Networked Robots

Vijay Kumar, Daniela Rus, Gaurav S. Sukhatme

This chapter discusses *networked robots*, multiple robots operating together coordinating and cooperating by *networked communication* to accomplish a specified task. This chapter presents an overview of the field with an emphasis on recent results and research challenges. Multiple robots enable new capabilities and the communication network enables new approaches and solutions that are difficult with just perception and control. Communication enables new control and perception capabilities in the system (e.g., access to information outside the perception range of the robot system). Conversely, control enables solutions for problems that are difficult without mobility (e.g., localization). Section 41.1 defines the field, examines the benefits of networking in robot coordination, and discusses applications. Section 41.2 highlights a few projects focused on networked robotics and discusses the application potential of the field. Section 41.3 discusses the research challenges at the intersection of control,

communication, and perception. Section 41.4 defines a model for the control of a networked system which is used in Sects. 41.5–41.8 to examine specific research issues and opportunities facilitated by the interplay between communication, control, and perception.

41.1 Overview

The term *networked robots* refers to multiple robots operating together coordinating and cooperating by *networked communication* to accomplish a specified task. Communication between entities is fundamental to cooperation (and coordination), hence there is a central role for the communication network in networked robots. Networked robots may also involve coordination and cooperation with stationary sensors, embedded computers, and human users. The central feature of networked robots is the ability of the system to perform tasks that are well beyond the abilities of a single robot or multiple uncoordinated robots.

The IEEE technical committee on networked robots has adopted the following definition of a networked robot:

A networked robot is a robotic device connected to a communications network such as the Internet or local-area network (LAN). The network could be wired or wireless, and based on any of a variety of protocols such as the transmission control protocol (TCP), the user datagram protocol (UDP), or 802.11. Many new applications are now being developed ranging from automation to exploration. There are two subclasses of networked robots:

1. Teleoperated, where human supervisors send commands and receive feedback via the network. Such systems support research, education, and public awareness by making valuable resources accessible to broad audiences.

- Autonomous, where robots and sensors exchange data via the network. In such systems, the sensor network extends the effective sensing range of the robots, allowing them to communicate with each other over long distances to coordinate their activity. Sensing, actuation, and computation need no longer be collocated. A broad challenge is to develop a science base that couples communication, perception, and control to enable such new capabilities.

This definition of autonomous networked robots also includes a third class of distributed systems, mobile sensor networks, which is a natural evolution of sensor networks. Robot networks allow robots to measure spatially and temporally distributed phenomena more efficiently. The robots in turn can deploy, repair, and maintain the sensor network to increase its longevity, and utility. The focus of this chapter is *autonomous networked robots*.

Embedded computers and sensors are becoming ubiquitous in homes and factories, and increasingly wireless ad hoc networks or plug-and-play wired networks are becoming commonplace. Human users interact with embedded computers and sensors to perform tasks ranging from monitoring (e.g., supervising the operation of a factory and surveillance in a building) to control (e.g., running an assembly line consisting of sensors, actuators, and material-handling equipment). In most of these cases, the human users, embedded comput-

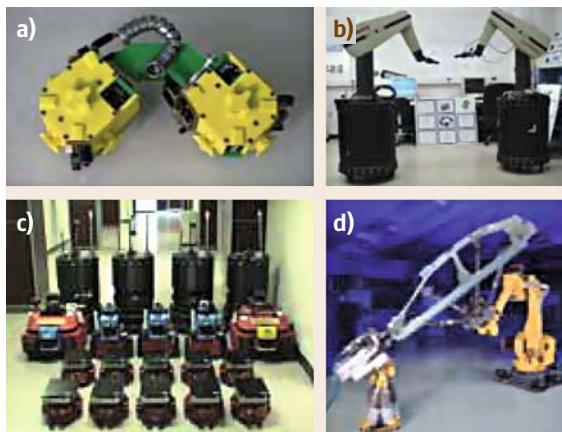

Fig. 41.1a–d Small modules [41.1] can automatically connect and communicate information to perform locomotion tasks (a); robot arms [41.2] on mobile bases can cooperate to perform household chores (b); swarms of robots [41.3] can be used to explore an unknown environment (c); and industrial robots can cooperate in welding operations (d)

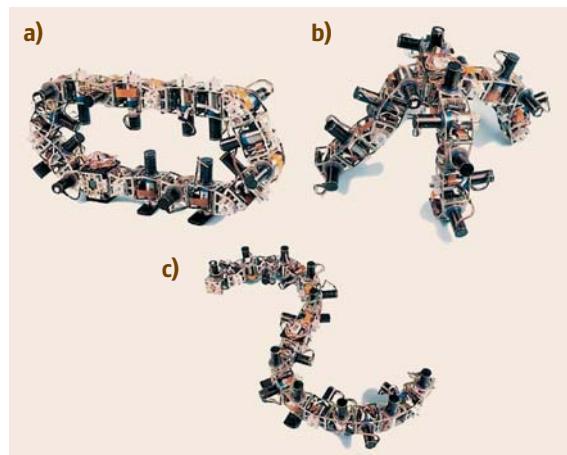

Fig. 41.2a–c Robotic modules [41.4] can be reconfigured to morph into different locomotion systems including a wheel-like rolling system (a), a snake-like undulatory locomotion system (b), a four-legged walking system (c)

ers, and sensors are not collocated and the coordination and communication happens through a network. *Networked robots* extends this vision to multiple robots functioning in a wide range of environments performing tasks that require them to coordinate with other robots, cooperate with humans, and act on information derived from multiple sensors.

Figure 41.1 shows prototype concepts derived from academic laboratories and industry. In all these examples, independent robot or robotic modules can cooperate to perform tasks that a single robot (or module) cannot perform. Robots can automatically couple to perform locomotion tasks (also see Fig. 41.2) and manipulation tasks that either a single robot cannot perform, or that would require a special-purpose larger robot to perform. They can also coordinate to perform search and reconnaissance tasks exploiting the efficiency that is inherent in parallelism. They can also perform independent tasks that need to be coordinated. Examples in the manufacturing industry include, for example, fixturing and welding.

Besides being able to perform tasks that individual robots cannot perform, networked robots also result in improved efficiency. Networking gives each robot access to information outside its perception range. Tasks such as searching or mapping can, in principle, be performed faster with an increase in the number of robots. A speed up in manufacturing operations can be achieved by deploying multiple robots performing operations in parallel but in a coordinated fashion.

Another advantage of using the network to connect robots is the ability to connect and harness physically removed assets. Mobile robots can react to information sensed by other mobile robots at a remote location. Industrial robots can adapt their end-effectors to new parts being manufactured upstream in the assembly line. Human users can use machines that are remotely located via the network.

The ability to network robots also enables fault tolerance in design. If robots can dynamically reconfigure themselves using the network, they are more tolerant to robot failures. This is seen in the Internet where multiple gateways, routers, and computers provide for a fault-tolerant system (although the Internet is not robust in other ways). Similarly, robots that can *plug* and *play* can be swapped in and out automatically to provide for a robust operating environment.

Finally, networked robots have the potential to provide great synergy by bringing together components

with complementary benefits and making the whole greater than the sum of the parts.

Applications for networked robots abound. The US military routinely deploys unmanned vehicles that are reprogrammed remotely based on intelligence gathered by other unmanned vehicles, sometimes automatically. The deployment of satellites in space, often by astronauts in a shuttle with the shuttle robot arm requires the coordination of complex instrumentation onboard the space shuttle, human operators on a ground station, the shuttle arm, and a human user on the shuttle. Home appliances now contain sensors and are becoming networked. As domestic and personal robots become more commonplace, it is natural to see these robots working with sensors and appliances in the house while cooperating with one or more human users. Networked robots will likely be used as critical ingredients in the environmental observatories of the future. Large-scale ecological monitoring precludes the use of monolithic infrastructure, and is envisioned to be built as a distributed, networked robotic system.

41.2 State of the Art and Potential

The Network Robot Forum established in Japan in 2003 [41.5] estimates that the size of the networked robot industry will be over \$200B by 2013, much larger than the industrial robot market for manufacturing applications. This growth is broad-based, across many industries. There is a strong connection between this industry and the industry connected to sensor networks. Sensor networks have been projected to grow dramatically in terms of commercialization and market value [41.6]. Robot networks are analogous to sensor networks except that they allow sensors to have mobility and allow the geographical distribution of the sensors to be adapted based on the information acquired.

A system of robots, embedded computers, actuators, and sensors has tremendous potential in civilian, defense, and manufacturing applications. Nature provides the proof of concept of what is possible [41.7]. Group behaviors in nature can be found in organisms that are only microns to those that are several meters in length. There are numerous examples of simple animals that execute simple behaviors with modest sensors and actuators but communicate with and sense nearest neighbors to enable complex emergent behaviors that are fundamental to navigation, foraging, hunting, constructing nests, survival, and eventually growth. As seen

in Fig. 41.3, relatively small agents are able to manipulate objects that are significantly larger in terms of size and payload by cooperating with fairly simple individual behaviors. The coordination between agents is completely decentralized, allowing scaling up to large numbers of robots and large objects [41.8]. Individuals do not recognize each other. In other words, there is no labeling or identification of robots. The number

Fig. 41.3 Ants are able to cooperatively manipulate and transport objects often in large groups, without identified or labeled neighbors, and without centralized coordination

of agents in the team is not explicitly encoded. Agents are identical, enabling robustness to failures and modularity. There is minimal communication, and even that which is present is only between neighbors. Furthermore, the optimal mode of group coordination may be scale dependent. Studies of wasps show strong evidence of centralized coordination among species with small colony sizes, but a distributed, decentralized coordination in larger colonies [41.9]. All these attributes are relevant to networked robots.

Biology has shown how simple decentralized behaviors in unidentified individuals (e.g., insects and birds exhibiting swarming behaviors) can exhibit a wide array of seemingly intelligent group behaviors. Similarly networked robots can potentially communicate and cooperate with each other, and even though individual robots may not be sophisticated, it is possible for networked robots to provide a range of intelligent behaviors that are beyond the scope of intelligent robots.

The significance and potential impact of networked robots is apparent from the following examples.

The manufacturing industry has always relied on integration between sensors, actuators, material-handling equipment, and robots. Today companies are finding it easier to reconfigure existing infrastructure by networking new robots and sensors with existing robots via wireless networks. There is also an increasing trend toward robots interacting with each other in operations like welding and machining, and robots cooperating with humans in assembly and material-handling tasks. Work-cells consist of multiple robots, numerous sensors and controllers, automated guided vehicles, and one or two human operators working in a supervisory role. However, in most of these cells, the networked robots operate in a structured environment with very little variation in configuration and/or operating conditions.

There is a growing emphasis on networking robots in applications of field robotics, for example, in the mining industry. Like the manufacturing industry, operating conditions are often unpleasant and the tasks are repetitive. However, these applications are less structured and human operators play a more important role.

