision. Applying this idea to behavior-based systems, by knowing the purpose of each of the behaviors and by observing their history of use, the robot can reason and ground its intentions in what it is experiencing in its operating environment. The concept of abstract behavior is exploited here as well, to activate behaviors and as a representation on which to learn.

Learning from history has been validated in behavior-based systems capable of making the robot change its behavior selection strategy for foraging colored objects (blocks) to a homing region in nonstationary, dynamically changing environments involving multiple concurrently learning robots [38.66, 67]. In that foraging task, the robot is given two subtasks: search for a block (searching task), and bring it to the home region (homing task). The robot is given behaviors to accomplish these tasks: one behavior for the searching task, called *searching-block*, and two for the homing task, *homing* and *drop-block*. A *velocity control* behavior is also used in both of these tasks to make the robot move. All these behaviors are referred to as *task behaviors*. Conditions for activating task behaviors are preprogrammed based on the presence or absence of a block in front of the robot and the proximity of the home region.

The robot also needs to navigate safely in the environment. In this approach, an *avoidance* behavior is activated unless the robot is near home and carrying a block; otherwise it is disabled, to allow the robot to approach the home region. This type of behavior, used for handling harmful situations and interference while accomplishing a task, is referred to as a *maintenance behavior*. The designer determines the conditions in which maintenance behaviors should be used, but cannot indicate when they will occur during the task, as that is tied to the dynamics of the interaction between the robot and its environment.

The robot learns to use *alternative behaviors* (*follow-side*, *rest*, and *turn-randomly*), which introduce variety into its action repertoire that changes the way it accomplishes its tasks. In contrast to other types of behaviors,

these have no *a priori* activation conditions; the objective is to allow the robot to learn when to activate these behaviors according to past experiences, for some pre-set periods of time, when it is experiencing interference in accomplishing its task. Figure 38.3 illustrates how the behaviors are prioritized using a fixed suppression mechanism, similar to the subsumption architecture [38.9] but with the difference that the activated behaviors, i. e., those allowed to issue outputs, change dynamically. Following behavior-based principles, an activated behavior may or may not be used to control the robot, depending on the sensory conditions it monitors and the arbitration mechanism. An activated behavior is used only when it provides commands that actually control the robot. Whenever a behavior is used, its corresponding symbol is sent to the interaction model, generating the sequence of behaviors used over time. Separate learning trees are used for each task; determining which one to use is done based on the activated task behavior.

The algorithm uses a tree structure to store the history of behavior use. The upper part of Fig. 38.3 shows a typical tree with nodes storing the behavior (H for use by *homing* and *drop-block*) used for controlling the robot while accomplishing its task, and n , the number of times a transition between the node itself and its successor has been made (as observed from behavior use). Initially, the tree for a particular task is empty and is incrementally constructed as the robot goes about its task. Leaf nodes are labeled with E (for end-node) and store the total *performance* of the particular tree path. Whenever a path is completely reused, when the same sequence of behaviors is used, the E node is updated with the average of the stored and current performances for recent trials.

Learning is done through reinforcement. Depending on the domains and the tasks, a variety of factors can be used to evaluate performance, and different metrics can be used with this learning algorithm. To see how far the idea of self-evaluation and learning by observing behavior use can be taken, the evaluation function used here is not based on characteristics about the environment or the task. Instead, it is based on the amount of time behaviors are used. Comparison between the time spent using behaviors associated with the tasks and the time spent exploiting maintenance behaviors is used to derive the evaluation criterion. Consequently, behavioral selection strategy is derived from what can be learned from the experiences of the robot in its environment, without having to characterize *a priori* what can be considered to be optimal operating conditions in the environment.

Using the tree and the evaluation function, the algorithm has two options for using a maintenance behavior:

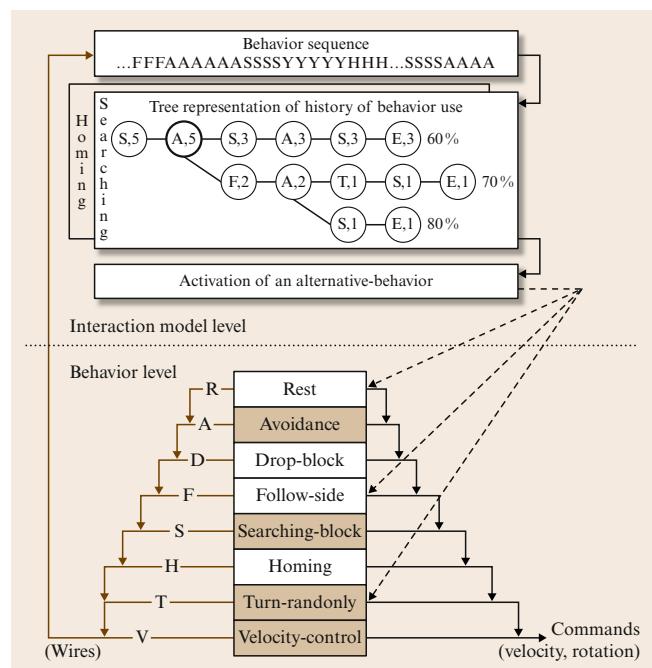

Fig. 38.3 Organization of the behavior level and the interaction model level. Behavior on colored background represent an example of activated behaviors for the searching task, with *Turn-randomly* as a chosen alternative behavior. For clarity, sensory inputs to behaviors are not shown

1. not to make any changes in its active behavior set (the *observe* option)
 2. to activate an alternative behavior

The sequence of nodes in a tree path characterizes the interactions experienced by the robot in the world. Different selection criteria can be used by comparing the performance at the current position in the tree with the expected performance, following an exploration (to learn the effects of alternative behaviors) then exploitation (to exploit what was learned in previous trials) strategy. The expected performance of a given node is the sum of the stored end-node performances in its subpaths, multiplied by the frequency of use of the subpaths relative to the current position in the tree. Finally, since this algorithm is used in noisy and nonstationary conditions, deleting paths is necessary to keep the interaction model up to date. This is done by keeping only a fixed number of the most recent paths in the tree.

Results obtained with this approach show that the robot is able to learn unanticipated strategies (like resting in front of a static obstacle to increase the turning angle

and locate a target) and original ones (like yielding when close to other robots or following walls when the center of the pen is crowded). Developing such capabilities

is important in general, because it makes it possible for robots to learn in nonstationary environments, which are common in the world applications.

38.6 Continuing Work

Behavior-based robots have demonstrated various standard capabilities, including obstacle avoidance, navigation, terrain mapping, following, chasing/pursuit, object manipulation, task division and cooperation, and learning maps, navigation and walking. They have also demonstrated some novel applications like large-scale group behaviors including flocking, foraging, and soccer playing, human–robot interaction, and modeling insect and even human behavior [38.68–70]. Behavior-based methods span mobile robots, underwater vehicles, planetary rovers for space exploration, interactive and social robots, as well as robots capable of grasping, manipulation, walking, running, and many others. Broadly adopted consumer market products, such as the iRobot Roomba Robotic Floorvac [38.71], also use behavior-based control, demonstrating its broad applicability.

The use of behavior-based architectures for robot control has evolved from single-system implementations to approaches that combine forms of learning, state estimation, and distributed computation. Behaviors have been combined with a fuzzy inference system for indoor navigation using mobile robots [38.29, 30, 72, 73], where a command fusion module acts as an arbiter that combines multiple fuzzy behavior outputs into a single control signal. This strategy ensures the robot is capable of making inferences in the face of uncertainty.

Behavior-based methods have been employed in multi-robot systems from the outset [38.38]. More recently, multi-robot researchers have begun to consider tasks requiring tightly coupled cooperation; see [38.74] for an overview and discussion. Such tasks typically require low-level sensor-sharing and/or for higher-level explicit coordination. Behavior-based controllers have been developed and extended in order to address these challenges. For example, Parker et al. [38.75] considered reusable behavior units that can be automatically redistributed for low-level information processing. Werger et al. [38.76] described broadcast of local eligibility (BLE) to enable higher-level group behaviors by allowing communications to influence each robot's local action selection mechanism. Gerkey et al. [38.77, 78] demonstrated scalable and efficient market-based co-

ordination algorithms for multi-robot coordination in a variety of tasks, including tightly coupled ones (e.g., box-pushing [38.79]).

Several researchers have shown that behavior-based controllers allow for sophisticated coordination through a utility-centered model of the collective task. Behaviors use this representation to produce actions that consider each robot's impact on the performance of the group as a whole. Iocchi et al. [38.80] have shown this in heterogeneous multi-robot system, while Batalin et al. [38.81] demonstrated that complex, interrelated and dynamic tasks can be performed in coordinated ways in robots with behavior-based controllers interacting with a sensor network. Stroupe et al. [38.82] considered a mapping task and developed move value estimation for robot teams (MVERT), essentially a behavior-based method for maximizing group knowledge.

Because behavior-based methods lend itself naturally to multi-robot control problems, they have had a significant influence on that field of research. Simmons et al. [38.83] described a hybrid architecture designed for group-level coordination which employs behaviors as a method for organizing low-level safety-critical controller code. Behaviors have also been used to structure controllers and networked communication in minimalist systems [38.84]. Some multi-robot research with a control-theoretic flavor has used separate executable processes that can be switched on and off dynamically depending on task constraints, in a manner very similar to behavior-based control [38.85].

Learning by demonstration has also been combined with behavior-based systems to produce one-shot learning and teaching mechanisms for robot control [38.35]. Furthermore, this type of behavior-based architecture has been used to learn ship navigation strategies [38.86]; during a learning phase, an instructor selects behaviors for a ship to execute in order to reach a specific goal, and a subsequent offline stage then generates dependency links between the behaviors that it witnessed during the learning phase.

Another form of learning by demonstration has used probabilistic methods to select and combine multiple behaviors [38.87]. There, the problem of learning what

behaviors to execute during autonomous navigation is treated as a state estimation problem. During a learning phase, the robot observes commands used by a teacher. A particle filter then fuses the control commands that were demonstrated by the teacher to estimate behavior activation. The method produces a robust controller that is well suited for dynamic environments.

Behavior-based architectures have also been used in complex vision systems, for identification rather than control. In those contexts, each behavior represents a small unit of visual computation, such as frame differencing, motion detection, and edge detection, resulting in biologically inspired vision and attention behavior [38.88, 89].

Behavior-based architectures have also been developed for the control and learning in humanoid robots. Figure 38.4 illustrates two robots used in ongoing projects. In the past, the Cog project demonstrated behavior-based control for articulated manual and eye-hand coordination [38.90, 91]. Edsinger [38.92] developed a lightweight behavior architecture for organizing perception and control of Domo. The architecture allows for specification of time-contingent behaviors and distributed computation, resulting in a real-time controller that allows Domo to operate in an environment with humans. Kismet [38.93] involved several behavior-based systems that controlled perception, motivation, attention, behavior, and movement in a human–robot interaction (HRI) context. Each behavior represented Kismet’s individual drives and motivations. Situated modules and episode rules were introduced as part of an HRI architecture by Ishiguro et al. [38.94] and Kanda et al. [38.95]; they employed an ordered set of general-use situated modules and behaviors that are contingent

on a condition, used in sequences defined by a set of task-specific episode rules.

38.6.1 Motivated Configuration of Behaviors

Designing robots capable of safely and effectively interacting with humans in real-world settings is one of the ultimate challenges in robotics. Representation and abstract reasoning may become necessary to keep up with and adapt to the inherently complex properties of such environments and tasks.

One possible solution currently being developed and validated is to add to a behavior-based architecture the idea of intentionally activating, monitoring, and configuring behaviors. Behaviors are considered basic control components that are selected and modified according to the intentions of the robot [38.57, 96, 97]. Such intentions can also comply with the distributed philosophy of behavior-based system by having multiple sources of influences. The motivated behavioral architecture (MBA) uses motivational modules to derive the robot’s intentions.