In the health care industry, networks allow health care professionals to interact with their patients, other professionals, expensive diagnostic instruments, and in the future surgical robots. Telemedicine is expected to provide a major growth impetus for remote networked robotic devices that will take the place of today's stand-alone medical devices.

There are already many commercial products, notably in Japan, where robots can be programmed via

and communicate with cellular phones. For example, the MARON robot developed by Fujitsu lets a human user dial up their robot and instruct it to conduct simple tasks including sending pictures back to the user via a cellular phone. Indeed these robots will interact with other sensors and actuators in the home – door openers equipped with Bluetooth cards and actuators and computer-controlled lighting, microwaves, and dishwashers. Indeed the Network Robot Forum [41.5] is already setting standards for how stationary sensors and actuators can interact with other robots in domestic and commercial settings.

Environmental monitoring is a key application for networked robots. By exploiting mobility and communication, robotic infrastructure enables observation and data collection at unprecedented scales in various aspects of ecological monitoring. This is significant for environmental regulatory policies (e.g., clean air and water legislation), as well as an enabler of new scientific discovery, for example, it is possible to obtain maps of salinity gradients in oceans, temperature and humidity variations in forests, the and chemical composition of air and water in different ecological systems [41.10]. In addition to mobile sensor networks, it is also possible to use robots to deploy sensors and to retrieve information from the sensors. Mobile platforms allow the same sensor to collect data from multiple locations while communication allows the coordinated control and aggregation of information. Examples include systems built for aquatic [41.11], terrestrial [41.12], and subsoil monitoring [41.13]. There are many efforts to developed networked underwater platforms [41.14–16]. Networks of static and robotic devices have been developed for aquatic monitoring [41.11] and to obtain high-resolution information on the spatial and temporal distributions of plankton assemblages and concomitant environmental parameters. The RiverNet project [41.17] at Rensselaer Polytechnic Institute ([RPI](#)) has focused on the development of robotic sensor networks for monitoring a river ecosystem. Recent work at University of California, Los Angeles (UCLA), University of Southern California (USC), University of California, Riverside, and University of California, Merced on the networked infomechanical system project [41.12] has focused on the development of robotic networks for monitoring the forest canopy, with a view to providing data for modeling canopy and undercover growth. Networked robotic mini-rhizotrons [41.13] are being deployed in the forest to monitor root growth in the soil.

In the defense industry, countries like the USA have invested heavily in the concept of networked, geo-

graphically distributed assets. Unmanned aerial vehicles like the Predators are operated remotely. Information from sensors on the Predators triggers the deployment of other vehicles and weapon systems at a different remote location and allows commanders in a third location to control and command all these assets. The US military is engaged in the large Future Combat Systems initiative to develop network-centric approaches to deploying autonomous vehicles. The network-centric tactical paradigms for modern warfare have created networked robots for defense and homeland security. While networked robots are already in operation, current approaches are limited to human users commanding a single vehicle or sensor system. However, it takes many human operators (between 2–10 depending on the complexity of the system) to deploy complex systems like unmanned aerial vehicles. A Predator unmanned aerial vehicle (UAV) is operated from a tactical control station, which may be on an aircraft carrier, with a basic crew of 3–10 operators.

The eventual goal, however, is to enable a single human user to deploy networks of unmanned aerial, ground, surface, and underwater vehicles. There have been several recent demonstrations of multirobot systems exploring urban environments [41.20, 21] and the interiors of buildings [41.19, 22] to detect and track intruders, and transmit all of the above information to a remote operator. These examples show that it is possible to deploy networked robots using an off-the-shelf 802.11b wireless network and have the team be remotely tasked and monitored by a single operator. An example of a project with heterogeneous vehicles in an urban setting is shown in Fig. 41.4. An example of a project with heterogeneous vehicles in an indoor setting is shown in Fig. 41.5 wherein robots map an environment and deploy themselves to form a sensor network to detect intruders.

Many research projects are addressing group behaviors or collective intelligence by realizing swarming behaviors observed in nature. For example, the European Union (EU) has several EU-wide coordinated projects on collective intelligence or swarm intelligence. The I-Swarm project in Karlsruhe [41.23] and the Swarm-Bot project at Ecole Polytechnique Fédérale

Fig. 41.4 A single operator commanding a network of aerial and ground vehicles from a command and control vehicle in an urban environment for scouting and reconnaissance in a recent demonstration by the University of Pennsylvania, Georgia Tech. and University of Southern California [41.18]

Fig. 41.5 Under the DARPA SDR program, a team from the University of Southern California, the University of Tennessee, and Science Applications and International Corporation (SAIC) demonstrated mapping, and intruder detection by a team of networked robots [41.19]

de Lausanne (EPFL) [41.24] are examples of swarm intelligence. The Laboratory for Analysis and Architecture of Systems (LAAS) has a strong group in robotics and artificial intelligence. This group has had a long history of basic and applied research in multirobot systems. The integration of multiple unmanned vehicles for applications such as terrain mapping and fire-fighting is addressed in [41.25]. A recent multi-university US project addresses the development of networked vehicles for swarming behaviors [41.26]. Projects such as these are exploring the scalability of the basic concepts to large numbers of robots, sensors, and actuators.

41.3 Research Challenges

While there are many successful embodiments of networked robots with applications to manufacturing industry, the defense industry, space exploration,

domestic assistance, and civilian infrastructure, there are significant challenges that have to be overcome.

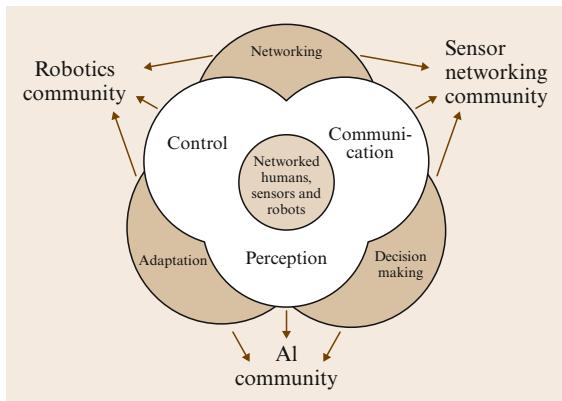

Fig. 41.6 The paradigm of *networked robots* introduces fundamental challenges at the intersection of control, perception, and communication that is of interest to the robotics, sensor networks, and artificial intelligence communities

The problem of coordinating multiple autonomous units and making them cooperate creates problems at the intersection of communication, control, and perception. Who should talk to who and what information should be conveyed, and how? How does each unit move in order to accomplish the task? How should the team members acquire information? How should the team aggregate information? These are all basic questions that need basic advances in control theory, perception, and networking. In addition, because humans are part of the network (as in the case of the Internet), we have to devise an effective way for multiple humans to be embedded in the network and command/control/monitor the network without worrying about the specificity of individual robots in the network. Thus the underlying research challenges lie at the intersection of control theory, perception, and communication/networks, as shown in Fig. 41.6.

It is also worth noting that robot networks are dynamic unlike networks of sensors, computers or machines which might be networked together in a fixed topology. When a robot moves, its neighbors change and its relationship to the environment changes. As a consequence, the information it acquires and the actions it executes must change. Not only is the network topology dynamic, but the robot's behavior also changes as the topology changes. It is very difficult to predict the performance of such dynamic robot networks, yet it is this analysis problem that designers of robot networks must solve before deploying the network.

This notion of a changing topology inevitably leads us to complicated mathematical models. Tradi-

tionally, models of group behavior have been built on continuous models of dynamics of individuals, including local interactions with neighbors, and models of control and sensing with a fixed set of neighbors. While dynamics at the level of individual units may be adequately described by differential equations, the interactions with neighbors are best described by edges on a graph. Modeling, analysis, and control of such systems will require a comprehensive theoretical framework and new representational tools. New mathematical tools that marry dynamical system theory, switched systems, discrete mathematics, graph theory, and computational geometry are needed to solve the underlying problems. We need a design methodology for solving the *inverse problem in navigation* – behaviors for controlling individuals to achieve a specified aggregate *motion* and *shape* of the group, and the application to active perception and coverage. An overview of some of these methods is provided in Sect. 41.4.

Problems of perception have been studied extensively in the robotics community. However, the perception problems in a system of networked, mobile sensor platforms bring a new set of challenges; for example, consider the problem of estimating the state of the network. State estimation requires the estimation of the state of robots and the environment based on local, limited-range sensory information. Localization of n vehicles in an m -dimensional configuration space requires $O((nm)^k)$ computations, where k is somewhere between 3 and 6, depending on the algorithm and domain-specific assumptions. The estimation problem is further exacerbated by the fact that not all robots in the network may be able to get the necessary information in a time-critical fashion. There are deep issues of representation and algorithmic development, which are discussed in Sect. 41.6.

The paradigm of active perception [41.27] links the control of sensor platforms to perception, bringing control theory and perception together in a common framework. Extending this paradigm to networked robots requires approaches of distributed control to be merged with decentralized estimation. Robots can move in order to localize themselves with respect to their neighbors, to localize their neighbors, and also to identify, localize, and track features in the environment. These problems are discussed in Sect. 41.7.

As discussed earlier, the communication network is central to the functioning of a network of robots. However, if the network consists of mobile agents with transmitters and receivers with finite power, there is no

guarantee that all agents can talk to teach other. Unlike a static sensor network, robots in a network can move toward each other to facilitate communication and adaptively maintain a communication network. Some basic algorithmic problems and several pertinent results are provided in Sect. 41.8.

41.4 Control

The control of individual robots is critical to the performance and scope of robot networks. Indeed motion coordination algorithms have been proposed for the purpose of improving communication performance [41.28, 29], localization [41.30, 31], information integration, deployment [41.32], and coverage [41.33–35], among other tasks. Mobility allows the group of robots to self-deploy, and self-organize by relocating themselves in support of communication, sensing, or task needs; for example, they can reconfigure to guarantee a desired communication bandwidth, k -hop connectivity, or algebraic connectivity, enabling message delivery from one robot to another. The group can also self-organize to position sensors so as to cover a desired area and adapt to shifts in the focus of monitoring activities. Controlling sensor position also supports map making, tracking of objects and events, and goal-directed navigation for users of the network. Finally, mobility allows robots to accomplish tasks such as navigation, reconnaissance, transportation, and search and rescue.

Given a group of mobile sensors, we would like to have distributed control capabilities that realize desirable global specifications. Thus, it is necessary to be able to automatically determine the necessary position and orientation of the group members and/or the distribution of group members, and their motion to achieve the desired task. At a lower level, the robots must be able to use information from the communication network and from their own sensors to derive local estimates, reason about the spatial network (their neighbors and their relationship to the environment), and then use the appropriate control policies to achieve the desired group specifications. We briefly outline the simplest mathematical model that is necessary to formulate such problems in order to provide a better sense of the underlying challenges.