Motivational modules recommend the use or the inhibition of tasks to be accomplished by the robot. Tasks are data structures associated with particular configuration and activation of one or more behaviors. The processing of the robot’s intentions is done through the *dynamic task workspace* (DTW), which organizes tasks in a tree-like structure according to their interdependencies, from high-level abstract tasks (e.g., *deliver message*) to primitive behavior-related tasks (e.g., *avoid obstacles*). Through the DTW and task representation, motivational modules exchange information asynchronously on how to activate, configure, and monitor behaviors, by submitting modification requests and queries or subscribe to events regarding the task’s status. With multiple tasks being issued by the motivational modules, the *behavior activation and configuration* module determines which behaviors are to be activated according to recommendations made by motivational modules, with or without a particular configuration (e.g., a destination to go to). A recommendation can either be negative, neutral, or positive, or take on real values within this range to reflect the desirability of the robot to accomplish specific tasks. The decisional process implemented in the *behavior activation and configuration* module (which can be based on different methods of action selection, as set by the designer) takes these information to activate behaviors. Activation values reflect the resulting robot’s intentions

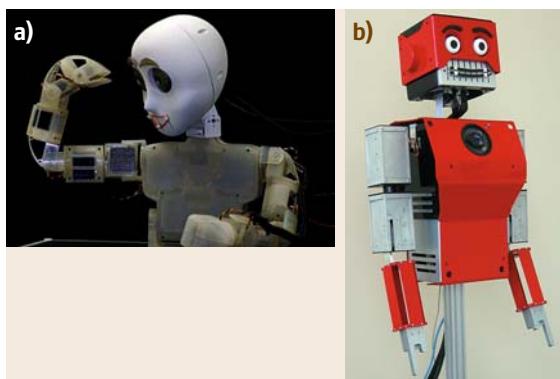

Fig. 38.4a,b Examples of behavior-based control systems used in human–robot interaction: USC Bandit (a) and University of Sherbrooke Melvin (b)

derived from interactions between the motivational modules. Behavior use and other information (useful for task representation and for monitoring how the behaviors are used by the robot to interact with the world) are also communicated through the *behavior activation and configuration* module.

Motivational modules are categorized as instinctual, rational, or emotional. Instinctual motivations provide basic operation of the robot through the use of simple rules. Rational motivations are related to cognitive processes, such as navigation and planning. Emotional motivations monitor conflicting or transitional situations between tasks, such as changes in commitments the robot establishes with other agents (humans or robot) in its environment. The manifested robot behavior can thus be appropriately influenced by direct perception, by reasoning, or by managing commitments and choices. By distributing motivational modules and distinguishing their roles, it is possible to more efficiently exploit and combine the various influences on the tasks the robot must accomplish. It is also by exchanging information through the DTW that motivational modules are kept generic and independent from each other, allowing for behavior configurations to arise in a distributed fashion, based on the capabilities available to the robot. For instance, one instinctual motivation may monitor the robot's energy level to issue a recharging task in the DTW, which activates a *recharge* behavior that would make the robot detect and dock to a charging station. Meanwhile, if the robot knows where it is and can determine a path to a nearby charging station,

a path-planning rational motivation can add a subtask of navigating to this position, using a *goto* behavior. Otherwise, the *recharge* behavior will at least allow the robot to recharge opportunistically, when it perceives a charging station.

The described architecture was used to integrate a number of intelligent decision-making capabilities on a robot named Spartacus, shown in Fig. 38.5. In the American Association for Artificial Intelligence (AAAI) mobile robot competition, Spartacus was used to demonstrate how a behavior-based system could integrate planning and sequencing tasks under temporal constraints and spatial localization capabilities, using a previously generated metric map. The system also used behavioral message reading [38.98], sound processing capabilities with an eight-microphone system for source localization, tracking, real-time sound separation [38.99, 100], and a touch screen interface to allow the robot to acquire information about where it is in the world, what it should do, and how it should do it [38.101, 102].

Figure 38.6 illustrates the navigation portion of the architecture implemented on Spartacus. Behavior action selection scheme used is priority based, and behavior recommendation and activation are binary. The behaviors used are: *stop/rest*, stopping the robot when the emergency stop or interacting with people using the graphical interface is required; *avoid*, making the robot move safely in the environment; *obey*, executing vocal navigation requests; *recharge*, stopping the robot while waiting to be connected to a charging station; *goto*, directing the robot to a specific location; *follow-sound*, making the robot follow an audio source; *follow-wall*, making the robot follow a wall (or corridor) when detected, otherwise generating a constant forward velocity. Only instinctual and rational motivations are implemented in this version, with rational motivations having greater priority over instinctual ones in case of conflicts. For instinctual motivations, the *task selector* selects one high-level task when none has yet been prioritized. For instance, between tasks that require the robot to go to a specific location, this motivation selects the task where the location is physically closest to the robot. *Safe navigation* urges the robot to maintain its physical integrity by recommending obstacle avoidance. For the rational motivations, *planner* determines which primitive tasks and sequences thereof are necessary to accomplish high-level tasks under temporal constraints and limited capabilities. The first implementation was a simple reactive planning module that interleaves planning and execution [38.103], as in [38.104] and [38.105]. Naviga-

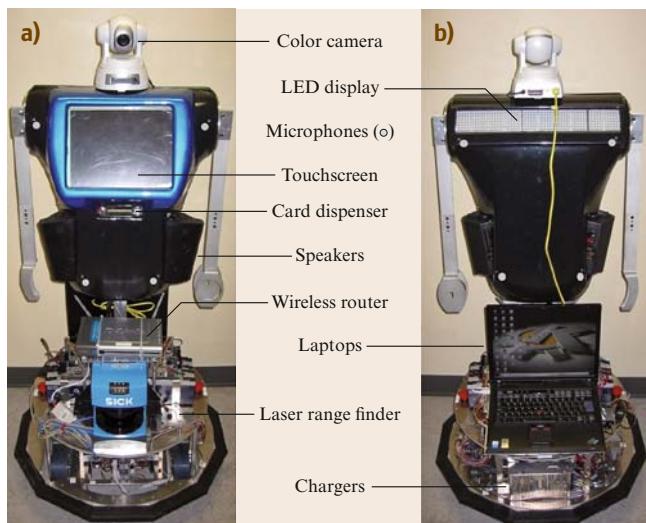

Fig. 38.5a,b Spartacus (front view (a), back view (b))

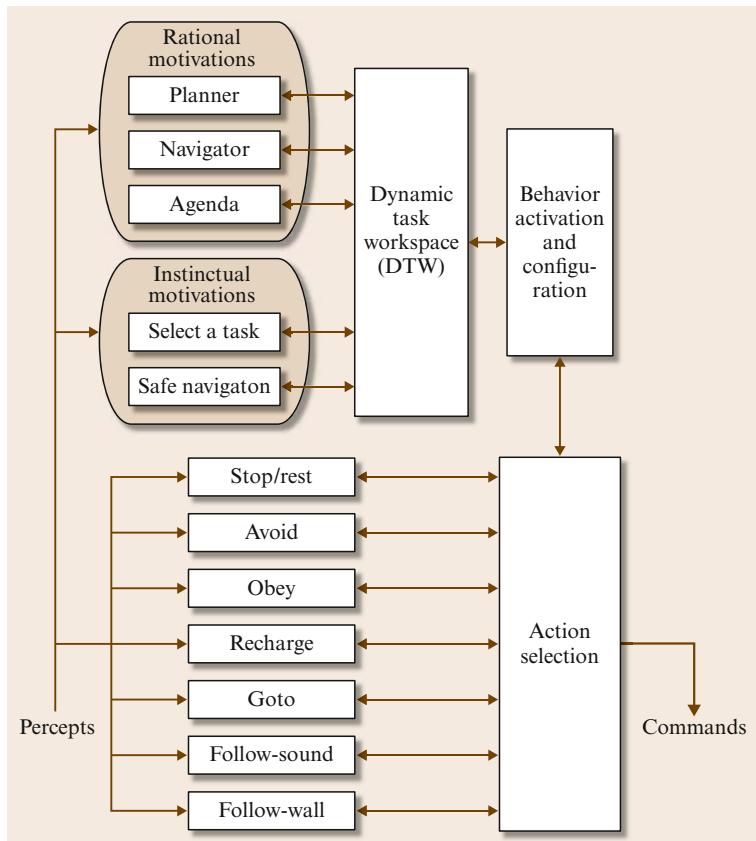

Fig. 38.6 Behavior-based architecture with distributed motivational modules

tor determined the path to a specific location, as required for tasks in the DTW. *Agenda* generated predetermined sequences of tasks to accomplish.

The underlying principles of the described architecture have also been applied to robots with different capabilities, such as a robot that uses activation variables, topological localization and mapping, and fuzzy behaviors to explore and characterize an environment [38.57, 97], and on an autonomous rolling robot that only uses simple sensors and a microcontroller to generate purposeful movements used in a study regarding interaction with toddlers [38.106, 107]. The MBA architecture is now being used on robots with increasing perceptual and action capabilities, in an attempt to provide robots with the necessary skills to be useful and efficient in daily life.

ment [38.57, 97], and on an autonomous rolling robot that only uses simple sensors and a microcontroller to generate purposeful movements used in a study regarding interaction with toddlers [38.106, 107]. The MBA architecture is now being used on robots with increasing perceptual and action capabilities, in an attempt to provide robots with the necessary skills to be useful and efficient in daily life.

38.7 Conclusions and Further Reading

This chapter has described behavior-based control, a methodology for single- and multi-robot control aimed at situated robots operating in unconstrained, challenging, and dynamic conditions in the real world. While inspired by the philosophy of reactive control, behavior-based systems are fundamentally more expressive and powerful, enabling representation, planning, and learning capabilities. Distributed

behaviors are used as the underlying building blocks for these capabilities, allowing behavior-based systems to take advantage of dynamic interactions with the environment rather than rely solely on explicit reasoning and planning. As the complexity of robots continues to increase, behavior-based principles and their applications in robot architectures and deployed systems will evolve as well, demonstrating

increasingly higher levels of situated intelligence and autonomy.

Interested readers can find more information regarding behavior-based systems in other chapters of this

Handbook, as well as in *Brooks* [38.108], *Arkin* [38.22], in artificial intelligence and robotics textbooks [38.109, 110], and in introductory textbooks on mobile robot control [38.111–113].

Distributed and Cellular Robots

Zack Butler, Alfred Rizzi

This chapter is organized according to a number of broad classes of problem where modular robotic systems can prove beneficial. For each such problem, the benefits of modularity are described, along with the ways that particular systems or proposed systems have explored those benefits. In particular, we discuss locomotion in Sect. 39.1, manipulation in Sect. 39.2, modular robot geometry in Sect. 39.3, and robust systems in Sect. 39.4. The systems under consideration in general have some level of independent computation on each module, and this discussion will focus on systems in which modules maintain some sort of kinematic constraint between them during operation. Compared to the types of multirobot teams described in Chap. 40, the systems of interest here are generally much more tightly coupled, both physically and conceptually. That is, we are primarily concerned with systems which, though they have many processors and independent actuators, have a single goal or small set of goals which can only be achieved collectively, rather than a set of goals

which can be apportioned to single (or a small number of) robots within the team.

For many families of tasks in robotics, including manipulation and locomotion, different instances of the task can be best solved by robots with different kinematics. For example, both legged robots and wheeled robots can be effective for locomotion, but each type is better suited to a particular type of environment (rough or generally smooth). Likewise, manipulator arms with different geometry can achieve good ma-

nipulability over different workspaces. The use of modularity in robots, whether by developing physically interchangeable parts for a single robot or creating completely independent robots that can join together as the situation demands, can make it possible for a single overall robotic system to achieve a variety of kinematic configurations that a fixed architecture can not.

39.1 Modularity for Locomotion

Modular robots can achieve a very wide variety of forms for locomotion over (or even through) rough terrain. A single robot system may be able to surmount obstacles

many times the size of the modules itself, while also being able to navigate tunnels just larger than a single module. Some systems have been designed primarily

for multimodal locomotion, while other more general-purpose machines can also perform in this way, albeit less efficiently.

39.1.1 Self-Reconfigurable Robot Locomotion

Self-reconfigurable robots are a potentially very powerful type of system in which the modules move themselves with respect to each other to autonomously attain different configurations for different purposes. Systems constructed to date generally fall into two categories, *chain based* and *lattice based*, defined by how a collection of modules lies in space. Chain-based systems form essentially one-dimensional skeleton structures which can move in a continuous way, while lattice-based structures tend to have space-filling modules that form configurations that are relatively dense in two or three dimensions.

In chain-based systems, the modules generally connect as links in a chain, such that most modules connect to two other modules along an axis about which the module can rotate. Additional junction modules provide for more complex structures, such as legged spiders in addition to wheels and snakes. Some examples of such systems are the PolyBot [39.1] and the configurable robot (**CONRO**) system [39.4]. There are two major challenges when building chain-based systems. First of all, control of reconfiguration presents an interesting kinematic problem – turning a snake into a loop requires coordination of all the joints to bring the two ends of the snake close enough to allow physical connection. This is similar to traditional inverse kinematics with computation distributed over the joints of the system.

Once a chain-based system has achieved a given configuration, in order to progress over the terrain, the

modules must produce a successful periodic gait. A gait is usually specified similarly to legged systems, that is, each joint has a schedule of angle with respect to time. The challenge here is that the gait will depend on the configuration – snakes of different lengths may require different gaits, and legged constructions with a varying number of legs are also possible. The work of *Zhang et al.* [39.5] on the Polybot system describes a set of scalable configuration types (loops, legs, snakes) and automated transitions between them as well as automatic gait generators. This work uses phase automata to generate the periodic angle for each joint, but specified in a way that can be easily recomputed as the configuration changes.

Modules in lattice-based systems fill space much like building blocks. This allows these robots to construct a much wider variety of shapes, and as such they may be able to surmount larger obstacles, but at the cost of less efficient locomotion. For example, as a wheeled or legged construct, a chain-based system cannot climb obstacles significantly higher than traditional wheeled or legged robots can, whereas a lattice-based robot can make scaffolding-like shapes limited only by the number of modules available, with modules then climbing the scaffolding and reforming a group on the opposite side of the obstacle. Here the hardware specifics become very important, as these systems perform locomotion by reconfiguring, that is, the modules will move over the remainder of the structure one at a time for the group to move forward. Figure 39.2 shows an example of lattice-based modules that actuate through compression and expansion climbing stairs using a hard-coded motion sequence.

Locomotion via shape change was formalized in a cellular-automata-like framework in [39.6] – in this work, each module independently runs a set of geometric rules and depending on the state of its neighborhood

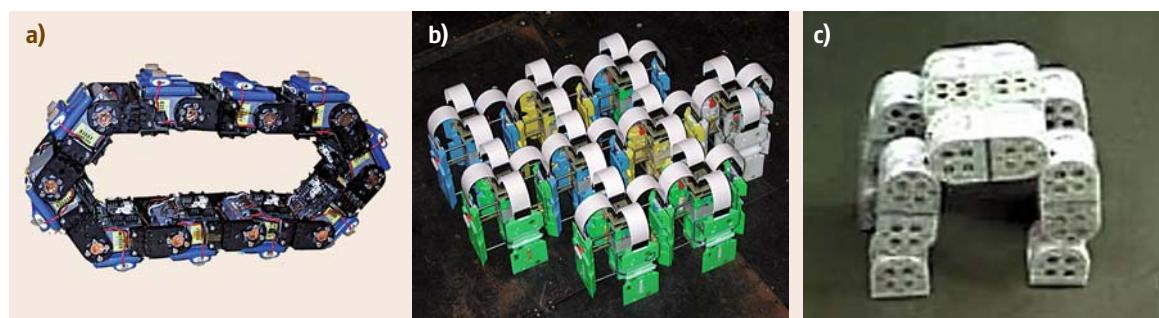

Fig. 39.1a–c Examples of self-reconfigurable robots: (a) the Polybot, a chain-based system [39.1]; (b) the Crystal, a two-dimensional lattice-based system [39.2]; (c) **MTRAN** [39.3], which can take on the characteristics of either type

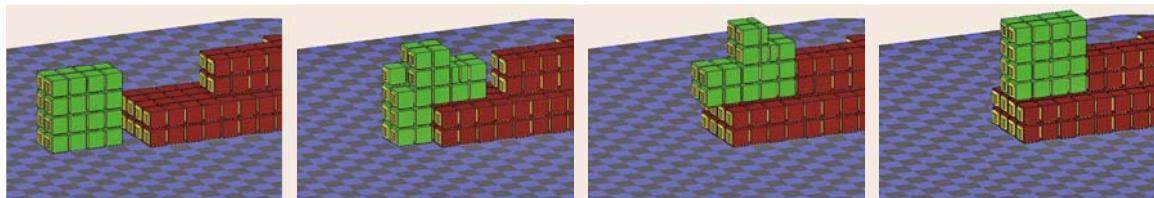

Fig. 39.2 A self-reconfigurable robot made of compressible modules climbing stairs that are two modules tall

(where other modules and obstacles are located), may move in a given direction. This technique was shown to ensure progress and avoid deadlock for straight-line motion over uneven terrain, traversing cliffs many modules high as well as narrow tunnels, and turning on flat ground, but is not trivially generalizable to more complex operations.

Lattice-based robots also have a wider variety of module types. Some systems are purely planar (e.g., [39.9, 10]) while others are three dimensional (e.g., [39.11]). They can be simple cubes or more complex shapes, though in general a single module is incapable of significant motion in isolation, instead requiring a substrate of other modules to connect to and walk across. Connections between modules can be mechanical [39.12] or magnetic [39.9]. The work of [39.6] proposed a generic model of a cubic module that can translate over other modules and make convex transitions, and showed that several different hardware systems can implement this model (though some require multiple hardware modules, termed metamodules, to implement a single generic module).

Recently this divide has been bridged with hardware that can operate in both chain-based and lattice-based modes. Modular transformer (**MTRAN**) and its successors [39.13] consist of 2-DOF modules, with each module containing two semicylindrical parts that rotate about a link between them. Each half of the module can make three connections to other modules through magnetic connectors that require energy only to disconnect. This robot can also operate completely untethered, including connecting and disconnecting, to effect true self-reconfiguration. This system has demonstrated self-reconfiguration in a lattice-based mode (where the discrete nature of the lattice makes the kinematics and therefore the docking problem much simpler) followed by conversion to a four-legged walker which uses the joints of the modules in a continuous fashion. The Superbot [39.14] is another recently developed system which promises to be at least as functional as the **MTRAN** due to an additional degree of freedom per module, however at present the ability to physically connect

and disconnect autonomously is still under development.

In all of these systems, constructing functional and robust hardware is a critical challenge. The primary con-

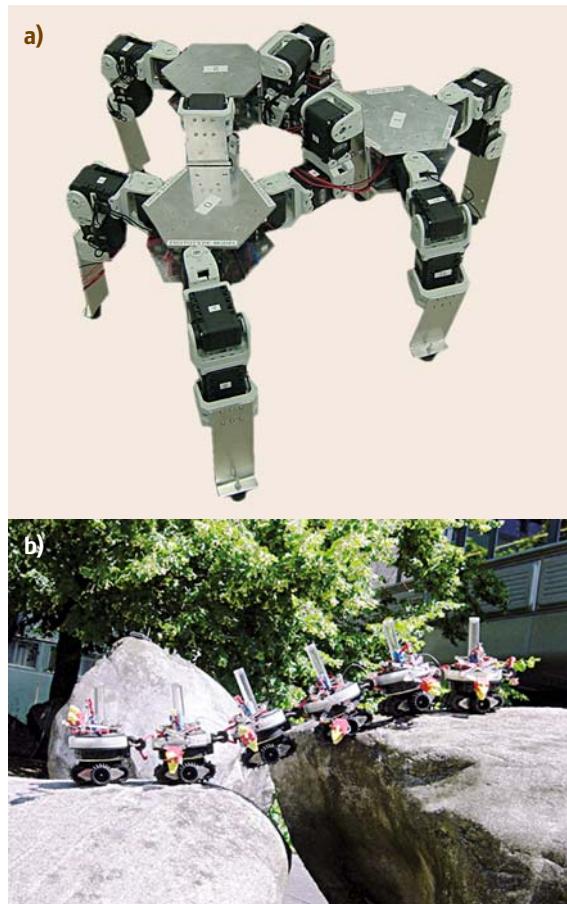

Fig. 39.3a,b Examples of independently capable mobile robots which can join together to perform more difficult tasks. **(a)** Three modules of the Ashigaru system [39.7] combined into a six-legged walker. **(b)** Swarmbots [39.8] connected together traversing a gap larger than a module in width

sideration is that of the connection mechanism – these will require fairly rigid connection, often including multiple electrical connections for communication and/or power transfer, while also allowing for physical connection in the face of position error. The position error can either be handled through sensing, such as the multiple beacons used in the CONRO modules, or through mechanical means, such as the grippers used in the Molecule robot. Connectors are especially critical for lattice-based systems, which must perform connection and disconnection to effect any significant geometric change.

39.1.2 Physically Cooperative Mobile Robots

In other situations, the locomotion requirements may be largely straightforward, with only certain specific areas requiring unusual abilities. In these cases, it may be more appropriate to use more traditional mobile robots as modules that can travel efficiently on their own but can also make rigid or semirigid connection to achieve greater capability.

One example of this is the Gunryu system proposed by Hirose et al. [39.15]. In this system, each module is a stand-alone tracked mobile robot approximately 0.5 m in length with a two-joint arm mounted on it. Each module can autonomously navigate moderately difficult terrain. Upon encountering very steep terrain or a hole in the ground larger than one module, the module can

use its manipulator arm to hold onto another module. The authors were able to demonstrate that two modules connected together could traverse steeper ground than a single module. Key to this ability is the strength of the manipulator; it must be sufficiently strong to hold the weight of another module. A more recent robot called Ashigaru uses modules that each have three legs and can execute simple crawling gaits alone. Modules can grab each other in a variety of ways, as each leg can act as a grabber. Demonstrations have included forming quadrupeds and hexapods (such as in Fig. 39.3a), climbing steps taller than single modules are able to, and even using one module as a simple manipulator while it is held by other modules. It is currently manually reconfigured, though plans include the ability for self-reconfiguration [39.7].

More extensive work in this line is being carried out by in the SWARM-BOTS project [39.16]. The modules in this system are significantly smaller (circular robots 120 mm in diameter) but have a similar gripper that can grab other modules to allow for cooperative locomotion. In this case, the gripper is a 2-DOF wrist rather than a serial manipulator, which allows for greater rigidity. These modules have demonstrated the ability to cross a gap greater than one module diameter wide, as in Fig. 39.3b [39.8]. Each module also has a short serial manipulator to perform a wider variety of manipulation tasks, and the overall system has also demonstrated simple forms of cooperative manipulation.

39.2 Modularity for Manipulation

Modularity can also be a great advantage when manipulating a wide variety of payloads. In particular, the underlying kinematics of a manipulation system may be changed rapidly (either online or offline, depending on the system) so that the workspace and manipulability are most appropriate for a given task.

39.2.1 Independent Manipulators

One common task for which a group of robots can be beneficial is that of pushing or carrying a large object. If the object is significantly larger than a single robot can handle, a group is the only way to move it through the environment. When implementing such a system, the key issues include the frequency of data transfer and the effective sharing of the load. In order for the robots to maintain control over the object, the forces inherent must be shared so that no single robot is overwhelmed.

Khatib et al. proposed the virtual linkage as an solution to this problem [39.17].

Force control is less of a concern in a quasistatic pushing problem – in this case, the challenge is in producing the appropriate trajectory for the pushed object given the limited range of forces that can be applied by each pusher. Synchronization is still important in such systems, however. Mataric et al. [39.18] demonstrated cooperative pushing with two legged robots moving a box that neither could move alone, and showed that in general, without synchronization, one would move faster than the other and misorient the box or move past the end of the box. In this work, the synchronization is done through explicit communication and time-slicing of control, that is, each robot has a time in which it can move, after which it passes control (and sensory information) to its colleague. This explicit synchronization is not always necessary, however – if the robots have suffi-

cient sensing and understanding of the mechanics of the pushing task, they can implicitly cooperate through the pushing task itself. That is, as the pushed object moves, each robot can infer the state of the overall system and choose its actions and role appropriately. This idea of information in the task mechanics was developed by *Donald et al.* [39.19], where they provide a set of transformations for information channels between the virtual and the physical.

Cooperative manipulation can also be achieved by modules that are not necessarily mobile. Some manufacturing-oriented systems have been proposed in which the manipulation modules can be much simpler than otherwise would be required because many modules can work together to perform the required tasks. One such system is the virtual vehicle of *Luntz et al.* [39.20]. In this system, each module is simply a wheel which can be rotated. By assembling a large number of them in a bounded region, a programmable conveyor is created. Multiple objects can be handled simultaneously at different points in the system, and can be handled differently (e.g., one being stopped and rotated in place while another is moved past). Again, synchronization is critical here – the motion of an object is determined by the total force and torque acting on it, which in turn is determined not only by the velocity and angle of each wheel under it, but also the relative location of each wheel. In order for the object to maintain the correct trajectory, all wheels must inject the appropriate force for their location, which can change as the object moves. One way to handle this complexity is to simplify the task such that the forces are not time dependent, for example, simply operating as a conveyor belt in which all wheels move the same direction, or having two portions of the system push toward each other to move objects to a given location.

Another system in which the use of multiple modules allows for the use of simpler robots is the minifactory of *Hollis et al.* [39.21]. Here, traditional 4-DOF assembly operations are performed by two robots, each with two DOF. One robot is an overhead two-axis ($Z-\Theta$) manipulator and the other an $X-Y$ planar motor. The simplification of the robots, in particular the elimination of a serial chain in the overhead manipulator, allows for greatly increased precision and the performance of

micron-scale automated assembly. Here, however, the goal is to perform force-guided assembly, requiring the closing of a 1 kHz control loop between the two independent robots.