In a robot network, we have multiple agents or nodes in which each agent is a physical entity that can be a robot, a vehicle with actuators and sensors, a sensor platform (possibly static) or even a communication relay node. Each agent A_i is characterized by an identifier, $i \in I \subset Z$, a state $x_i \in X_i \subset \mathbb{R}^n$, and control inputs $u_i \in U_i \subset \mathbb{R}$, with $f_i : X_i \times U_i \rightarrow TX_i$ specifying the dynamics:

$$\dot{x}_i = f_i(x_i, u_i). \quad (41.1)$$

The state x_i will consist of the position (and orientation), r_i in some d -dimensional space, and its velocity, $\dot{r}_i : x_i = (r_i^T, \dot{r}_i^T)^T$, with $n = 2d$. $\mathcal{N}^c(r_i)$ and $\mathcal{N}^s(r_i)$ are neighborhoods of r that define the range and field of view of the communication hardware and sensors, respectively.

A network of robots S consists of N agents with a *sensing graph* and a *communications graph* that is defined by the physical distribution of the agents. The sensing graph (and similarly the communications graph) is defined by a map $E^s : X^1 \times X^2 \dots X^N \rightarrow I \times I$, where the edges of the graph are formed dynamically depending on the physical proximity of pairs of agents. Specifically, the $N \times N$ adjacency matrix, \mathcal{A}^s (and similarly \mathcal{A}^c) has entries

$$\mathcal{A}_{ij}^s = \begin{cases} 1, & \text{if } r_j \in \mathcal{N}^s(r_i), \\ 0, & \text{otherwise.} \end{cases} \quad (41.2)$$

Agent A_i has estimates of its own state and the states of neighbors (e.g., A_j), and these estimates are derived from information associated with edges in the sensing and communication graph

$$\hat{x}_j^{(i)} = h(x_i, z_{ij}), \quad (41.3)$$

where z_{ij} represents measurements of the state of agent A_j available to A_i by sensing or communication channels and h is the estimator used by A_i . Note that z_{ij} may have dimension less than n and may therefore not contain complete information about $x_{ij} = x_i - x_j$. Clearly the relative position vector denoted by $r_{ij} = r_i - r_j$ and its magnitude are important quantities that may need to be estimated for biological and artificial agents.

Finally, A_i can encode n_{b_i} behaviors, which we will denote by $\mathcal{B}_i = B_1, B_2, \dots, B_{n_{b_i}}$. Each behavior B_j is a controller, a function $k_j : \mathbb{R} \times X_i \rightarrow U_i$. All agents can be assigned identical or different behaviors. Each behavior represents a set of unsynchronized, locally executed computations (for control or estimation) being carried out for some collective purpose, with each processor using in its computations only data from its *neighboring*

processors. Furthermore, even for a fixed assignment of behaviors, each processor's neighbors typically *change* with time because the processors are moving in and out of the sets \mathcal{N}^c and \mathcal{N}^s . Thus the methodology for modeling and analyzing such systems will require the merging of graph theory and dynamical system theory at a fundamental level.

The reader is directed to the many survey articles on this subject for further information. An overview

of challenges for the controls community is presented in [41.36]. The underlying theory for networked mobile systems has been explored in the context of automated highway systems [41.37], cooperative robot reconnaissance [41.19] and manipulation [41.38], formation flight control [41.39], and the control of groups of unmanned vehicles [41.21]. Our goal in the following sections is to explore the connections between communication, perception, and control.

41.5 Communication for Control

Communication networks allow physically disconnected entities to exchange information. At the lowest level, when groups of vehicles coordinate their actions, communication allows vehicles to exchange state information [41.40–42]. At a higher level, robots can plan navigation and exploration tasks based on an integrated map of the world derived from information acquired from different robots [41.43].

The use of communication for control in the multivehicle context has been addressed in the PATH project where formations of inline vehicles were studied [41.37]. Problems of the stability of the formation [41.44], the convergence of the formation to shapes [41.45], and the overall performance of the system [41.46] are of great interest. The performance of the system is directly influenced by the interconnections between agents. In addition to impacting on stability [41.37], feedback of states from different agents and feedforward information from the plans of different agents affects the rates at which the system of agents can respond to external stimuli [41.46] or to commands from human operators [41.47].

In addition, communication can be used for high-level control and planning of robots. There is great interest in using static sensor nodes as beacons to guide robot navigation. In [41.48], the problem of coverage and exploration of an unknown dynamic environment using a mobile robot is considered. An algorithm is presented which assumes that global information is not available [neither a map, nor global positioning system (**GPS**) information]. The algorithm deploys a network of radio beacons that assists the robot in coverage. The network is also used by the robot for navigation. The deployed network can also be used for applications other than coverage (such as multirobot task allocation). A similar idea was presented using potential-field-based

navigation in [41.43]. In this work the notion of no-go or danger areas was incorporated into the navigation cost function. Recent work along these lines with experimental data from sensor nodes is reported in [41.49].

In such communication-enabled cooperative control and planning (see also [41.50]), the communication network plays an important role in the creation of a shared representation of information. This notion of a shared representation is important to the scaling of coordinated control algorithms to large numbers of devices. For example, in [41.41], the information form of the Kalman filter is used to derive a framework for decentralizing estimation and fusion algorithms. This approach was shown to be applicable to multiple heterogenous ground and aerial platforms [41.30]. Such methodologies are transparent to the specificity and identity of the cooperating vehicles. This is because vehicles share a common representation, which consists of a certainty grid that contains information about the probability of detection of targets, and an information vector–matrix pair that is used in the information form of the Kalman filter [41.21]. Observations are propagated through the network by changing both the certainty grid and the information vector/matrix. This allows each vehicle to choose the action that maximizes a utility function, which is the combined mutual information gain from onboard sensors towards the detection and localization of features in the environment.

Thus, in summary, at the lowest level, communication enables either partial or complete state feedback of the network and allows agents to exchange information for feedforward control. At the higher levels, agents can share information for planning and for control. This is also discussed in Sect. 41.6 where the communication network is shown to enable a network-centric approach to perception.

41.6 Communication for Perception

While individual robots have sensors and the ability to build maps and models by integrating sensory information, networked robots can exchange information and leverage sensory data, maps, and models from other robots. The challenge is to exploit communication for perception in tasks such as distributed mapping in the presence of the delays, limited bandwidth, and disruption that are typical of communication networks.

Distributed localization is the term used to describe the merging of communication and perception for state estimation. Localization is an essential tool for the development of low-cost robot networks for use in location-aware applications and ubiquitous networking [41.51]. Location information is needed to track the placement of the nodes and to correlate the values measured by the node with their physical location. Distributed computation and robustness in the presence of measurement noise are key ingredients for a practical localization algorithm that will give reliable results over a large-scale network.

The methods for distributed localization can be classified into two broad classes: algorithms that rely on anchor nodes for localization and algorithms that use no beacons. Localization may be computed using range information between nodes, bearing information, or both.

In [41.28] a theoretical foundation for network localization in terms of graph rigidity theory is provided. The problem is solved when nodes have perfect range information and it is shown that a network has a unique localization if and only if its underlying graph is *generically globally rigid*. In [41.52] the Cramér–Rao lower bound (**CRLB**) for network localization is derived. This work computes the expected error characteristics for an ideal algorithm, and compares this to the actual error in an algorithm based on multilateration, drawing the important conclusion that the error introduced by the algorithm is just as important as the measurement error in assessing end-to-end localization accuracy. In [41.53] a distributed algorithm that uses no beacons and is guaranteed to compute correct location information under measurement noise for nodes that can range to neighbors is presented. This algorithm relies on the notion of robust quadrilaterals to compute robustly a global system of coordinates among the nodes. The computation supports moving nodes. Extensions of this work to passive tracking have been discussed in [41.54]. Localization based on the propagation of location information

from known reference nodes based on connectivity includes [41.55, 56]. Mobility-assisted localization is introduced in [41.57]. Other techniques use distributed propagation of location information using multilateration [41.52, 58].

Two approaches for cooperative relative localization of mobile robot teams are given in [41.59, 60]. Neither method uses GPS, landmarks, or maps of any kind; instead, robots make direct measurements of the relative pose of nearby robots and broadcast this information to the team as a whole. In [41.59], each robot processes this information independently to generate an egocentric estimate for the pose of other robots using a Bayesian formalism with a particle filter implementation. In [41.60], maximum-likelihood estimation (**MLE**) and numerical optimization is used to achieve a similar result.

A key issue is to be able to scale these computations for building a shared representation to large numbers of robots and sensors. This problem was studied in recent experiments under the US Defense Advanced Research Projects Agency (**DARPA**-funded software for distributed robotics (**SDR**) program. The goal of these experiments was to develop and demonstrate a multi-robot system capable of carrying out a specific mission. This required the ability to deploy a large number of robots into an unexplored building, map the building interior, detect and track intruders, and transmit all of the above information to a remote operator. A report on one set of experiments is presented in [41.19]. A tiered strategy for deploying the robots is described, where highly capable robots formed the first wave to enter and map a building, followed by a second wave which used the resulting map to self-deploy and monitor the environment for intruders. Both approaches relied extensively on networking the robots using commercial 802.11b wireless technology. This task involved both communication for building a shared representation as well control for perception.

Another important set of problems arises when robot networks are used for identifying, localizing, and then tracking targets in a dynamic setting. An embedded stationary wireless sensor network is like a virtual sensor spread over a large geographical area. Such a network can provide information to mobile robots about remote locations. Robot networks allow this virtual sensor to move in response to external stimuli and to track moving targets. Indeed, it is possible to cast this scenario as a pursuit-evasion game

with robotic sensor networks [41.61]. For example, the Tenet project at USC addresses the design of network primitives and abstractions for tiered network architectures, with robotic pursuit evasion as one of the target applications. Algorithms for guiding the sampling strategy of a robotic boat to model and locate phenomena of interest (e.g., hotspots) in aquatic environments are discussed in [41.11]. The networked infomechanical systems (**NIMS**) project has focused on sensor-assisted techniques for mobile robot-based adaptive sampling for event response [41.62] and field reconstruction [41.63].

The information collected by the nodes in a sensor network can be processed at a central location or in a decentralized fashion. Such in-network data processing techniques make better use of network communication and computation resources than centralized processing. This also enables the network to compute accurate and up-to-date global pictures of the global perception landscape that are available to all the robots in the system. Methods for in-network data processing with static nodes include artificial potential-field computation, gradient computations, particle filters, Bayesian inference, and signal processing. Algorithms

have been developed for computing maps, paths, and predictors [41.43, 48, 64].