39.2.2 Reconfigurable Manipulators

A very different type of modularity for manipulation is that for a more or less traditional robot arm that can be easily rebuilt or reconfigured to achieve different kinematics. If the arm is constructed as a sequence of identical modular components (joints), these can then be attached to provide as many degrees of freedom as needed, with the appropriate workspace. The reconfigurable modular manipulator system (**RMMS**) was designed with these aims in mind [39.22]. The challenge here is to calculate the inverse kinematics and the dynamics automatically as the system changes, and in fact the **RMMS** does provide this functionality, though these systems usually have centralized computation with at most local joint controllers. This type of simplicity through modularity can be taken to a more extreme point, in which each module is a linkage with binary actuation, that is, only two possible states. Combining many of these binary modules with different geometry in different configurations creates robots with different workspaces from the same selection of components [39.23]. Here the kinematics and inverse kinematics are discrete, though the inverse kinematics are not closed form since the workspace is a set of discrete points in space. However, the control scheme is much simpler, since little or no feedback is required to direct the endpoint to a given location once the desired linkage positions are determined.

One of the earliest systems described in the field of self-reconfiguration is the cellular robot (**CEBOT**) of *Fukuda et al.* [39.24]. This system falls between the extremes of pure self-reconfiguring modules and mobile robots, as it does include modules which are independently mobile, but also includes nonmobile modules and expects that several modules will be used for most tasks. In one task described for **CEBOT**, individual modules can move through a small opening into a tank, and then reconfigure into a larger manipulator to perform operations across the entire tank.

39.3 Modularity for Geometric Reconfiguration of Robot Systems

The use of modularity allows for systems of many independent components to be reconfigured quickly between

task operations with a minimum of effort. This is useful in manufacturing systems, where the modules may

be capable of stand-alone operation, as well as self-reconfiguring robots, where sensors can be repositioned as the robot performs its tasks. In both cases, there are several issues to consider: ease of reconfiguration, determination of the current configuration, choosing good configurations for a particular task, and the design of the underlying task-performance algorithms for use with arbitrary configurations.

39.3.1 Manually Reconfigured Systems

Traditional manufacturing can be performed in workcells, in which usually a single robot has access to several stations and performs a series of assembly operations. These workcells are designed to be fairly modular from a component point of view, swapping different portions of the product in and out as the manufacturing task changes. Several workcells can then be laid out along a conveyor or other line mechanism to create an assembly line. While they may be very similar in construction, they tend to be fairly independent in operation. Scheduling in the traditional sense may be important, but real-time interactions are less likely to be.

In the Minifactory project, on the other hand, the entire system including the conveyances is part of a single modular system. All modules conform to a common interface, both in hardware and software [39.21]. This allows rapid reconfiguration, with each robot able to be placed in the system with clamps and simple connectors. The robots share a common high-level language and a centralized simulation environment, so that tasks can be programmed into the system ahead of time. When the modules are assembled, the robots that ferry the products through the system can also be used to discover the exact locations of all of the components as placed. The task algorithms, written under a common framework, are then automatically updated with the exact locations

to be visited. This allows for a smooth and efficient transition from a simulated assembly line to an operating set of hardware.

39.3.2 Shape Generation via Self-Reconfiguring Systems

Self-reconfigurable robots, as the name implies, can autonomously change their overall shape to fit the task at hand. In addition to using this capability to perform a variety of locomotion tasks, lattice-based systems in particular have the capability to make nearly arbitrary three-dimensional shapes. This may be useful for generating different sizes and shapes of payload carriers, manipulators, or other devices. In more recent research, systems of heterogeneous modules, where the capabilities of each module are not necessarily the same, have again received more attention [39.25]. These may be useful for positioning cameras or other specialized sensors at varying positions during the completion of a task even as the shape of the system remains the same. Figure 39.4 shows a simulation of a heterogeneous reconfiguration from a chair to a table – in this technique, the system first achieves the desired shape without regard to module type (denoted by module color), after which the modules physically sort themselves into the correct locations.

To perform self-reconfiguration, the modules in a system need to cooperate to plan their motions so that they can form the desired configuration. In common practice, the modules run without a central controller, but the global desired shape in some specification is given to all modules, at which point each module makes local decisions about if and where to move. To perform the reconfiguration, primarily local algorithms as well as more global planners have been developed.

Local shape-formation techniques tend to be connection based, that is, the desired shape is specified by

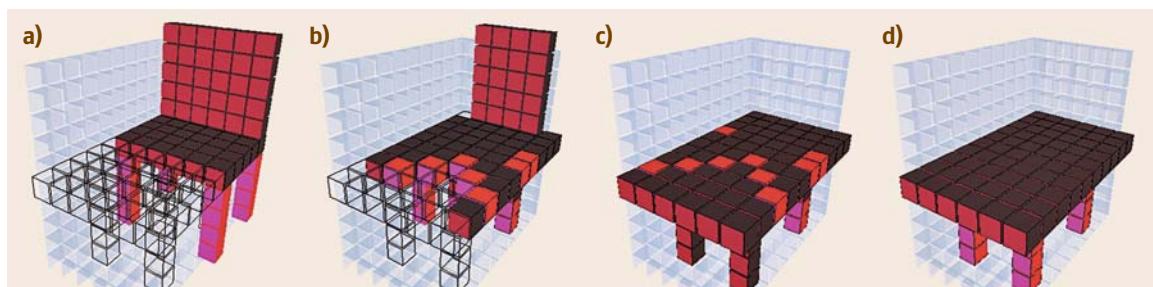

Fig. 39.4a–d Heterogeneous reconfiguration of a chair-shaped system to a table shape. **(a)** Initial configuration. **(b)** Modules moving in parallel to achieve the correct configuration. **(c)** Final system shape. **(d)** Final module locations based on heterogeneous module types

listing the connections to be made between modules. Each module is then responsible for ensuring it has the appropriate set of modules connected to it. Tomita et al. first proposed a shape generation scheme of this nature for two-dimensional systems [39.26], in which a single seed module collects modules around in successive layers, with each layer collecting appropriate modules as specified by the global design. Along a similar vein, work by Lipson et al. [39.27] constructs shapes out of modules that do not contain traditional actuation, but rather exist in a moving fluid medium. The modules can only control when and where to allow other modules to connect to them to build the desired shape, and so a connection-based scheme is natural. Recent work by Klavins [39.28] avoids the need for a seed module, and uses reaction network theory to allow modules that move stochastically (e.g., due to external forces) to intelligently detach and reattach and achieve many copies of the desired shape in an efficient and reliable way.

Global techniques tend to look more like traditional path planners – the modules discover local mismatches between the current configuration and the desired configuration, and paths are planned in a distributed fashion for modules to move into empty locations. One interesting feature is that the available paths are over the surface of other modules, so there is computation available wherever the search needs to take place, and distributed planning is quite natural. In addition, the paths are naturally discrete, so no artificial constraints need to be applied to perform the planning.

Here there are two main concerns: first, a matching problem must be solved, to ensure that each goal location is the destination of only one module and that each location is accounted for; and second, deadlock must be avoided and traversability maintained if and when multiple plans are being generated and executed within the system. The first can be solved by having each goal location spoken for by a particular module, and having that module initiate a path search for a module that can fill the location. In addition, these techniques also tend to build the goal shape one layer at a time, starting from the current shape and extending outward. Each individual path search must be filled by only one module, either by executing a depth-first search that terminates when a capable module is found (which is the approach taken in [39.29]) or having some other way to choose a module if multiple modules attempt to fill the requested location. Modules also must know to attempt motion only if they are not required at their current position and can move without disconnecting the overall structure. *MeltGrow* [39.30] and its heterogeneous successor,

MeltSortGrow, handle this latter problem by moving all the modules to an intermediate shape (a line) from which the end of the line can be locally detected and only this module will move to a goal location. However, modules can detect whether they will disconnect the structure through a depth-first search from their neighbors, and so this melting step is unnecessary. During motion, care must be taken to ensure that paths are still valid as other modules begin to move. This can be done through serialization or through a localized traffic control scheme [39.29], in which modules communicate to take turns passing through a particular area. Shape reconfiguration algorithms can be shown to require $O(n^2)$ module motions for n modules [39.31], but usually only $O(n)$ time if the motions are executed in parallel.

If the systems are heterogeneous, that is, the modules are of different types, modules must also determine which type is required at a given location, and only modules of that type can respond to the particular request. Fitch et al. [39.25] propose a planning system for identically sized but arbitrarily typed modules in which the correct shape is first achieved regardless of type, after which modules swap location. This algorithm still only requires $O(n^2)$ motion under most circumstances and can be efficiently executed in a distributed way.

39.3.3 Configuration Optimization

The determination of an appropriate configuration is another key issue in both manually reconfigured and self-reconfiguring systems, but has been little discussed in the literature. One common approach is an empirical one – to simulate a particular task or set of tasks (e.g., an assembly process) under different configurations and compare efficiency in each case. For example, in describing the *RMMS* system, [39.22] mentions that a simulator is available for determining the best configuration for a particular manipulation task. Similar work was performed for the *CEBOT* system, in which the location of the manipulator as well as the required number of modules and their configuration was optimized [39.32]. There is work with binary manipulators to find an optimal configuration for a given set of points to be reached, in which Lagrange multipliers are used to minimize the change from a base structure to a structure that can achieve the desired locations [39.23].

In systems such as self-reconfiguring robots, where hundreds of modules may be placed in fairly arbitrary ways, there are vast numbers of configurations to be considered, and the tasks themselves can be more complex. An evolutionary approach to optimizing con-

figurations of modular (though not self-reconfiguring) robots is described in Chap. 61. More general configuration optimization approaches from multirobot teams may be applicable for tasks such as surveillance, though they would need to be modified to handle the added capabilities of self-reconfiguring systems.

39.3.4 Self-Replicating Systems

One type of system that obviates the question of configuration determination is the self-replicating mod-

ular robot. In these systems, one group of modules builds a copy from a supply of modules. While the theory of self-replication was established by *von Neumann* [39.33], engineering such a robotic system is a significant challenge. This capability has been demonstrated in restricted form by *Suthakorn* et al. [39.34], in which the robots are constructed of four fairly complex modules, and one robot can construct a second, and by *Zykov* et al. [39.35] in a system of more traditional lattice-based self-reconfiguring modules.

39.4 Modularity for Robustness

Finally, the use of a large number of simple modules to complete a task allows for robustness in the event of failure. If the modules are completely homogeneous, then they can simply be swapped out and replaced. If the system is engineered with sufficient redundancy, modules may even be done without as they fail. This process of self-repair may be possible to execute in an autonomous fashion, as has been proposed for some self-reconfigurable systems [39.26, 36]. In these cases, the failed module is ejected from the system either by selective disassembly to get the failed module to the surface, or by a pushing gait that moves the module. The DRAGON connector [39.37] can always be detached from either side in the event of module failure, so that the system can continue with minimal disruption. How-

ever, despite the presumed importance of this self-repair capability of modular systems, this has not been a major focus of research.

On the other hand, systems which are manually reconfigured may not have the option to evict a nonfunctional module. Instead, they may be built with inherent redundancy so that nonfunctional modules can simply be handled, either actively or passively. For example, in the virtual vehicle, the failure of a single unit may not affect the overall performance if the objects in transport are large relative to the actuators. Likewise, redundant manipulators such as the RMMS [39.22] can continue to function if a single joint seizes, though this must be actively detected so that their changed kinematics and dynamics can be taken into account.

39.5 Conclusions and Further Reading

The benefits of modularity can be seen in many different task domains, whether the systems change their configuration on their own or require assistance from humans. The modularity can be used to simply create larger machines, for example, for more capable locomotion, or more complex machines that still retain a notion of simplicity at the module level. At present, hardware systems have largely remained in the research realm, while algorithmic progress has been notably more advanced in several areas, such as self-reconfiguration. It is hoped that the costs associated with modular robot development can be reduced as a byproduct of mass production,

enabling more deployments that take advantage of the robustness and versatility inherent to such systems.

Interested readers may find more details of some self-reconfiguring robots in a survey paper [39.38], and workshops in this area are often held in conjunction with international conferences, such as the 2006 Robotics: Science and Systems conference, and the 2007 International Conference on Intelligent Robots and Systems. Distributed robotic systems in general are the subject of the biennial distributed autonomous robotics systems (**DARS**) conference, including many papers relevant to this topic.

40. Multiple Mobile Robot Systems

Lynne E. Parker

Within the context of multiple *mobile* robot systems, this chapter explores the current state of the art. After a brief introduction, we first examine architectures for multirobot cooperation, exploring the alternative approaches that have been developed. Next, we explore communications issues and their impact on multirobot teams in Sect. 40.3, followed by a discussion of swarm robot systems in Sect. 40.4. While swarm systems typically assume large numbers of homogeneous robots, other types of multirobot systems include heterogeneous robots. We therefore next discuss heterogeneity in cooperative robot teams in Sect. 40.5. Once robot teams allow for individual heterogeneity, issues of task allocation become important; Sect. 40.6 therefore discusses common approaches to task allocation. Section 40.7 discusses the challenges of multirobot learning, and some representative approaches. We outline some of the typical application domains which serve as test beds for multirobot systems research in Sect. 40.8. Finally, we conclude in Sect. 40.9 with some summary remarks and suggestions for further reading.