A recent **DARPA** demonstration showed how communication networks can be used effectively in perception tasks involving heterogeneous robots [41.20]. In cooperative search, identification, and localization unmanned aerial vehicles (**UAVs**) can be used to cover large areas, searching for targets. However, sensors on **UAVs** are typically limited in their accuracy of localization of targets on the ground. On the other hand, ground robots can be deployed to accurately locate ground targets but have the disadvantage of not being able to move rapidly and see through obstacles such as buildings or fences. In [41.30], the synergy between these two devices is exploited by creating a seamless network of **UAVs** and unmanned ground vehicles (**UGVs**). As discussed in Sect. 41.5, the key to such network-centric approaches for search and localization is a shared representation of state information, which in this case is easily scalable to large numbers of **UAVs** and **UGVs** and is transparent to the specificity of individual platforms. However, how to do this more generally and for more unstructured information remains an issue for future research.

41.7 Control for Perception

Networked mobile robots enable the exploration of dynamic environments and the recovery of three-dimensional information via distributed active perception [41.27]. Since the nodes are mobile, a natural question is: where should the nodes be placed in order to ensure successful integration of information from multiple nodes, and to maximize the quality of the estimates returned by the team? Since there is a cost associated with transmitting and processing data, it is important to consider which sensor readings should be used in the state estimation and what information should be communicated to the rest of the system. The quality of the information computed by the network depends on the locations of the sensor platforms both in an absolute and relative sense. The quality also depends on the noise characteristics of each sensor, and the communication network.

A robot network goes well beyond a fixed sensor network, which can only collect data at fixed positions in space; for example, when an event is detected at a specific location it is possible to direct more sensors toward the location of observation of the event for more infor-

mation (for example, higher-resolution data or higher sampling frequency). Reconfiguring the node locations for adaptive resolution sampling relies on distributed control strategies.

Various strategies have been introduced for controlling mobile sensor network coverage. Mobile sensing agents are controlled using gradients of information-based objective functions [41.65]. Stability results are derived without concerns for the optimality of the network configuration, but local guarantees are provided. A body of results reported in [41.66] and [41.67] describes decentralized control laws for positioning mobile sensor networks optimally with respect to a known event distribution density function. This approach is advantageous because it guarantees that the network (locally) minimizes a cost function relevant to the coverage problem. However, the control strategy requires that each agent have a complete knowledge of the event distribution density, thus it is not reactive to the sensed environment. The work by [41.68, 69] generalizes these results to situations in which the nodes estimate rather than know ahead of time the event distribution density

function. A local (decentralized) control law requires that each agent can measure the value and gradient of the distribution density function at its own position. This results in a sensor network that is reactive to its sensed environment while maintaining or seeking a near-optimal sensing configuration. In addition, the distribution density function approximation yields a closed-form expression for the control law in terms of the vertices of an agent's Voronoi region. This eliminates the need for the numerical integration of a function over a polynomial domain at every time step, thereby providing a significant reduction in computational overhead for each agent. Other work in event monitoring for unknown distributions includes [41.33]. Krause et al. [41.70] have recently proposed an approach for sensor placement that considers both the sensing quality and communication cost of imperfect sensing and communication components. They use a parametric model for link reception rate that assumes no acknowledgement and no temporal correlation of lossy links.

Beginning with the art gallery problem, there have been multiple efforts to determine an optimal configuration of sensors to cover a given region [41.71–73]. A variant which allows the use of mobile sensors is

known as the *watchmen tours* problem. In these approaches the sensor model is abstract and not well suited to real environments and cameras. Distributed geometric optimization methods [41.67] have also been used for mobile sensor network reconfiguration. A related class of methods is the use of estimation-theoretic optimization metrics and the application of information filters to coordinate network-wide motion [41.30]. There are other distributed optimization methods which use a distributed control law and show that it optimizes a global metric of interest, such as using a potential field or other linear control law based only on local neighbor interactions [41.74]. Research focusing on the control of cameras with pan, tilt, and zoom capabilities is due to [41.34, 75, 76]. In [41.75] an approach is developed to calibrate a pan–tilt–zoom camera automatically over its full zoom range and to build very high-resolution panoramas. In [41.34], the cameras are constantly moved to track observed targets, using a factor graph. A recent algorithm due to [41.77] significantly improves on this by positioning cameras to make the network better suited to detect and classify targets as they emerge. Pan–tilt–zoom cameras allow the construction of far more flexible vision systems than static cameras.

41.8 Control for Communication

In Sect. 41.5, we briefly discussed the benefits of using the communication network to synthesize and improve controller design. Conversely, the movement of robots affects the network and data transmission in the network. This gives rise to many challenges. If the controllers for individual robots are known, can we provide guarantees about communication in the network and can we develop robust information routing and networking algorithms in the presence of robot motion? Another challenge concerns how information propagates and diffuses in these networks. If the robots move under a given control model, how does a piece of information propagate through the network and what can we say about when and where that piece of information will be heard? If we know the answers to such questions, it may be possible to design controllers to realize desired communication network characteristics.

One simple control strategy that can affect network performance is to control the robot motion to ensure messages are transmitted between designated nodes. The movement of robots in a network of robots and sensors may cause network partitioning when nodes go out of

range. However, the ability of the robots to move in a controlled way also leads to an opportunity to address the information routing problem in disconnected networks by turning the robots into relay nodes. The key idea here is to enable the robot holding a current message to an unavailable destination to modify their trajectory in order to relay a message. This problem has been formulated as an optimization problem. The goal is to minimize the trajectory modifications necessary to send a message to its destination. Several solutions have been proposed depending on the information that is available to the robots. If the robots' trajectories are known, path planning techniques can be used to compute who moves where to relay what. If the robots' trajectories are not known, a distributed spanning tree can be created to enable robots to keep track of each other. Each robot is assigned a region of movement and a parent in the spanning tree. When the robot leaves its region, the parent is informed. When the robot moves too far away, the spanning tree is modified.

Mobile robots can be used to create desired network topologies under suitable models of network commu-

nication. If a robot is used to emplace nodes in an environment (or if sensor nodes robotically self-deploy) to build a network, the problem is referred to as deployment. It is possible to control the motion of individual nodes to guarantee that a specified topology is maintained [41.29]. It is also possible to repositioning nodes with the explicit aim of changing the network topology – the so-called mobility-based topology control problem.

A distributed algorithm for the deployment of mobile robot teams has been described by [41.78] using the concept of virtual pheromones: localized messages from one robot to another. These messages are used to generate either a gas expansion or a guided growth deployment model. Similar algorithms based on artificial potential fields are described in [41.79, 80], where the latter incorporates a connectivity constraint. An incremental deployment algorithm for mobile sensor networks is given in [41.32]; nodes are deployed one at a time into an unknown environment, with each node making use of information gathered by previously deployed nodes to determine its deployment location. The algorithm is designed to maximize network coverage while ensuring that nodes retain line of sight with one another.

Most work on network topology control has dealt with uncontrolled deployments, where there is no explicit control of the positions of individual nodes. The primary mechanisms proposed are power control and sleep scheduling. These methods involve pruning an already existing, well-connected communication graph in order to save power while ensuring that the resultant subgraph preserves connectivity. Given a network that is connected when all nodes are operating at maximum power, the aim of power control is to use the minimum power level at each node for which the network remains connected [41.81]. Given an overdeployed network, sleep scheduling seeks to activate a minimal subset of nodes to maintain connectivity and achieve other desired metrics [41.82]. In contrast, controlled deployments are feasible when the positions of individual nodes can be altered. Such deployments are interesting for two reasons. First, network topology with wireless communication relates directly to proximity relations and hence the position of the nodes. Second, there is increasing evidence that a large number of deployments are likely to involve careful, nonrandom placement of

nodes. The positioning of nodes is controlled either by the nodes themselves or by external agents. Such networks present a different and interesting scenario for topology control since it is possible to exploit control of the motion and placement of the nodes to build efficient topologies. A local, completely decentralized technique for topology control using mobility is given in [41.83].

An important application for networked robots is in monitoring and surveillance, where it is important that the robots cover the space while remaining within communication range [41.84]. Probing environment and adaptive sleeping protocol (**PEAS**) was one of the first attempts to address communication connectivity and sensing coverage simultaneously using heuristic algorithms [41.85]. Wang et al. [41.86] proposed a new coverage configuration protocol (**CCP**) to produce an approach that simultaneously optimizes coverage and connectivity while maximizing the number of nodes that are placed into sleep mode. Furthermore, they also identified three different classes of coverage–connectivity problems with respect to the ratio of radio and sensing ranges and recognized the critical ratio where the former range is twice as long as the latter. Zhang and Hou proved that, if the communication range is at least twice the sensing range, complete coverage of a convex area guarantees network communication connectivity, and then used this theorem as a basis for a localized density control algorithm [41.82]. This was subsequently generalized to show that the condition that the communication range is twice the sensing range is sufficient and is the tight lower bound to guarantee that complete coverage preservation implies communication connectivity among nodes if the original network topology is connected [41.87].

In summary, if the state of the communication network and the desired state of the communication network is known to each agent, it should be possible to synthesize distributed controllers to move agents to attain desired network characteristics. However, the assumptions on the global state are clearly not justified. Also, the desired motion to optimize network characteristics will conflict with the motion that is required to perform the desired task. However, as the brief discussion above illustrates, there are many interesting studies that point to promising directions for future work in this very fertile research field.

41.9 Conclusions and Further Reading

The paradigm of networked robots offers significant potential for accomplishing tasks that cannot be accomplished by individual robots. Indeed this paradigm is critical to such tasks as environmental monitoring, surveillance and reconnaissance, and security for civilian or defense purposes. However, there are many scientific challenges to realizing this vision for networked robots. The main overarching challenges are summarized here.

Technical challenges to scalability: We do not yet have a methodology for creating self-organizing robot networks that are robust to labeling (or numbering), with completely decentralized controllers and estimators, and with provable emergent response. This requires basic research at the intersection of control, perception, and communication.

Performing physical tasks in the real world: Most of our present applications emphasize going from static sensor networks to mobile sensor networks and, as such, are able to acquire and process information. We are a long way from creating robust robot networks that can perform physical tasks in the real world.

Human interaction for network-centric control and monitoring: Advances over the last decade have provided human users with the ability to interact with hundreds or thousands of computers on the Internet. It is necessary to develop similar network-centric approaches to interfacing, both for control and for monitoring.

Finally, a major challenge is to create robot networks that are proactive and anticipate our needs and commands rather than reacting (with delays) to human commands.

While there are major challenges ahead, there is no denying the tremendous potential of networked robots. This chapter and other related chapters in Part D (Chap. 31) and Part E (Chap. 40) show that the research community is making steady progress and confronting these challenges head on.

The references for this chapter includes many pointers to the specific research issues covered here. For some excellent further background on networked robotics we direct the reader to [41.5, 6, 19, 26, 29, 50, 64, 77].

Part F, Field and Service Robotics, covers the most recent advances concerned with the growing area of robot applications, ranging from industrial robotics, through a diverse array of air, land, sea, and space applications to educational robotics. The future vision for robotics is for the pervasive application of robots. The robots of the future will perform all the dangerous, dirty, and dreary (DDD) tasks. Joe Engelberger, the pioneer of the robotics industry, wrote in his 1989 book *Robotics in Service* that the inspiration to write the book came as a reaction to a forecast study of robot applications, which predicted that in 1995 applications of robotics outside factories (the traditional domain of industrial robots) would account for less than 1% of total sales. Engelberger believed that this forecast was wrong, and he instead predicted that the non-industrial class of robot applications would become the largest class of robot applications. Engelberger's prediction has yet to come to pass. However, he did correctly foresee the growth in nontraditional applications of robots. Previous parts of this Handbook show the great strides that robotics technology has made in the past 50 years. The technology has reached a level of maturity such that robots are now marching from the factories into field and service applications.

The topics in Part F cover the essentials of what is required to create robots that can work in all environments. Part F describes fit-for-purpose robots and includes hardware design, control (of locomotion, manipulation, and interaction), perception, and user interfaces. The economic/social drivers for the particular applications are also discussed. Part F builds on all of the previous parts of the Handbook. Robot Foundations (Part A) and Robot Structures (Part B) are essential for providing the basic mechanisms and control structures for any robot that is targeted for applications work. Sensing and Perception (Part C) and Manipulation and Interfaces (Part D) are critical capabilities for robots that need to interact with changing environments and perform manipulation tasks under human supervision. To fully utilize the potential of a working robot requires mobility and the ability to cooperate with other robotics, the basic technologies described in Mobile and Distributed Robotics (Part E) are essential.

Chapter 42, Industrial Robotics, gives a history and description of typical industrial robot applications. Most robots today can trace their origin to early industrial robot designs. All the important foundations for robot control were initially developed with industrial applications in mind. The chapter describes how robots

with different mechanisms are designed to fit different applications.

Chapter 43, Underwater Robotics, deals with challenges of technology to support marine applications. A historical background showing the expanding role of robotics in oceanic engineering applications is given. The chapter deals with modeling underwater dynamic effects, sensors and actuators for marine robots, mission control systems, guidance and control algorithms. Underwater localization and manipulation are discussed. Fault detection and fault tolerance aspects, together with the coordination control of multiple underwater vehicles are also covered. The chapter reports on successful deployments of marine robotics.

Chapter 44, Aerial Robotics, describes the technology, challenges, and applications of airborne robotics. The wide range of potential uses for robots that can fly, from military to civilian applications, is described. The challenges for aerial robots span many fields, including state regulations, man-machine interface design issues, path planning, navigation, safety/reliability, collision prevention, take-off/landing techniques, and dealing with other aerial vehicles. Basic aerial robot flight concepts including propulsion systems, control systems, and flight vehicle types including lighter-than-air systems are covered. The chapter ends with a description of integrated automated aerial robotics systems.

Chapter 45, Space Robots and Systems, deals with robotics technology for space applications. It covers two classes of robotics: orbital and surface. Any unmanned spacecraft is a robotic spacecraft. However, space robots are more capable devices that can facilitate manipulation, assembly, assisting astronauts, or extending exploration to remote planets as surrogates for human explorers. This chapter covers the key issues in space robots and systems: manipulation, mobility, sensing and perception, teleoperation and autonomy, and dealing with extreme environments. A historical overview and a review of technical advances for space robots is provided. A description of the mathematics for the control of robotic devices in microgravity environments is also given.

Chapter 46, Robotics in Agriculture and Forestry, describes how robotics has made a impact in the agricultural and forestry industries. Automatic vehicle guidance of farming machinery are being widely used. Automatic sensing, handling, and processing of produce are commonplace, and there has been a substantial automation of processes and procedures for livestock handling. In forestry, legged harvesters and automation of trimming are maturing technologies. Computer vision is being

applied to allow tractors to follow a row of crops, collecting macadamia nuts, and for sorting and grading of produce. A number of farm automation projects, such as automated milking of cows or sorting sheep from goats using a swinging gate to separate different species using computer vision are a commercial success. The chapter emphasizes the agricultural field as a fruitful source for robotics applications, some sufficiently demanding to require the development of new theoretical techniques and methods.

Chapter 47, Robotics in Construction, describes the construction automation concepts that have been developed and presents examples of construction robots that are in use and/or in various stages of development. The chapter gives an overview of the construction industry and discusses the concept of automation versus robotics. Sensing systems that enable the use of robots and automation in construction are reviewed. The chapter also discusses economic aspects of implementing robotics in construction. Unsolved technical challenges including interoperability, connection systems, tolerances, power, and communications are discussed.

Chapter 48, Robotics in Hazardous Applications, discusses robot technologies for dealing with difficult and dangerous environments. The technology solutions that are adopted depend on the nature and magnitude of the hazards. When the magnitudes of hazards reach the point that human exposure represents a direct threat to life or has long-term health consequences, e.g., nuclear radiation, some form of remote operation must be used. This chapter describes robotics technologies for dealing with eradicating landmines, and hazardous materials handling, e.g., explosives disposal, and handling of dangerous biological and nuclear material. Enabling technologies to support demining and hazardous material handling are discussed, including mobile platforms, manipulator design, teleoperation and control, and the supply of energy and communication signals through reliable and robust tethers. The chapter ends with a discussion of the advances that are required to progress the field. Progress is needed in mechatronics design, sensing, machine intelligence, and fully understanding the application and its associated economic factors.

Chapter 49, Mining Robotics, discusses the application of robotics to the mining industry. Mining remains physically demanding and hazardous work. The scope for the application of robotics is great since mining requires the handling of enormous quantities of material in a cost-effective and safe manner. High operational costs, the need for greater productivity, and improved health and safety outcomes are powerful drivers for

robotics. Existing approaches to improving productivity and safety through training, work practices, and larger and improved machine design are providing diminishing returns. The industry is at a tipping point where robotics and automation will provide the next step change in productivity and safety. This chapter reviews the history of robotic mining; it describes the enabling robot technologies associated with metalliferous mining and coal mining (open-cut and underground).

Chapter 50, Search and Rescue Robotics, describes the state of the art of an emerging applications field. Rescue robots serve as extensions of responders to a disaster, providing real-time video and other sensory data about the situation. The technology is still emerging and is still to be adopted by the international emergency response community. Rescue robots are beginning to be used by fire departments and for bomb disposal. This chapter describes the basic characteristics of disasters and the impact on robotic design, describes the robots actually used in disasters to date, promising robot designs, and concepts and methods of evaluation in benchmarks for rescue robotics. The chapter discusses the fundamental challenges facing rescue robotics, including the key challenge of evolution from a concept to the adoption as a solution technology.

Chapter 51, Intelligent Vehicles, describes the emerging robotics application field of intelligent vehicles: motor vehicles that have autonomous functions and capabilities. The chapter describes why the development of intelligent vehicles is important and gives a brief history of the field and the potential benefits of the technology. It describes the enabling technologies for intelligent vehicles to sense vehicle, environment, and driver state, work with digital maps and satellite navigation, and communicating with intelligent transportation infrastructure. The chapter describes the challenges and solutions associated with road scene understanding. Advanced driver assistance systems which use robotics technologies to create new safety and convenience systems for motor vehicles, such as collision avoidance, lane keeping, parking assistance, as well as driver monitoring to mitigate against driver fatigue, inattention, and impairment are described.

Chapter 52, Medical Robots and Systems, describes the development of medical robotics. In the last 20 years starting with brain surgery, orthopaedics, endoscopic surgery, and microsurgery, the field has expanded to include commercially marketed, clinically deployed systems and an active research community. This chapter provides a historical review of the field and discusses the major thrusts using examples from current and past

research. Medical robots are described within the context of larger computer-integrated systems including presurgical planning, intraoperative execution, and post-operative assessment and follow-up. The basic concepts of computer-integrated surgery including the critical factors affecting the deployment and acceptance of medical robots are described. An overview of medical robot systems is provided, including remote telesurgery and robotic surgical simulators.

Chapter 53, Rehabilitation and Health Care Robotics, describes robotic systems that assist persons who have a disability or provide rehabilitation therapy for persons. The chapter provides a historical review of the field. Physical therapy and training robots as well as robotic aids for people with disabilities are described. Advances in smart prostheses and orthoses for rehabilitation robotics are also described. An overview of work in diagnosis and monitoring for rehabilitation is provided. The chapter provides a solid understanding of the future challenges for rehabilitation and health care robotics.

Chapter 54, Domestic Robots, describes the technology that everyone would one day like in their home, that will vacuum the house, clean the kitchen, load the dishwasher, or polish the shoes. In spite of hundreds of millions of potential users surprisingly not many domestic robots exist. This chapter examines what it means not only to develop but also to commercialize domestic robots using cleaning robots as a representative example. The chapter reviews domestic floor cleaning

robots, robotic pool cleaners, window cleaning robots, and robotic lawn mowing. The chapter also examines smart appliances such as ironing robotics, intelligent refrigerators, and digital wardrobes. A description of research projects on smart environments and smart homes is presented. The chapter concludes on the importance of the economic case for the development of service robots.

Chapter 55, Robots for Education, describes robotics technologies for the education market, both as motivational tools for research programs and as concrete, real-world deployments that demonstrate the state of the art in robotic technologies. This chapter provides a technology overview of education robots. The chapter also provides a survey of robot-themed tournaments and an overview of robotic installations in informal learning spaces. Robotic technology is being used in hands-on, active-learning museums; this requires a new level of technology robustness and standardization. The chapter discusses physical robot platforms that have successfully supported active learning. An important tool in the study and execution of educational robotic systems is the formally evaluation of the efficacy of a robot system in an educational context. The chapter summarizes the manner in which conventional analytical tools may be used to evaluate educational programs that use robotic technologies as learning tools.

Sincere thanks and acknowledgement for help and assistance in preparing Part F are extended to Vivian Cateaux and Philippa V'Landys.

Industrial R

42. Industrial Robotics

Martin Hägele, Klas Nilsson, J. Norberto Pires

Most robots today can trace their origin to early industrial robot designs. Much of the technology that makes robots more human-friendly and adaptable for different applications has emerged from manufacturers of industrial robots. Industrial robots are by far the largest commercial application of robotics technology today. All the important foundations for robot control were initially developed with industrial applications in mind. These applications deserve special attention in order to understand the origin of robotics science and to appreciate many unsolved problems that still prevent the wider use of robots in manufacturing. In this chapter we present a brief history and descriptions of typical industrial robotics applications. We show how robots with different mechanisms fit different applications. Even though robots are well established in large-scale manufacturing, particularly in automobile and related component assembly, there are still many challenging problems to solve. The range of feasible applications could significantly increase if robots were easier to install, to integrate with other manufacturing processes,

and to program, particularly with adaptive sensing and automatic error recovery. We outline some of these remaining challenges for researchers.