Researchers generally agree that multirobot systems have several advantages over single-robot systems [40.1, 2]. The most common motivations for developing multirobot system solutions are that:

1. the task complexity is too high for a single robot to accomplish;
2. the task is inherently distributed;
3. building several resource-bounded robots is much easier than having a single powerful robot;
4. multiple robots can solve problems faster using parallelism; and

5. the introduction of multiple robots increases robustness through redundancy.

The issues that must be addressed in developing multirobot solutions are dependent upon the task requirements and the sensory and effector capabilities of the available robots.

The types of robots considered in the study of multiple *mobile* robot systems are those robots that move around in the environment, such as ground vehicles, aerial vehicles, or underwater vehicles. This chapter focuses specifically on the interaction of multiple *mobile*

robots, as distinguished from other types of multirobot interaction. For example, a special case of multiple mobile robot systems are the *reconfigurable* or *modular* robots that interconnect with each other for the purposes of navigation or manipulation. This type of multirobot system is covered in detail in Chap. 39. *Networked* robotics, covered in Chap. 41, is also very closely re-

lated to multiple mobile robot systems; however, the focus in networked robotics is on systems of robots, sensors, embedded computers, and human users that are all connected by networked communication. Another variant of multirobot cooperation is multiple manipulator arm cooperation; Chap. 29 describes these systems in detail.

40.1 History

Since the earliest work on multiple mobile robot systems in the 1980s, the field has grown significantly, and covers a large body of research. At the most general level, approaches to multiple mobile robot systems fall into one of two broad categories: *collective swarm* systems and *intentionally cooperative* systems. *Collective swarm* systems are those in which robots execute their own tasks with only minimal need for knowledge about other robot team members. These systems are typified by the assumption of a large number of homogeneous mobile robots, in which robots make use of local control laws to generate globally coherent team behaviors, with little explicit communication among robots. On the other hand, robots in *intentionally cooperative* systems have knowledge of the presence of other robots in the environment and act together based on the state, actions, or capabilities of their teammates in order to accomplish the same goal. Intentionally cooperative systems vary in the extent to which robots take into account the actions or state of other robots, and can lead to either strongly or weakly cooperative solutions [40.3]. *Strongly cooperative* solutions require robots to act in concert to achieve the goal, executing tasks that are not trivially serializable. Typically, these approaches require some type of communication and synchronization among the robots. *Weakly cooperative* solutions allow robots to have periods of operational independence, subsequent to coordinating their selection of tasks or roles. Inten-

tionally cooperative multirobot systems can deal with heterogeneity in the robot team members, in which team members vary in their sensor and effector capabilities. In these teams, the coordination of robots can be very different from in collective swarm approaches, since robots are no longer interchangeable.

Most of the work specific to multiple mobile robot cooperation can be categorized into a set of key topics of study. These topics, which are the foci of this chapter, include *architectures*, *communication*, *swarm robots*, *heterogeneity*, *task allocation*, and *learning*. *Architectures* and *communication* in multirobot systems are relevant for all types of multirobot systems, as these approaches specify how the robot team members are organized and interact. *Swarm robots* is a particular type of multirobot system, typified by large numbers of homogeneous robots that interact implicitly with each other. Such systems are often contrasted with *heterogeneous* robots, in which team members may vary significantly in their capabilities. When robots vary in capabilities, challenges arise in determining which robots should perform which tasks – a challenge commonly referred to as *task allocation*. Finally *learning* in multirobot teams is of particular interest in designing teams that are adaptive over time and can learn new behaviors. Illustrating the advances in each of these areas often takes place in a set of representative application domains; these *applications* are the final major topic of discussion in this chapter.

40.2 Architectures for Multirobot Systems

The design of the overall control architecture for the multirobot team has a significant impact on the robustness and scalability of the system. Robot architectures for multirobot teams are composed of the same fundamental components as in single-robot systems, as described in Chap. 8. However, they also must address the inter-

action of robots and how the group behavior will be generated from the control architectures of the individual robots in the team. Several different philosophies for multirobot team architectures are possible; the most common are *centralized*, *hierarchical*, *decentralized*, and *hybrid*.

Centralized architectures that coordinate the entire team from a single point of control are theoretically possible [40.4], although often practically unrealistic due to their vulnerability to a single point of failure, and due to the difficulty of communicating the entire system state back to the central location at a frequency suitable for real-time control. Situations in which these approaches are relevant are cases in which the centralized controller has a clear vantage point from which to observe the robots, and can easily broadcast group messages for all robots to obey [40.5].

Hierarchical architectures are realistic for some applications. In this control approach, each robot oversees the actions of a relatively small group of other robots, each of which in turn oversees yet another group of robots, and so forth, down to the lowest robot, which simply executes its part of the task. This architecture scales much better than centralized approaches, and is reminiscent of military command and control. A point of weakness for the hierarchical control architecture is recovering from failures of robots high in the control tree.

Decentralized control architectures are the most common approach for multirobot teams, and typically require robots to take actions based only on knowledge local to their situation. This control approach can be highly robust to failure, since no robot is responsible for the control of any other robot. However, achieving global coherency in these systems can be difficult, because high-level goals have to be incorporated into the local control of each robot. If the goals change, it may be difficult to revise the behavior of individual robots.

Hybrid control architectures combine local control with higher-level control approaches to achieve both robustness and the ability to influence the entire team's actions through global goals, plans, or control. Many multirobot control approaches make use of hybrid architectures.

A plethora of multirobot control architectures have been developed over the years. We focus here on three approaches that illustrate the spectrum of control architectures. The first, the Nerd Herd, is representative of a pure *swarm* robotics approach using large numbers of homogeneous robots. The second, ALIANCE, is representative of a behavior-based approach that enables coordination and control of possibly heterogeneous robots without explicit coordination. The third, distributed robot architecture (DIRA), is a hybrid approach that enables both robot autonomy and explicit coordination in possibly heterogeneous robot teams.

40.2.1 The Nerd Herd

One of the first studies of social behaviors in multirobot teams was conducted by Mataric [40.6], with results being demonstrated on the Nerd Herd team of 20 identical robots (shown in Fig. 40.1). This work is an example of swarm robotic systems, as described further in Sect. 40.4. The decentralized control approach was based on the subsumption architecture (see Chap. 8), and assumed that all robots were homogeneous, but with relatively simple individual capabilities, such as detecting obstacles and *kin* (i.e., other robot team members). A set of basic social behaviors (see also Chap. 38) were defined and demonstrated, including obstacle avoidance, homing, aggregation, dispersion, following, and safe wandering. These basic behaviors were combined in various ways to yield more composite social behaviors, including flocking (composed of safe wandering, aggregation, and dispersion), surrounding (composed of safe wandering, following, and aggregation), herding (composed of safe wandering, surrounding, and flocking), and foraging (composed of safe wandering, dispersion, following, homing, and flocking). The behaviors were implemented as rules, such as the following rule for aggregate:

```
Aggregate:
  If agent is outside aggregation
    distance
    turn toward aggregation centroid
    and go.
  Else
    stop.
```

This work showed that collective behaviors could be generated through the combination of lower-level basic behaviors. Related work on this project studied

Fig. 40.1 The Nerd Herd robots

issues such as using bucket brigades to reduce interference [40.7], and learning [40.8].

40.2.2 The ALLIANCE Architecture

Another early work in multirobot team architectures is the ALLIANCE architecture (shown in Fig. 40.2), developed by Parker [40.9] for fault-tolerant task allocation in heterogeneous robot teams. This approach builds on the subsumption architecture by adding behavior sets and motivations for achieving action selection without explicit negotiations between robots. Behavior sets group low-level behaviors together for the execution of a particular task. The motivations consist of levels of impatience and acquiescence that can raise and lower a robot's interest in activating a behavior set corresponding to a task that must be accomplished.

In this approach, the initial motivation to perform a given behavior set is set to zero. Then, at each time step, the motivation level is recalculated based on

1. the previous motivation level
2. the rate of impatience
3. whether the sensory feedback indicates the behavior set is needed
4. whether the robot has another behavior set already activated
5. whether another robot has recently begun work on this task
6. whether the robot is willing to give up the task, based on how long it has been attempting the task

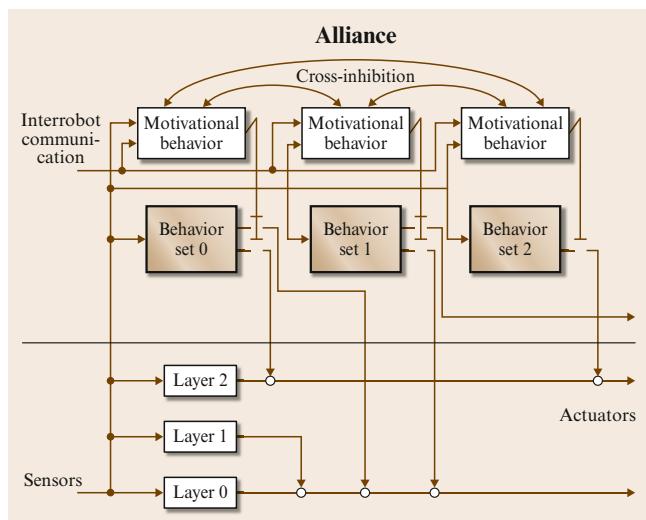

Fig. 40.2 The ALLIANCE architecture

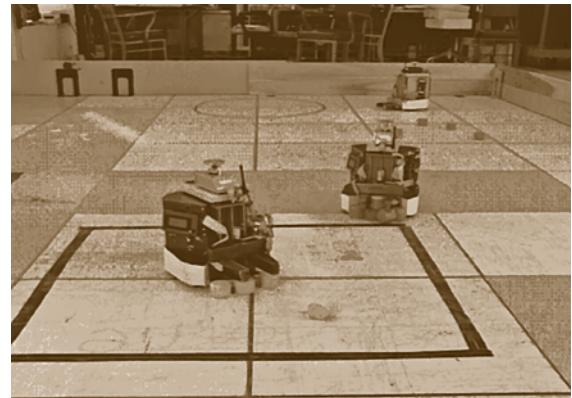

Fig. 40.3 Robots using the ALLIANCE architecture for a mock clean-up task

Effectively, the motivation continues to increase at some positive rate unless one of four situations occurs:

1. the sensory feedback indicates that the behavior set is no longer needed
2. another behavior set in the robot activates
3. some other robot has just taken over the task for the first time
4. the robot has decided to acquiesce the task

In any of these four situations, the motivation returns to zero. Otherwise, the motivation grows until it crosses a threshold value, at which time the behavior set is activated and the robot can be said to have selected an action. When an action is selected, cross-inhibition within that robot prevents other tasks from being activated within that same robot. When a behavior set is active in a robot, the robot broadcasts its current activity to other robots at a periodic rate.

The L-ALLIANCE extension [40.10] allows a robot to adapt the rate of change of the impatience and acquiescence values depending on the quality with which that robot is expected to accomplish a given task. The result is that robots that have demonstrated their ability to better accomplish certain tasks are more likely to choose those tasks in the future. Additionally, if problems occur during team performance, then robots may dynamically reallocate their tasks to compensate for the problems. This approach was demonstrated on a team of three heterogeneous robots performing a mock clean-up task, two robots performing a box-pushing task, and four robots performing a cooperative target observation problem. The approach has also been demonstrated in the simulation of a janitorial service task and a bound-

ing overwatch task. Figure 40.3 shows robots using ALLIANCE to perform the mock clean-up task.

40.2.3 The Distributed Robot Architecture

Simmons et al. [40.11] have developed a hybrid architecture called the distributed robot architecture (**DIRA**). Similar to the Nerd Herd and ALLIANCE approaches, the **DIRA** approach allows autonomy in individual robots. However, unlike the previous approaches, **DIRA** also facilitates explicit coordination among robots. This approach is based on layered architectures that are popular for single-robot systems (see Chap. 8). In this approach (shown in Fig. 40.4), each robot's control architecture consists of a *planning* layer that decides how to achieve high-level goals; an *executive* layer that synchronizes agents, sequences tasks, and monitors task execution; and a *behavioral* layer that interfaces to the robot's sensors and effectors. Each of these layers interacts with those above and below it. Additionally, robots can interact with each other via direct connections at each of the layers.