Industrial robots are considered as a cornerstone of competitive manufacturing, which aims to combine high productivity, quality, and adaptability at minimal cost. In 2007 more than one million industrial robot installations were reported, with automotive industries as the predominant users with a share of more than 60% [42.1]. However, high-growth industries (in life sciences, electronics, solar cells, food, and logistics) and emerging manufacturing processes (gluing, coating, laser-based processes, precision assembly etc.) will increasingly depend on advanced robot technology. These industries' share of the number of robot installations has been growing steadily.

The production of industrial robots on the one hand, and the planning, integration, and operation of robot workcells on the other hand, are largely independent engineering tasks. In order to be produced in sufficiently large quantities, a robot design should meet the requirements for the widest set of potential applications. As this is difficult to achieve in practice, various classes of robot designs regarding payload capacity, number of robot axes, and workspace volume have emerged for application categories such as assembly, palletizing, painting, welding, machining, and general handling tasks.

Generally, a robot workcell consists of one or more robots with controllers and robot peripherals: grippers

or tools, safety devices, sensors, and material transfer components for moving and presenting parts. Typically, the cost of a complete robot workcell is four times the cost of the robots alone.

A robot workcell is usually the result of customized planning, integration, programming, and configuration, requiring significant engineering expertise. Standardized engineering methods, tools, and best-practice examples have become available to reduce costs and provide more predictable performance [42.2].

Today's industrial robots are mainly the result of the requirements of capital-intensive large-volume manufacturing, mainly defined by the automotive, electronics, and electrical goods industries. Future industrial robots will not be a mere extrapolation of today's designs with respect to features and performance data, but will rather follow new design principles addressing a wider range of application areas and industries. At the same time, new technologies, particularly from the information technol-

ogy (IT) world, will have an increasing impact on the design, performance, and cost of future industrial robots.

International and national standards now help to quantify robot performance and define safety precautions, geometry, and media interfaces. Most robots operate behind secure barriers to keep people at a safe distance [42.3]. Recently, improved safety standards have allowed direct human–robot collaboration, permitting robots and human factory workers to share the same workspace [42.4].

We will first present a historical introduction to industrial robotics with a selection of contemporary application examples, then the basic principles that are used in industrial robotics and a review of programming methods will be presented. We will also discuss tools (end-effectors) and system integration requirements. The chapter will be closed with the presentation of selected, unsolved problems that currently inhibit the wider application of industrial robots.

42.1 A Short History of Industrial Robots

The invention of the industrial robot dates back to 1954 when George Devol filed a patent on a *programmed article transfer* (Fig. 42.1). After teaming up with Joseph Engelberger, the first robot company, Unimation, was founded and put the first robot into service at a General Motors plant in 1961 for extracting parts

from a die-casting machine. Most of the hydraulically actuated *Unimates* were sold through the following years for workpiece handling and for spot-welding of car bodies [42.5]. Both applications were successful, which means that the robots worked reliably and ensured uniform quality. Soon, many other companies

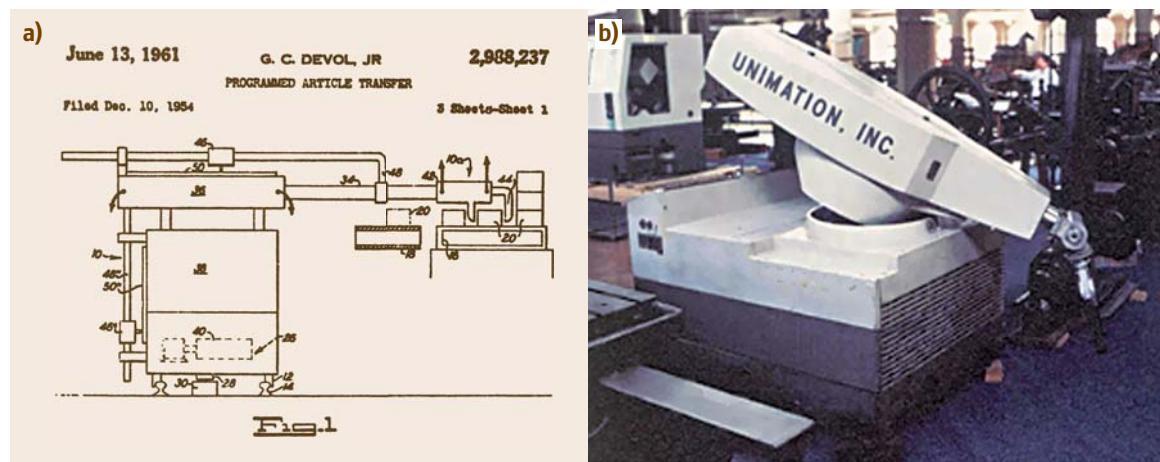

Fig. 42.1a,b The invention of the industrial robot (a) This patent was the start of a joint effort of G. Devol and J. Engelberger to form the first robot company, Unimation, a fusion of the words universal and automation. The company was acquired by Westinghouse in the late 1980s. (b) The first Unimation performed a rather simple handling task in 1961 at a General Motors plant. Other car manufacturers followed. The photo shows the first robot installed at Ford from their Museum in Dearborn

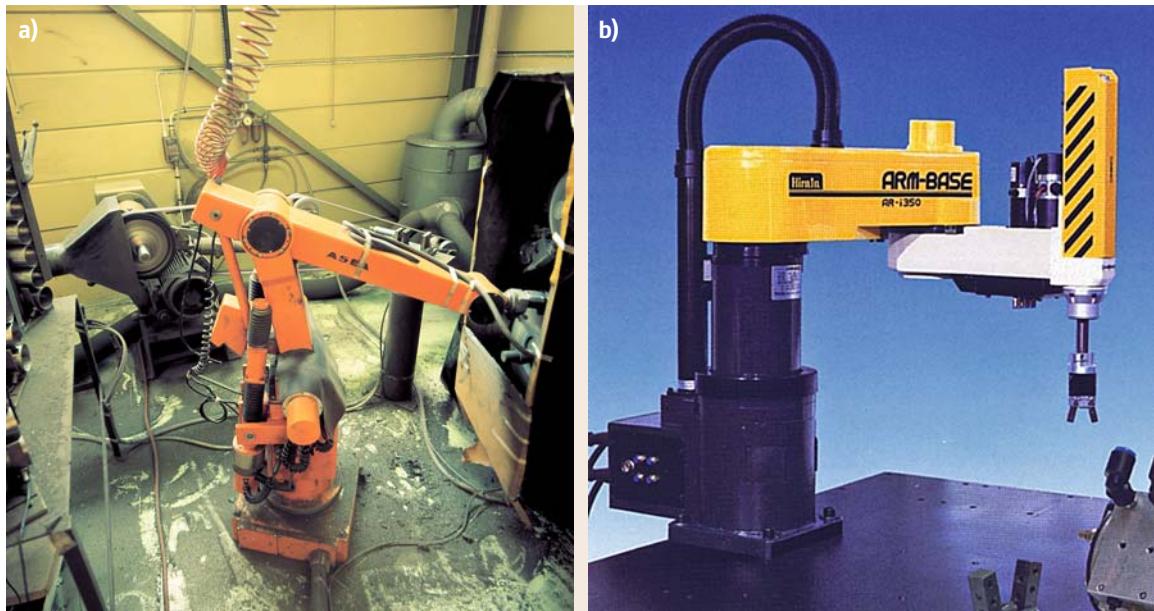

Fig. 42.2a,b The all electric (a) IRB-6 and (b) a SCARA-type kinematic (a) First introduced in 1973, the IRB-6 has been a breakthrough development as it was the first serially-produced robot product, which combined all-electric-drives technology and a microcomputer for programming and motion control. The robot proved very robust. Life-times of more than 20 years in harsh productions were reported (by courtesy ABB Automation, Friedberg) (b) The selective compliance assembly robot arm (SCARA) is particularly suited for assembly tasks as it combines rigidity in the vertical axis and compliance in the horizontal axis. In 1978, the first Hirata AR-300 was put together. Depicted is the successor design, the AR-i350. The SCARA design combines three or four rotational and one translational axis (by courtesy HIRATA Robotics, Mainz)

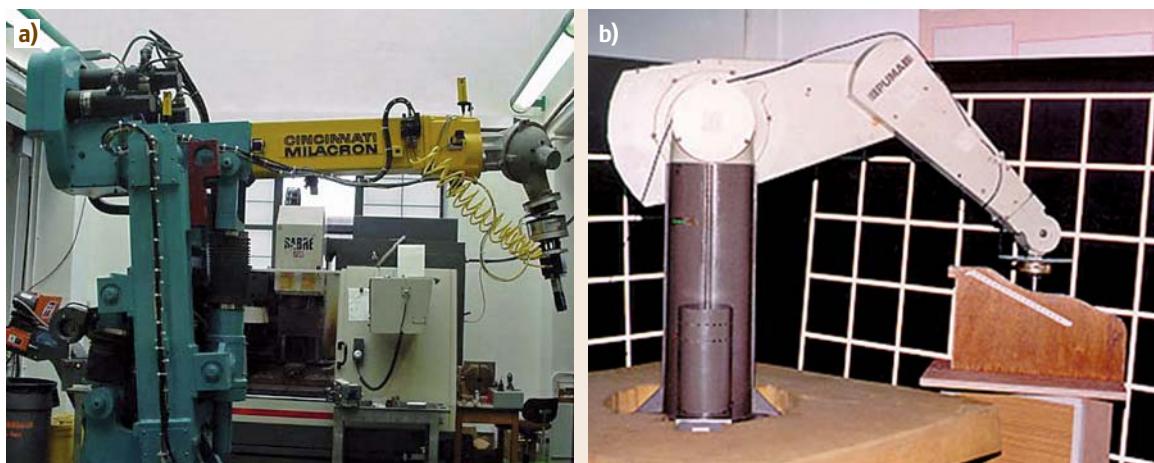

Fig. 42.3a,b Cincinnati Milacron T3 and the Unimation PUMA 560 (a) In 1974, Cincinnati Milacron introduced the first microcomputer controlled robot. The first T3 (*The Tomorrow Tool*) models used hydraulic drives, later they were replaced by electric motors as shown in the photo. The CM robotics division was acquired by ABB in the late 1970s (b) This 6 axis PUMA (programmable universal machine for assembly) came close to the dexterity of a human arm. After its launch in 1979 by Unimation it became one of the most popular arms and was used as a reference in robotics research for many years