This architecture has been demonstrated in a team of three robots – a crane, a roving eye, and a mobile manipulator – performing a construction assembly task (see Fig. 40.5). This task requires the robots to work together to connect a beam at a given location. In these demonstrations, a *foreman* agent decides which robot should move the beam at which times. Initially, the crane moves the beam to the vicinity of the emplacement based on encoder feedback. The foreman then sets up a behavioral loop between the roving eye and the crane robot to servo the beam closer to the point of emplacement. Once the beam is close enough, the foreman tasks the

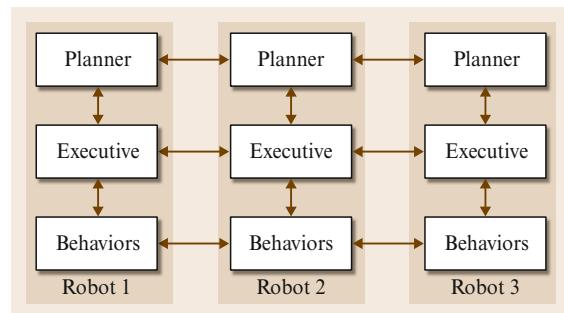

Fig. 40.4 The distributed robot architecture

Fig. 40.5 Robots using the distributed robot architecture for assembly tasks

roving eye and the mobile manipulator to servo the arm to grasp the beam. After contact is made, the foreman tasks the roving eye and the mobile manipulator to coordinate to servo the beam to the emplacement point, thus completing the task.

40.3 Communication

A fundamental assumption in multirobot systems research is that globally coherent and efficient solutions can be achieved through the interaction of robots lacking complete global information. However, achieving these globally coherent solutions typically requires robots to obtain information about their teammates' states or actions. This information can be obtained in a number of ways; the three most common techniques are

1. the use of implicit communication *through the world* (called *stigmergy*), in which robots sense the effects of teammate's actions through their effects on the world (e.g., [40.6, 12–16])

2. passive action recognition, in which robots use sensors to directly observe the actions of their teammates (e.g., [40.17])
3. explicit (intentional) communication, in which robots directly and intentionally communicate relevant information through some active means, such as radio (e.g., [40.9, 18–20])

Each of these mechanisms for exchanging information between robots has its own advantages and disadvantages [40.21]. *Stigmergy* is appealing because of its simplicity and its lack of dependence upon explicit communications channels and protocols. However, it is

limited by the extent to which a robot's perception of the world reflects the salient states of the mission the robot team must accomplish. *Passive action recognition* is appealing because it does not depend upon a limited-bandwidth, fallible communication mechanism. As with implicit cooperation, however, it is limited by the degree to which a robot can successfully interpret its sensory information, as well as the difficulty of analyzing the actions of robot team members. Finally, the *explicit communication* approach is appealing because of its directness and the ease with which robots can become aware of the actions and/or goals of its teammates. The major uses of explicit communication in multirobot teams are to synchronize actions, exchange information, and to negotiate between robots. Explicit communication is a way of dealing with the *hidden-state* problem [40.22], in which limited sensors cannot distinguish between different states of the world that are important for task performance. However, explicit communication is limited in terms of fault tolerance and reliability, because it typically depends upon a noisy, limited-bandwidth communications channel that may not continually connect all members of the robot team. Thus, approaches that make use of explicit communications must also provide mechanisms to handle communication failures and lost messages.

Selecting the appropriate use of communication in a multirobot team is a design choice dependent upon the tasks to be achieved by the multirobot team. One needs to carefully consider the costs and benefits of alternative communications approaches to determine the method that can reliably achieve the required level of system performance. Researchers generally agree that communication can have a strong positive impact on the performance of the team. One of the earliest illustrations of this impact was given in the work of MacLennan [40.23], which investigates the evolution of communication in simulated worlds and concludes that

the communication of local robot information can result in significant performance improvements. Interestingly, for many representative applications, researchers have found a nonlinear relationship between the amount of information communicated and its impact on the performance of the team. Typically, even a small amount of information can have a significant impact on the team, as found in the study of Balch and Arkin [40.24]. However, more information does not necessarily continue to improve performance, as it can quickly overload the communications bandwidth without providing an application benefit. The challenge in multirobot systems is to discover the *optimal* pieces of information to exchange that yield these performance improvements without saturating the communications bandwidth. Currently, no general approaches to identifying this critical information are available; thus, the decision of what to communicate is an application-specific question to be answered by the system designer. Dudek's taxonomy of multirobot systems [40.25] includes axes related to communication, including communication range, communication topology, and communication bandwidth. These characteristics can be used to compare and contrast multirobot systems.

Several related issues of active research in communications for multirobot teams deal with dynamic network connectivity and topologies; for example, robot teams must either be able to maintain communications connectivity as they move, or employ recovery strategies that allow the robot team to recover when the communications connectivity is broken. These concerns may require robots to adapt their actions in response to the anticipated effects on the communications network, or in response to knowledge of the anticipated propagation behavior of information through the dynamic network. These and related issues are discussed in some detail in the context of *networked robotics*; see Chap. 41 for more information.

40.4 Swarm Robots

Historically, some of the earliest work in multirobot systems [40.12, 13, 26–33] dealt with large numbers of homogeneous robots, called *swarms*. Still undergoing active study today, the swarm approaches obtain inspiration from biological societies – particularly ants, bees, and birds – to develop similar behaviors in multirobot teams. Because biological societies are able to accomplish impressive group capabilities, such as the

ability of termites to build large complex mounds, or the ability of ants to collectively carry large prey, robotics researchers aim to reproduce these capabilities in robot societies.

Swarm robotics systems are often called *collective robotics*, indicating that individual robots are often unaware of the actions of other robots in the system, other than information on proximity. These approaches aim

to achieve a desired team-level global behavior from the interaction dynamics of individual robots following relatively simple local control laws. Swarm robotic systems typically involve very little explicit communication between robots, and instead rely on stigmergy (i.e., communication through the world) to achieve emergent cooperation. Individual robots are assumed to have minimal capabilities, with little ability to solve meaningful tasks on their own. However, when grouped with other similar robots, they are collectively able to achieve team-level tasks. Ideally, the entire team should be able to achieve much more than individual robots working alone (i.e., it is *superadditive*, meaning that the whole is bigger than the sum of the parts). These systems assume very large numbers of robots (at least dozens, and often hundreds or thousands) and explicitly address issues of scalability. Swarm robotic approaches achieve high levels of redundancy because robots are assumed to be identical, and thus interchangeable with each other.

Many types of swarm behaviors have been studied, such as foraging, flocking, chaining, search, herding, aggregation, and containment. The majority of these swarm behaviors deal with spatially distributed multi-robot motions, requiring robots to coordinate motions either

1. relative to other robots
2. relative to the environment
3. relative to external agents

4. relative to robots and the environment
5. relative to all (i.e., other robots, external agents, and the environment)

Table 40.1 categorizes swarm robot behaviors according to these groupings, citing representative examples of relevant research.

Much of the current research in swarm robotics is aimed at developing specific solutions to one or more of the swarm behaviors listed in Table 40.1. Some of these swarm behaviors have received particular attention, notably formations, flocking, search, coverage, and foraging. Section 40.8 discusses these behaviors in more detail. In general, most current work in the development of swarm behaviors is aimed not just at demonstrating group motions that are similar to biological systems, but also at understanding the formal control theoretic principles that can predictably converge to the desired group behaviors, and remain in stable states.

Demonstration of physical robot swarms is both a hardware and a software challenge. As discussed in Sect. 40.2, the first demonstrations were by Matarić [40.6], involving about 20 physical robots performing aggregation, dispersion, and flocking. This work defined composable *basis behaviors* as primitives for structuring more complex systems (see Chap. 38 for more information). More recently, McLurkin [40.50] developed an extensive catalog of swarm behavior software, and demonstrated these behaviors on about 100 physical robots (called the

Table 40.1 Categories of swarm behaviors

| Relative motion requirements | Swarm behaviors |
|----------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Relative to other robots | Formations [40.34, 35], flocking [40.29], natural herding (as in herds of cattle), schooling, sorting [40.14], clumping [40.14], condensation, aggregation [40.36], dispersion [40.37] |
| Relative to the environment | Search [40.38], foraging [40.39], grazing, harvesting, deployment [40.40], coverage [40.41], localization [40.42], mapping [40.43], exploration [40.44] |
| Relative to external agents | Pursuit [40.45], predator-prey [40.46], target tracking [40.47], forced herding/shepherding (as in shepherding sheep) |
| Relative to other robots and the environment | Containment, orbiting, surrounding, perimeter search [40.48] |
| Relative to other robots, external agents, and the environment | Evasion, tactical overwatch, soccer [40.49] |

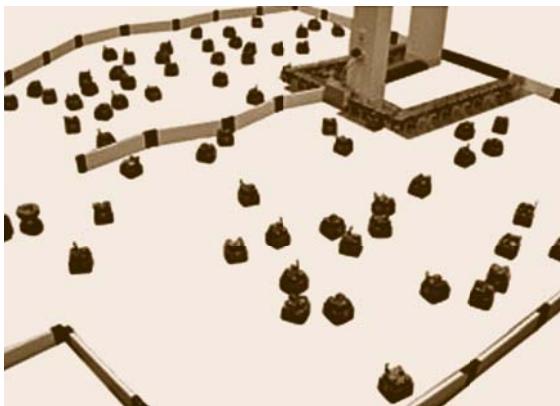

Fig. 40.6 The SwarmBot robots

SwarmBot robots), developed by iRobot, as shown in Fig. 40.6. He created several group behaviors, such as avoidManyRobots, disperseFromSource, disperseFromLeaves, disperseUniformly, computeAverageBearing, avoidManyRobots, followTheLeader, orbitGroup, navigateGradient, clusterOnSource, and clusterIntoGroups. A swarm of 108 robots used the developed dispersion algorithms in an empty schoolhouse of area of about 300 m^2 , and were able to locate an object of interest and lead a human to its location [40.37].

The European Union has sponsored several swarm robot projects, leading toward decreasingly smaller sized individual robots. The I-SWARM project, for instance, is aimed at developing millimeter-sized robots

with full onboard sensing, computation, and power for performing biologically inspired swarming behaviors, as well as collective perception tasks. This project is both a hardware and a software challenge, in that developing microscale robots that are fully autonomous and can perform meaningful cooperative behaviors will require significant advances in the current state of the art.

Another notable effort in swarm robotics research is the US multi-university SWARMS initiative led by the University of Pennsylvania. Research in this project is aimed at developing a new system-theoretic framework for swarming, developing models of swarms and swarming behavior, analyzing swarm formation, stability, and robustness, synthesizing emergent behaviors for active perception and coverage, and developing algorithms for distributed localization.

Besides the hardware challenges of dealing with large numbers of small robots, there are many important software challenges that remain to be solved. From a practical perspective, the usual approach to creating homogeneous multirobot swarms is to hypothesize a possible local control law (or laws), and then study the resulting group behavior, iterating until the desired global behavior is obtained. However, the longer-term objective is to be able to both predict group performance based on known local control laws, and to generate local control laws based upon a desired global group behavior. Active research by many investigators is ongoing to develop solutions to these key research challenges.

40.5 Heterogeneity

Robot heterogeneity can be defined in terms of variety in robot behavior, morphology, performance quality, size, and cognition. In most large-scale multirobot systems work, the benefits of parallelism, redundancy, and solutions distributed in space and time are obtained through the use of homogeneous robots, which are completely interchangeable (i.e., the swarm approach, as described in Sect. 40.4). However, certain complex applications of large-scale robot teams may require the simultaneous use of multiple types of sensors and robots, all of which cannot be designed into a single type of robot. Some robots may need to be scaled to smaller sizes, which will limit their payloads, or certain required sensors may be too expensive to duplicate across all robots on the team. Other robots may need to be large to carry application-specific

payload or sensors, or to navigate long distances in a limited time. These applications, therefore, require the collaboration of large numbers of heterogeneous robots.

The motivation for developing heterogeneity in multirobot teams is thus twofold: heterogeneity may be a design feature beneficial to particular applications, or heterogeneity may be a necessity. As a design feature, heterogeneity can offer economic benefits, since it can be easier to distribute varying capabilities across multiple team members rather than to build many copies of monolithic robots. Heterogeneity can also offer engineering benefits, as it may simply be too difficult to design individual robots that incorporate all of the sensing, computational, and effector requirements of a given application. Heterogeneity in behavior may also arise in

an emergent manner in physically homogeneous teams, as a result of behavior specialization.

A second compelling reason to study heterogeneity is that it may be a necessity, in that it is nearly impossible in practice to build a truly homogeneous robot team. The realities of individual robot design, construction, and experience will inevitably cause a multirobot system to drift to heterogeneity over time. This is recognized by experienced roboticists, who have seen that several copies of the same model of robot can vary widely in capabilities due to differences in sensor tuning, calibration, etc. Over time, even minor initial differences among robots will grow due to individual robot drift and wear and tear. The implication is that, to employ robot teams effectively, we must understand diversity, predict how it will impact performance, and enable robots to adapt to the diverse capabilities of their peers. In fact, it is often advantageous to build diversity explicitly into the design of a robot team.