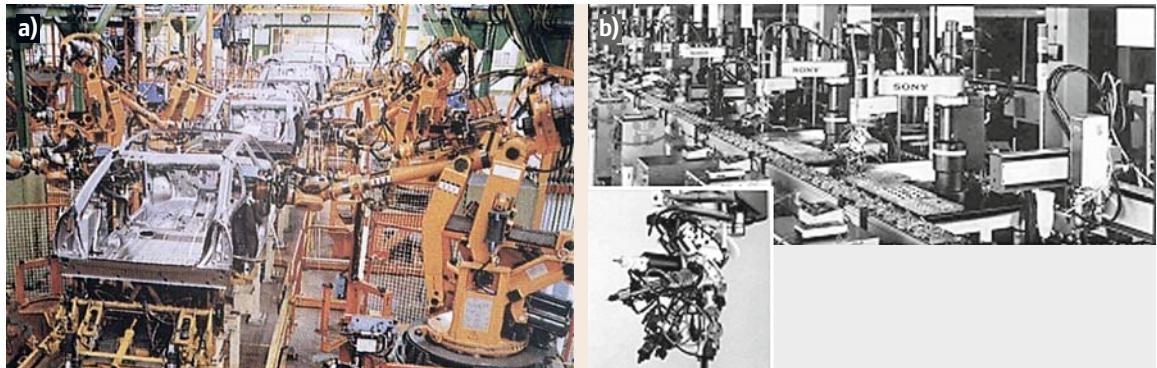

Fig. 42.4a,b Spot-welding line and videocassette recorder (VCR) assembly as pioneering applications for industrial robot applications. (a) Spot welding quickly became a primary application for robots as these jobs were particularly exhausting and hazardous for workers. A typical car body welding line from 1985 is displayed. The car model shown is a French Citroën CX (b) An automated VCR assembly line (ca. 1989) with SCARAAs carrying a turret with multi-gripper tools. Typically five parts are added by one robot before the VCR is moved to the next station of the fully automated assembly line

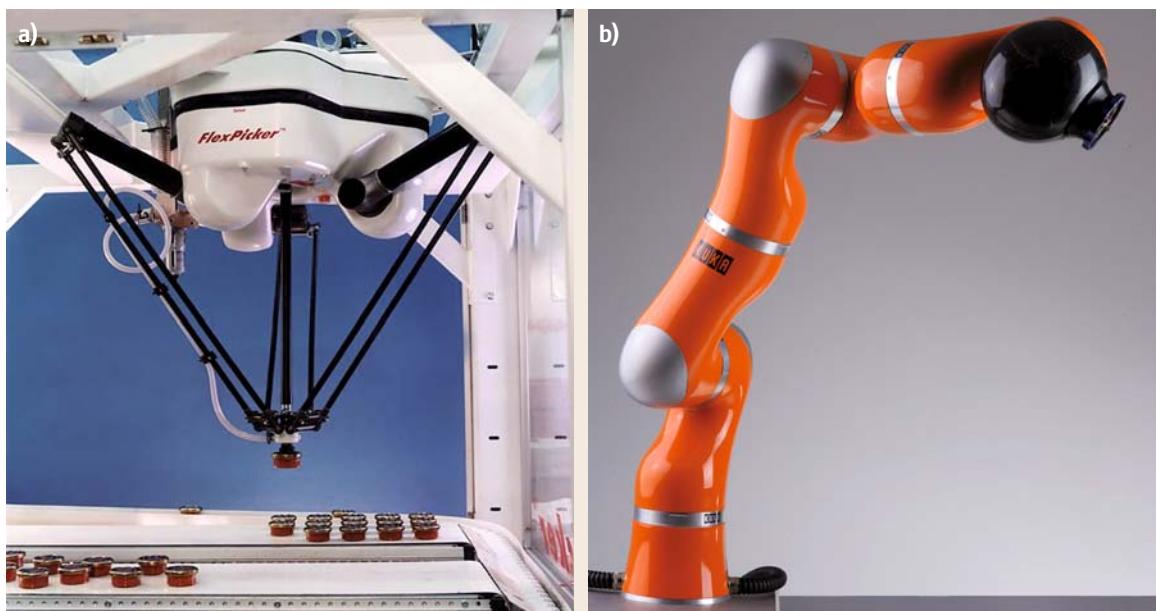

Fig. 42.5a,b The ABB FlexPicker parallel robot for high speed picking and the KUKA light weight robot arm (a) *Parallel kinematic machines (PKM)* represent an interesting approach to achieve high stiffness at low inertia, thus allowing accurate, high speed motions. Initially suggested by Clavel this 4 axis robot (called Delta) is used for high speed pick-and-place tasks. The robot reaches accelerations of up to 10 g (b) The KUKA light-weight robot is the result of a long research and development process by DLR, towards an arm design with a weight-to-payload ratio of 1:1. The 7 axis arm which is suited for human-robot cooperation imitates the dexterity of a human arm

started to develop and manufacture industrial robots. An innovation-driven industry was born. However, it took many years until this industry became profitable.

The breakthrough Stanford Arm was designed as a research prototype in 1969 by *Victor Scheinman* (see Chap. 3), at that time a mechanical engineering stu-

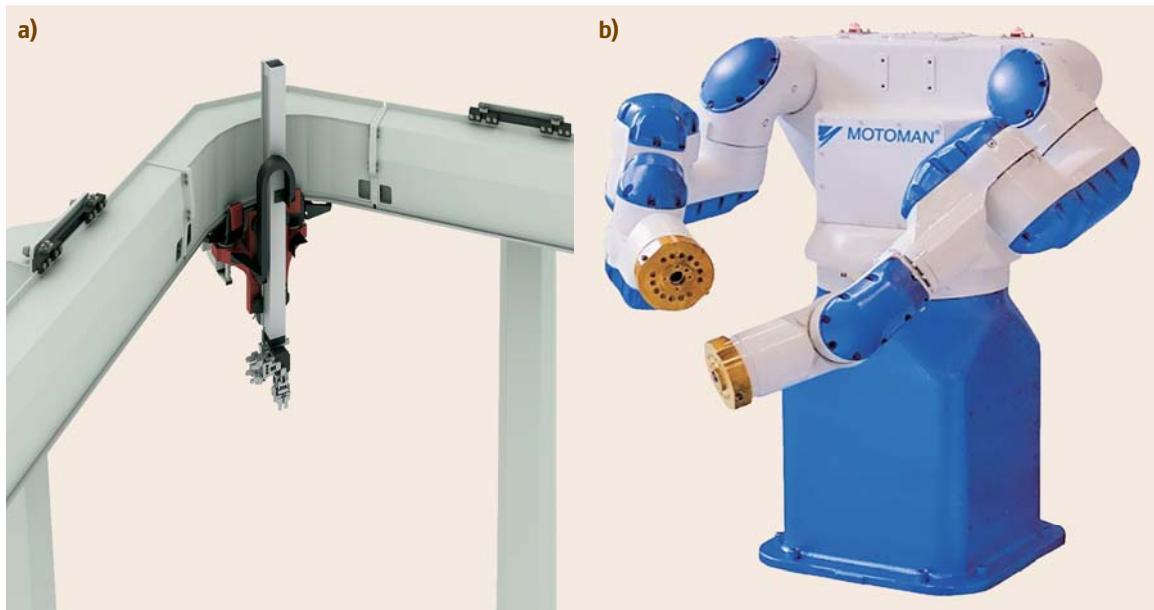

Fig. 42.6a,b Cartesian robot mobility and two-armed robot dexterity (a) The roboLoop of Güdel is a curved-track gantry and transfer system. One or more robot arms circulate as carriers in a closed transfer system. The system can be installed suspended, in gantry configuration, or as a floor-standing system. A signal bus allows the control and coordination of multiple robo-carriers (by courtesy Güdel, Langenthal) (b) Motoman's DA-20 dual-arm robot provides high-speed motion with two six-axis arms that provide enhanced, human-like flexibility of movement. The robot also provides jig-less operation with one robot arm holding a part while the other performs operations on the held part (by courtesy Motoman, Kalmar)

dent working in the Stanford Artificial Intelligence Laboratory ([SAIL](#)) [42.6]. The six-degree-of-freedom (6-DOF) all-electric manipulator was controlled by a standard computer, a Digital Equipment PDP-6. The non-anthropomorphic kinematic configuration with one prismatic and five rotational joints was configured such that the equations for solving the robot kinematics were simple enough to speed up computations. Drives consisted of direct-current (DC) electric motors, harmonic drive and spur gear reducers, potentiometers and tachometers for position and velocity feedback. Subsequent robot designs were strongly influenced by Scheinman's concepts (Figs. 42.2 and 42.3).

In 1973, the company ASEA (now ABB) introduced the first microcomputer-controlled all-electric industrial robot, the IRB-6, which allowed continuous path motion, a precondition for arc-welding or machining (Fig. 42.2). The design proved to be very robust and robot lifetimes of more than 20 years were reported [42.7]. In the 1970s intense diffusion of robots into car manufacturing set in mostly for (spot-)welding and handling applications (Fig. 42.4).

In 1978, the *selective compliance assembly robot arm (SCARA)* was invented by Hiroshi Makino of Yamanashi University, Japan [42.8]. The ground-breaking four-axis low-cost design was perfectly suited for small parts assembly as the kinematic configuration allows fast and compliant arm motions (Fig. 42.2). Flexible assembly systems based on the [SCARA](#) robot in conjunction with compatible product designs (design for assembly, DFA) have contributed significantly to creating a worldwide boom in high-volume electronics production and consumer products [42.9].

Requirements regarding a robot's speed and weight have led to novel kinematic and transmission designs. From early on, the reduction of the mass and inertia of robot structures was a primary research target, where the human arm with a weight-to-load ratio of 1:1 was considered the ultimate benchmark. In 2006, this goal was reached in the form of the company KUKA lightweight robot, a compact 7-DOF robot arm with advanced force-control capabilities [42.10]. Another approach towards lightweight and stiff structures has been pursued since the 1980s by developing parallel kinematic machines