There are a variety of research challenges in heterogeneous multirobot systems. A particular challenge to achieving efficient autonomous control is when overlap in team member capabilities occurs, thus affecting task allocation or role assignments [40.51]. Techniques as described in Sect. 40.6 can typically deal with heterogeneous robots for the purposes of task allocation. Another important topic in heterogeneity is how to recognize and quantify heterogeneity in multirobot teams. Some types of heterogeneity can be evaluated quantitatively, using metrics such as the social entropy metric developed by *Balch* [40.52]. Most research in heterogeneous multirobot systems assumes that robots have a common language and a common understanding of symbols in their language; developing a common understanding of communicated symbols among robots with different physical capabilities is a fundamental challenge, addressed by *Jung* in [40.53].

As discussed in Sect. 40.2, one of the earliest research demonstrations of heterogeneity in physical robot teams was in the development of the ALLIANCE architecture by *Parker* [40.9]. This work demonstrated the ability of robots to compensate for heterogeneity in team members during task allocation and execution. *Murphy* has studied heterogeneity in the context of marsupial robot deployment, where a *mothership* robot assists smaller robots in applications such as search and rescue [40.54]. *Grabowski* et al. [40.43] developed modular millibots for surveillance and reconnaissance that could be composed of interchangeable sensor and effector components, thus creating a variety of different heterogeneous teams. *Simmons* et al. [40.11]

Fig. 40.7 Heterogeneous team of an air and two ground vehicles that can perform cooperative reconnaissance and surveillance

demonstrated the use of heterogeneous robots for autonomous assembly and construction tasks relevant to space applications. *Sukhatme* et al. [40.55] demonstrated a helicopter robot cooperating with two ground robots in tasks involving marsupial-inspired payload deployment and recovery, cooperative localization, and reconnaissance and surveillance tasks, as shown in Fig. 40.7. *Parker* et al. [40.56] demonstrated assistive navigation for sensor network deployment using a more intelligent leader robot for guiding navigationally challenged simple sensor robots to goal locations, as part of a larger demonstration by *Howard* et al. [40.57] of 100 robots performing exploration, mapping, deployment, and detection. *Chaimowicz* et al. [40.58] demonstrated a team of aerial and ground robots cooperating for surveillance applications in urban environments. *Parker* and *Tang* [40.59] developed ASyMTRe (Automated Synthesis of Multirobot Task solutions through software Reconfiguration), which enables heterogeneous robots to share sensory resources to enable the team to accomplish tasks that would be impossible without tightly coupled sensor sharing.

Many open research issues remain to be solved in heterogeneous multirobot teams; for example, the issue of optimal team design is a very challenging problem. Clearly, the required behavioral performance in a given application dictates certain constraints on the physical design of the robot team members. However, it is also clear that multiple choices may be made in designing a solution to a given application, based upon cost, robot availability, ease of software design, flexibility in robot use, and so forth. Designing an optimal robot team for a given application requires significant analysis and consideration of the tradeoffs in alternative strategies.

40.6 Task Allocation

In many multirobot applications, the mission of the team is defined as a set of tasks that must be completed. Each task can usually be worked on by a variety of different robots; conversely, each robot can usually work on a variety of different tasks. In many applications, a task is decomposed into independent subtasks [40.9], hierarchical task trees [40.60], or roles [40.11, 58, 61, 62] either by a general autonomous planner or by the human designer. Independent subtasks or roles can be achieved concurrently, while subtasks in task trees are achieved according to their interdependence. Once the set of tasks or subtasks have been identified, the challenge is to determine the preferred mapping of robots to tasks (or subtasks). This is the *task allocation* problem.

The details of the task allocation problem can vary in many dimensions, such as the number of robots required per task, the number of tasks a robot can work on at a time, the coordination dependencies among tasks, and the time frame for which task assignments are determined. *Gerkey and Mataric* [40.63] defined a taxonomy for task allocation that provides a way of distinguishing task allocation problems along these dimensions, which is referred to as the multirobot task allocation (**MRTA**) taxonomy.

40.6.1 Taxonomy for Task Allocation

Generally, tasks are considered to be of two principal types: *single-robot tasks* (**SR**, according to the **MRTA** taxonomy) are those that require only one robot at a time, while *multirobot tasks* (**MR**) are those that require more than one robot working on the same task at the same time. Commonly, single-robot tasks that have minimal task interdependencies are referred to as *loosely coupled tasks*, representing a *weakly cooperative* solution. On the other hand, multirobot tasks are often considered to be sets of subtasks that have strong interdependencies. These tasks are therefore often referred to as *tightly coupled tasks* that require a *strongly cooperative* solution. The subtasks of a loosely coupled multirobot task require a high level of synchronization or coordination between subtasks, meaning that each task must be aware of the current state of the coordinated subtasks within a small time delay. As this time delay becomes progressively larger, coordinated subtasks become more loosely coupled, representing weakly cooperative solutions.

Robots can also be categorized as either *single-task robots* (**ST**), which work on only one task at a time or *multitask robots* (**MT**), which are able to make progress

on more than one task at a time. Most commonly, task allocation problems assume robots are single-task robots, since more capable robots that perform multiple tasks in parallel are still beyond the current state of the art.

Tasks can either be assigned to optimize the instantaneous allocation of tasks (**IA**), or to optimize the assignments into the future (**TA**, for time-extended assignment). In the case of instantaneous assignment, no consideration is made for the effect of the current assignment on future assignments. Time-extended assignments attempt to assign tasks so that the performance of the team is optimized for the entire set of tasks that may be required, not just the current set of tasks that need to be achieved at the current time step.

Using the **MTRA** taxonomy, triples of these abbreviations are used to categorize various task allocation approaches, such as **SR-ST-IA**, which refers to an assignment problem in which single-robot tasks are assigned once to single-task robots. Different variations of the task allocation problem have different computational complexities. The easiest variant is the **ST-SR-IA** problem, which can be solved in polynomial time since it is an instance of the optimal assignment problem [40.64]. Other variants are much more difficult, and do not have known polynomial time solutions. For example, the **ST-MR-IA** variant can be shown to be an instance of the set partitioning problem [40.65], which is strongly *NP-hard*. The **ST-MR-TA**, **MT-SR-IA**, and **MT-SR-TA** variants have also all been shown to be *NP-hard* problems. Because these problems are computationally complex, most approaches to task allocation in multirobot teams generate approximate solutions.

40.6.2 Representative Approaches

Approaches to task allocation in multirobot teams can be roughly divided into behavior-based approaches and market-based (sometimes called negotiation-style or auction-based) approaches. The following subsections describe some representative architectures for each of these general approaches. Refer to [40.63] for a comparative analysis of some of these approaches, in terms of computation and communications requirements and solution quality.

Behavior-Based Task Allocation

Behavior-based approaches typically enable robots to determine task assignments without explicitly discussing individual tasks. In these approaches, robots use

knowledge of the current state of the robot team mission, robot team member capabilities, and robot actions to decide, in a distributed fashion, which robot should perform which task.

One of the earliest architectures for multirobot task allocation that was demonstrated on physical robots was the behavior-based ALLIANCE architecture [40.9] and the related L-ALLIANCE architecture [40.10]. ALLIANCE addresses the ST-SR-IA and ST-SR-TA variants of the task allocation problem without explicit communication among robots about tasks. As described in Sect. 40.2.2, ALLIANCE achieves adaptive action selection through the use of motivational behaviors, which are levels of impatience and acquiescence within each robot that determine its own and its teammates' relative fitness for performing certain tasks. These motivations are calculated based upon the mission requirements, the activities and capabilities of teammates, and the robots' internal states. These motivations effectively calculate utility measures for each robot–task pair.

Another behavior-based approach to multirobot task allocation is broadcast of local eligibility (**BLE**) [40.66], which addresses the ST-SR-IA variant of task allocation. **BLE** uses a subsumption style behavior control architecture [40.67] that allows robots to efficiently execute tasks by continuously broadcasting locally computed eligibilities and only selecting the robot with the best eligibility to perform the task. In this case, task allocation is achieved through behavior inhibition. **BLE** uses an assignment algorithm that is very similar to *Botelho* and *Alami*'s M+ architecture [40.68].

Market-Based Task Allocation

Market-based (or negotiation-based) approaches typically involve explicit communications between robots about the required tasks, in which robots bid for tasks based on their capabilities and availability. The negotiation process is based on market theory, in which the team seeks to optimize an objective function based upon individual robot utilities for performing particular tasks. The approaches typically greedily assign subtasks to the robot that can perform the task with the highest utility.

Smith's contract net protocol (CNP) [40.69] was the first to address the problem of how agents can negotiate to collectively solve a set of tasks. The use of a market-based approach specifically for multirobot task allocation was first developed by *Botelho* and *Alami* with their M+ architecture [40.68]. In the M+ approach, robots plan their own individual plans for the task they have been assigned. They then negotiate with other teammates to incrementally adapt their actions to suit the

team as a whole, through the use of social rules that facilitate the merging of plans.

Since these early developments, many alternative approaches to market-based task allocation have been developed. A thorough survey on the current state of the art in market-based techniques for multirobot task allocation is given in [40.70], comparing alternative approaches in terms of solution quality, scalability, dynamic events and environments, and heterogeneous teams.

Most of the current approaches in market-based task allocation address the ST-SR problem variant, with some approaches (e.g., [40.11, 71–73]) dealing with instantaneous assignment (IA), and others (e.g., [40.44, 74–76]) addressing time-extended assignments (TA). More recent methods are beginning to address the allocation of multirobot tasks (i.e., the MR-ST problem variant), including [40.59, 77–81]. An example approach to the MR-MT problem variant is found in [40.82].

Some representative market-based techniques include MURDOCH [40.71], TraderBots [40.60, 76], and Hoplites [40.78]. The MURDOCH approach [40.71] employs a resource-centric, publish–subscribe communication model to carry out auctions, which has the advantage of anonymous communication. In this approach a task is represented by the required resources, such as the environmental sensors. The methods for how to use such a sensor to generate satisfactory results is preprogrammed into the robot.

The TraderBots approach [40.60, 76] applies market economy techniques for generating efficient and robust multirobot coordination in dynamic environments. In a market economy, robots act based on selfish interests. A robot receives revenue and incurs cost when trying to accomplish a task. The goal is for robots to trade tasks through auctions/negotiations such that the team profit (revenue minus cost) is optimized.

The Hoplites approach [40.78] focuses on the selection of an appropriate joint plan for the team to execute by incorporating joint revenue and cost into the bid. This approach couples planning with passive and active coordination strategies, enabling robots to change coordination strategies as the needs of the task change. Strategies are predefined for a robot to accomplish a selected plan.

Some alternative approaches formulate the objects to be assigned as *roles*, which typically package a set of tasks and/or behaviors that a robot should undertake when acting in a particular role. Roles can then be dynamically assigned to robots in a similar manner as in the auction-based approaches (e.g., [40.11, 61]).

40.7 Learning

Multirobot learning is the problem of learning new cooperative behaviors, or learning in the presence of other robots. The other robots in the environment, however, have their own goals and may be learning in parallel [40.83]. The challenge is that having other robots in the environment violates the Markov property that is a fundamental assumption of single-robot learning approaches [40.83]. The multirobot learning problem is particularly challenging because it combines the difficulties of single-robot learning with multiagent learning. Particular difficulties that must be considered in multirobot learning include continuous state and action spaces, exponential state spaces, distributed credit assignment, limited training time and insufficient training data, uncertainty in sensing and shared information, nondeterministic actions, difficulty in defining appropriate abstractions for learned information, and difficulty of merging information learned from different robot experiences.

The types of applications that have been studied for multirobot learning include multitarget observation [40.84, 85], air fleet control [40.86], predator-prey [40.46, 87, 88], box pushing [40.89], foraging [40.22], and multirobot soccer [40.49, 90]. Particularly challenging domains for multirobot learning are those tasks that are *inherently* cooperative. Inherently cooperative tasks are those that cannot be decomposed into independent subtasks to be solved by individual robots. Instead, the utility of the action of one robot is dependent upon the current actions of the other team members. This type of task is a particular challenge in multirobot learning, due to the difficulty of assigning credit for the individual actions of the robot team members.

The credit assignment problem is a particular challenge, since it is difficult for a robot to determine whether the fitness (either good or bad) is due to its own actions, or due to the actions of another robot. As discussed by *Pugh and Martinoli* in [40.91], this problem can be especially difficult in situations where robots do not explicitly share their intentions. Two different variations of the credit assignment problem are common in multirobot learning. The first is when robots are learning individual behaviors in the presence of other robots that can affect their performance. The second is when robots are attempting to learn a task with

a shared fitness function. It can be difficult to determine how to decompose the fitness function to appropriately reward or penalize the contributions of individual robots.

While learning has been explored extensively in the area of single-robot systems (see, for example, the discussion of learning in behavior-based systems in Chap. 38, and a discussion of fundamental learning techniques in Chap. 9) and in *multiagent* systems [40.92], much less work has been done in the area of *multirobot* learning, although the topic is gaining increased interest. Much of the work to date has focused on reinforcement learning approaches. Some examples of this multirobot learning research include the work by *Asada* et al. [40.93], who propose a method for learning new behaviors by coordinating previously learned behaviors using Q-learning, and apply it to soccer-playing robots. *Matarić* [40.8] introduces a method for combining basic behaviors into higher-level behaviors through the use of unsupervised reinforcement learning, heterogeneous reward functions, and progress estimators. This mechanism was applied to a team of robots learning to perform a foraging task. *Kubo* and *Kakazu* [40.94] proposed another reinforcement learning mechanism that uses a progress value for determining reinforcement, and applied it to simulated ant colonies competing for food. *Fernandez* et al. [40.84] apply a reinforcement learning algorithm that combines supervised function approximation with generalization methods based on state-space discretization, and apply it to robots learning the multiobject tracking problem. *Bowling* and *Veloso* [40.83] developed a general-purpose, scalable learning algorithm called GraWoLF (Gradient-based Win or Learn Fast), which combines gradient-based policy learning techniques with a variable learning rate, and demonstrated the results in the adversarial multirobot soccer application.

Other multirobot learning approaches not based on reinforcement include *Parker's* L-ALLIANCE architecture [40.10], which uses parameter tuning, based on statistical experience data, to learn the fitness of different heterogeneous robots in performing a set of tasks. *Pugh and Martinoli* [40.91] apply particle swarm optimization techniques to distributed unsupervised robot learning in groups, for the task of learning obstacle avoidance.

40.8 Applications

Many real-world applications can potentially benefit from the use of multiple mobile robot systems. Example applications include container management in ports [40.95], extraplanetary exploration [40.96], search and rescue [40.54], mineral mining, transportation, industrial and household maintenance, construction [40.11], hazardous waste cleanup [40.9], security [40.97, 98], agriculture, and warehouse management [40.99]. Multiple robot systems are also used in the domain of localization, mapping, and exploration; Chap. 37 mentions some of the work in multirobot systems applied to these problems. Part F of this Handbook outlines many application areas that are relevant not only to single-robot systems, but also to multiple mobile robot systems. To date, relatively few real-world implementations of these multirobot systems have occurred, primarily due to the complexities of multiple robot systems and the relative newness of the supporting technologies. Nevertheless, many proof-of-principle demonstrations of physical multirobot systems have been achieved, and the expectation is that these systems will find their way into practical implementations as the technology continues to mature.

Research in multiple mobile robot systems is often explored in the context of common application test domains. While not yet elevated to the level of benchmark tasks, these common domains do provide opportunities for researchers to compare and contrast alternative strategies to multirobot control. Additionally, even though these common test domains are usually just laboratory experiments, they do have relevance to real-world applications. This section outlines these common application domains; see also [40.2] and [40.100] for a discussion of these domains and a more detailed listing of related research.

40.8.1 Foraging and Coverage

Foraging is a popular testing application for multirobot systems, particularly for those approaches that address swarm robotics, involving very large numbers of mobile robots. In the foraging domain, objects such as pucks or simulated food pellets are distributed across the planar terrain, and robots are tasked with collecting the objects and delivering them to one or more gathering locations, such as a home base. Foraging lends itself to the study of weakly cooperative robot systems, in that the actions of individual robots do not

have to be tightly synchronized with each other. This task has traditionally been of interest in multirobot systems because of its close analogy to the biological systems that motivate swarm robotics research. However, it also has relevance to several real-world applications, such as toxic waste cleanup, search and rescue, and demining. Additionally, since foraging usually requires robots to completely explore their terrain in order to discover the objects of interest, the *coverage* domain has similar issues to the foraging application. In coverage, robots are required to visit all areas of their environment, perhaps searching for objects (such as landmines) or executing some action in all parts of the environment (e.g., for floor cleaning). The coverage application also has real-world relevance to tasks such as demining, lawn care, environmental mapping, and agriculture.

In foraging and coverage applications, a fundamental question is how to enable the robots to explore their environments quickly without duplicating actions or interfering with each other. Alternative strategies can include basic stigmergy [40.14], forming chains [40.28], and making use of heterogeneous robots [40.39]. Other research demonstrated in the foraging and/or coverage domain includes [40.22, 41, 101–106].

40.8.2 Flocking and Formations

Coordinating the motions of robots relative to each other has been a topic of interest in multiple mobile robot systems since the inception of the field. In particular, much attention has been paid to the flocking and formation control problems. The flocking problem could be viewed as a subcase of the formation control problem, requiring robots to move together along some path in the aggregate, but with only minimal requirements for paths taken by specific robots. Formations are stricter, requiring robots to maintain certain relative positions as they move through the environment. In these problems, robots are assumed to have only minimal sensing, computation, effector, and communications capabilities. A key question in both flocking and formation control research is determining the design of local control laws for each robot that generate the desired emergent collective behavior. Other issues include how robots cooperatively localize themselves to achieve formation control (e.g., [40.42, 107]), and how paths can be planned for permutation-invariant multirobot formations (e.g., [40.108]).

Early solutions to the flocking problem in artificial agents were generated by *Reynolds* [40.109] using a rule-based approach. Similar behavior- or rule-based approaches have been used physical robot demonstrations and studies, such as in [40.29, 110]. These earlier solutions were based on human-generated local control rules that were demonstrated to work in practice. More recent work is based on control theoretic principles, with a focus on proving stability and convergence properties in multirobot team behaviors. Examples of this work include [40.36, 111–119].

40.8.3 Box Pushing and Cooperative Manipulation

Box pushing and cooperative manipulation are popular domains for demonstrating multirobot cooperation, because they offer a clear domain where close coordination and cooperation is required. Box pushing requires robot teams to move boxes from their starting positions to defined goal configurations, sometimes along specified paths. Typically, box pushing operates in the plane, and the assumption is made that the boxes are too heavy or too long to enable single robots to push alone. Sometimes there are several boxes to be moved, with ordering dependencies constraining the sequence of motions. Cooperative manipulation is similar, except it requires robots to lift and carry objects to a destination. This test bed domain lends itself to the study of strongly cooperative multirobot strategies, since robots often have to synchronize their actions to successfully execute these tasks. The domain of box pushing and cooperative manipulation is also popular because it has relevance to several real-world applications [40.100], including warehouse stocking, truck loading and unloading, transporting large objects in industrial environments, and assembly of large-scale structures.

Researchers usually emphasize different aspects of their cooperative control approach in the box pushing and cooperative manipulation domain. For example, *Kube* and *Zhang* [40.13] demonstrate how swarm-type cooperative control techniques could achieve box pushing, *Parker* [40.10, 120] illustrates aspects of adaptive task allocation and learning, *Donald* et al. [40.121] illustrates concepts of information invariance and the interchangeability of sensing, communication, and control, and *Simmons* et al. [40.11] demonstrate the feasibility of cooperative control for building planetary habitats. A significant body of additional research has been illustrated in this domain; representative examples include [40.3, 6, 31, 71, 96, 122–130].

40.8.4 Multitarget Observation

The domain of multitarget observation requires multiple robots to monitor and/or observe multiple targets moving through the environment. The objective is to maximize the amount of time, or the likelihood, that the targets remain in view by some team member throughout task execution. The task can be especially challenging if there are more targets than robots. This application domain can be useful for studying strongly cooperative task solutions, since robots have to coordinate their motions or the switching of targets to follow in order to maximize their objective. In the context of multiple mobile robot applications, the planar version of this test bed was first introduced in [40.131] as cooperative multirobot observation of multiple moving targets (CMOMMT). Similar problems have been studied by several researchers, and extended to more complex problems such as environments with complex topography or three-dimensional versions for multiple aerial vehicle applications. This domain is also related to problems in other areas, such as art gallery algorithms, pursuit evasion, and sensor coverage. This domain has practical application in many security, surveillance, and reconnaissance problems. Research applied to the multitarget observation problem in multirobot systems includes [40.47, 66, 132–136].

40.8.5 Traffic Control and Multirobot Path Planning

When multiple robots are operating in a shared environment, they must coordinate their actions to prevent interference. These problems typically arise when the space in which robots operate contains bottlenecks, such as networks of roadways, or when the robots take up a relatively large portion of the navigable space. In these problems, the open space can be viewed as a resource that robots must share as efficiently as possible, avoiding collisions and deadlocks. In this domain, robots usually have their own individual goals, and must work with other robots to ensure that they receive use of the shared space to the extent needed to achieve their goals. In some variants, the entire paths of multiple robots need to be coordinated with each other; in other variants, robots must simply avoid interfering with each other.

A variety of techniques have been introduced to address this problem, including traffic rules, subdividing the environment into single-ownership sections, and geometric path planning. Many of the earliest research approaches to this problem were based on heuristic approaches, such as predefining motion control (or traffic)

rules that were shown to prevent deadlock [40.137–140], or using techniques similar to mutual exclusion in distributed computing [40.141, 142]. These approaches have the benefit of minimizing the planning cost for obtaining a solution. Other, more formal, techniques view the application as a geometric multirobot path planning problem that can be solved precisely in configuration space–time. Chapter 5 includes a discussion of motion planning for multiple robots relevant to this domain. While geometric motion planning approaches provide the most general solutions, they can often be too computationally intensive for practical application, impractical due to the dynamic nature of the environment, or simply unnecessary for the problem at hand. In these cases, heuristic approaches may be sufficient.

40.8.6 Soccer

Since the inception of the RoboCup multirobot soccer domain as a proposed challenge problem for studying coordination and control in multirobot systems [40.143], research in this domain has grown tremendously. This domain incorporates many challenging aspects of multirobot control, including collaboration, robot control architectures, strategy acquisition, real-time reasoning and action, sensor fusion, dealing with adversarial environments, cognitive modeling, and learning. Annual competitions show the ever-improving team capabilities of the robots in a variety of settings, as shown

Fig. 40.8 Legged robot teams competing in robot soccer

in Fig. 40.8. A key aspect of this domain that is not present in the other multirobot test domains is that robots must operate in *adversarial* environments. This domain is also popular because of its educational benefits, as it brings together students and researchers from across the world in competitions to win the RoboCup challenges. The RoboCup competitions have added an additional search-and-rescue category to the competition [40.144], which has also become a significant area of research (see Chap. 50 for more details on this field). Annual proceedings of the RoboCup competitions document much of the research that is incorporated into the multirobot soccer teams. Some representative research works include [40.145–149].

40.9 Conclusions and Further Reading

This chapter has surveyed the current state of the art in multirobot systems, examining architectures, communications issues, swarm robot systems, heterogeneous teams, task allocation, learning, and applications. Clearly, significant advances have been made in the field in the last decade. The field is still an active area of research, however, since many open research issues still remain to be solved. Key open research questions remain in the broad areas of system integration, robustness, learning, scalability, generalization, and dealing with heterogeneity.

For example, in the area of system *integration*, an open question is how to effectively allow robot teams to combine a spectrum of approaches toward achieving complete systems that can perform more than a limited set of tasks. In the area of *robustness*, multirobot teams still need improvements in the ability to degrade

gracefully, to reason for fault tolerance, and to achieve complexity without escalating failure rates. The area of *learning* in multirobot teams is still in its infancy, with open questions including how to achieve continual learning in multirobot teams, how to facilitate the use of complex representations, and how to enable humans to influence and/or understand the results of the team learning. *Scalability* is still a challenging problem, in terms of more complex environments as well as ever-larger numbers of robots. Open issues in *generalization* include enabling the robot team to reason about context and increasing the versatility of systems so that they can operate in a variety of different applications. In dealing with *heterogeneity*, open questions include determining theoretical approaches to predicting system performance when all robots are not equal, and determining how to design a robot team optimally for a given application.

These problems, and others, promise to keep the field of multiple mobile robot systems active for many years to come.

For further reading on the topic of multiple mobile robot systems, the reader is referred to survey articles in the field, including [40.2, 100, 150, 151]. Additionally, several special journal issues on this topic have

appeared, including [40.1, 152–154]. Some taxonomies of multirobot systems are given in [40.25, 100, 155]. A variety of symposia and workshops have been held on a regular basis on the topic of multirobot systems; recent proceedings of these workshops and symposia include [40.156–163]. An additional edited text on this topic is [40.164].