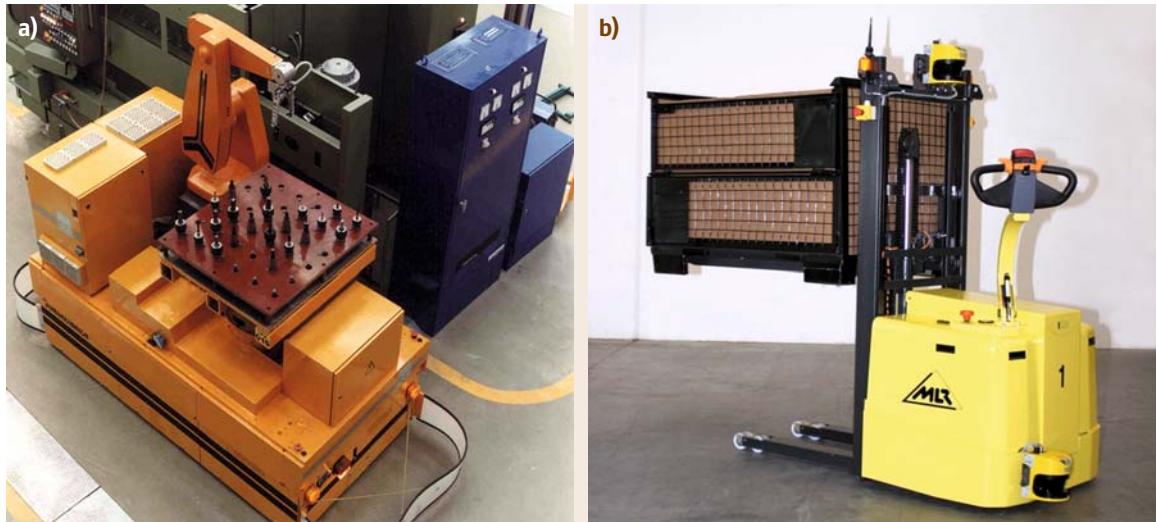

Fig. 42.7a,b A mobile robot arm for machine (un)loading and an autonomous fork lift (a) The MORO (mobile robot, 1984), developed at Fraunhofer IPA, Stuttgart, was one of the first prototypes to combine a robot arm on a wire-bound mobile platform which follows a wire buried in the floor. Mobile arms were particularly used in highly automated clean room manufacturing facilities to automatically load and unload process equipment (b) This automated fork-lift by MLR combines manual operation with fully autonomous navigation and (un-)loading of boxes and pallets. A laser scanner using retro-reflecting tapes or other landmarks (walls, pillars) avoids constraints imposed by simple buried wire guidance technology (by courtesy MLR System, Ludwigsburg)

which connect the machine's basis with its end-effector by three to six parallel struts [42.11]. These so-called parallel robots (see Chaps. 3 and 12) are particularly suited to achieve the highest speeds (e.g., for picking), precision (e.g., for machining), or handling high work loads (Fig. 42.5). However, workspace volumes tend to be smaller than those of serial or open kinematic chain robots which are comparable in size.

Still, Cartesian robots are ideally suited for covering large workspaces. Apart from the traditional design using three orthogonal translational axes, the company Güdel introduced a curved-track gantry in 1998. The concept allows one or more robot arms to track curves and to circulate in a closed transfer system. Thus, the workspace of robot can be immensely increased at high speed and precision. This may be particularly valuable in logistics or machine tending [42.12].

Two-handed dexterous manipulation can be critical for complex assembly tasks, simultaneous handling and processing of workpieces, or the handling of large objects. The first commercial robot for synchronized, two-handed manipulation was introduced by MOTOMAN in 2005 [42.13]. As a dual-arm robot imi-

tates the reach and dexterity of human arms, it can be placed on a site that previously accommodated human workers. Thus, capital expenditure can be reduced. It features 13 axes of motion: six axes per arm, plus a single axis for the base rotation (Fig. 42.6).

In parallel to industrial robots *automated guided vehicles (AGVs)* have emerged. These mobile robots are used for moving workpieces or loading equipment from point to point. Within the concept of automated *flexible manufacturing systems (FMS)* AGVs have become an important part of their routing flexibility. Initially AGVs relied on prepared floors such as embedded wires or magnets for motion guidance. Meanwhile, freely navigating AGVs are used in large-scale manufacturing and logistics. Usually, their navigation is based on laser scanners that provide an accurate two-dimensional map of the actual environment for self-localization and obstacle avoidance [42.14]. Early on, combinations of AGVs and robot arms were realized to automatically load and unload machine tools (Fig. 42.7). Only in some selected environments such as (un-)loading process equipment in the semiconductor industry these mobile arms were economically advantageous.

By 2007, the evolution of industrial robots was marked by the following main trends [42.15]:

- The average robot unit price fell to about one-third of its equivalent price in 1990, which meant that automation is becoming more affordable. At the same time, robot performance parameters such as speed, load capacity, and mean time between failures (**MTBF**) have dramatically improved. These improvements provide a faster return on investment, particularly for small, short-run batch production.
- Off-the-shelf components from personal computer (**PC**) technologies, consumer software, and the **IT** industry have contributed to improved performance-to-cost ratios. Today, most manufacturers integrate **PC**-based processors in their controllers as well as software for programming, communication, simulation, and maintenance from high-volume **IT**-markets.

- Multiple robots can be programmed and synchronized in real time by one controller, which allows robots to cooperate precisely on a single workpiece.
- Increasingly, vision systems for object identification, localization, and quality control have become an integral part of the robot controller.
- Robots are networked by fieldbuses or ethernet for control, configuration, and maintenance.
- New financing arrangements allow end-users to rent a robot or even have a robot workcell operated by a specialized company or even the robot supplier in order to reduce risks or to save on investment capital.
- Training and education have become important services to end-users to increase acceptance of robot technology. Specific multimedia material and courses aim at educating industrial engineers and workforce to effectively plan, program, operate, and maintain industrial robot workcells.

42.2 Typical Applications and Robot Configurations

42.2.1 Welding

Welding ranks among the most important joining processes in manufacturing. Manual welding requires highly skilled workers, as small imperfections in the weld can lead to severe consequences. Why is a robot suited to perform this critical job? Modern welding robots have the following characteristics:

- Computer control allows the programming of task sequences, robot motions, external actuators, sensors, and communication with external devices.
- Free definition and parameterization of robot positions/orientations, reference frames, and trajectories.
- High repeatability and positioning accuracy of trajectories. Typically repeatability is some ± 0.1 mm and positioning accuracy is of the order of ± 1.0 mm.
- High speeds of the end-effector of up to 8 m/s.
- Typically, articulated robots have six **DOF** so that commanded orientations and positions in their workspace can be reached. Workspace extensions by mounting the robot on a linear axis (seventh **DOF**) are common, especially for welding of large structures.
- Typical payloads of 6–100 kg.
- Advanced programmable logic controller (**PLC**) capabilities such as fast input/output control and synchronizing actions within the robot workcell.

- Interfacing to high-level factory control through fieldbuses or ethernet.

Metal inert/active gas (**MIG/MAG**) welding is the predominant application of industrial robotics today. The automatic arc-welding process is based on a consumable wire electrode and a shielding gas that are fed through a welding gun (Fig. 42.8). Electric current sources, torches, and peripheral devices for automatic cleaning and maintaining the torch (anti-splatter, wire-cutting, tool changer etc.) are offered by specialized companies. Often sensors are used to track welding gaps and measure weld seams either before or synchronously to the welding process, thus adapting the robot's trajectory in the presence of workpiece variation and distortion. Also, cooperating robots have been introduced where one robot fixes and moves the workpiece in synchronization with another robot carrying a welding tool so that the weld can be performed with the pool of molten metal horizontal.

Another interesting robot task is multilayer welding. In regular intervals the robot measures the profile of the weld gap and adaptively generates subsequent tool paths to apply successive weld seams until the final required geometry is reached. In the example shown in Fig. 42.8c up to 70 seams can be produced by the robot to weld thick metal plates.

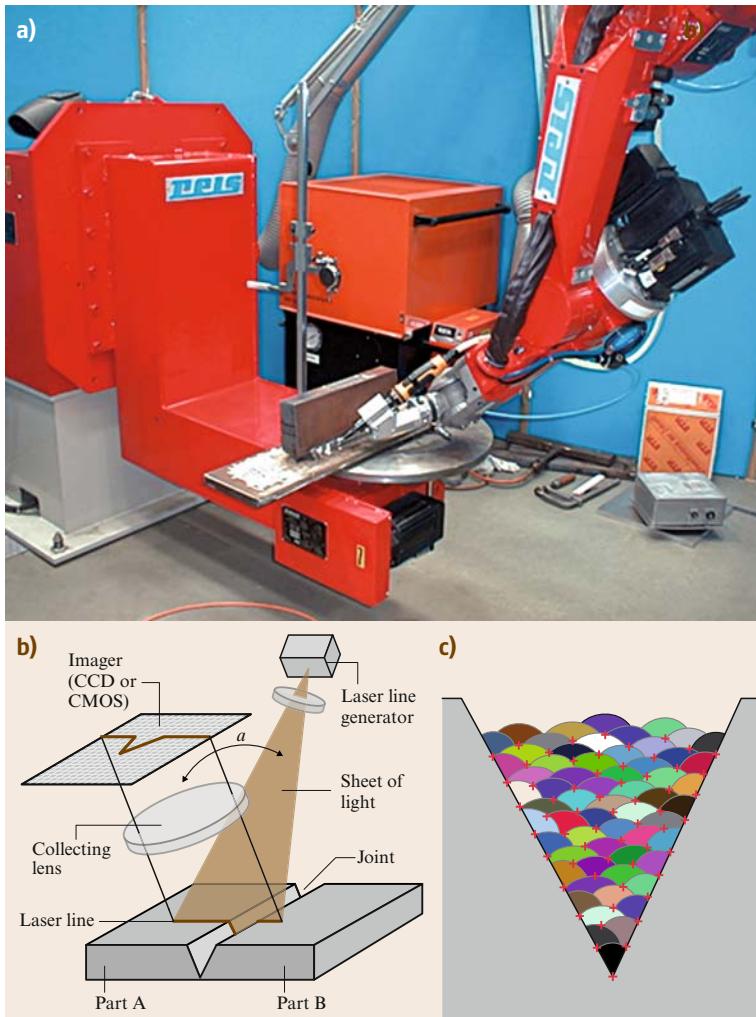

Fig. 42.8a–c Robot welding with sensor guidance. (a) The welding robot workcell consists of a 6 DOF robot, a turning table so that the seam is accessible and welded in a flat position, the weld source with a fume extractor and the welding torch. Safety fences and light shields are not shown. The welding torch is attached to the robot flange. A service station (not shown) in the robot workcell is approached regularly to clean the gas nozzle. (b) A typical weld seam sensor is based on the so-called laser triangulation principle. The sensor is attached to the robot and a laser projects a sharp stripe on the seam. The stripe is detected by an imager, typically a 2-D CCD camera. From the extracted contour the position of the seam relative to the sensor is calculated. (c) Multiple seams can be generated based on this information

42.2.2 Car Body Assembly

Early on, car body assembly became the predominant robot application as the benefit for robot automation was apparent. Handling and positioning the metal sheets, spot welding, and transport of the body frames was either hazardous, physically demanding to the worker, or difficult to realize on fixed automation lines given the desired variety of car body configurations to be assembled on the one production line (Fig. 42.9). In the stamping section metal sheets are cut into plates (or *blanks*) ready for pressing into body panels. In subsequent steps robots load the panels onto a tray that fixes the panels for other robots to be spot-welded. After inspection the finished bodies are transferred by conveyor to the paint shop.

Individual assembly units and components such as motors, transmissions, axles, doors or fenders are pre-mounted in separate areas. The car body is delivered to the body assembly area *just in sequence*, i.e. at the right time and place on the assembly line. The climax of the assembly process(welding) – when the engine, drive and chassis first meet takes place before the last parts are mounted on the car.

Today's industrial robots, particularly in the workload category of 100–300 kg, are to a large extent the results of the requirements stemming from this application:

- Required repeatability of at least ± 0.5 mm under typical loads of some 100 kg for the spot-welding

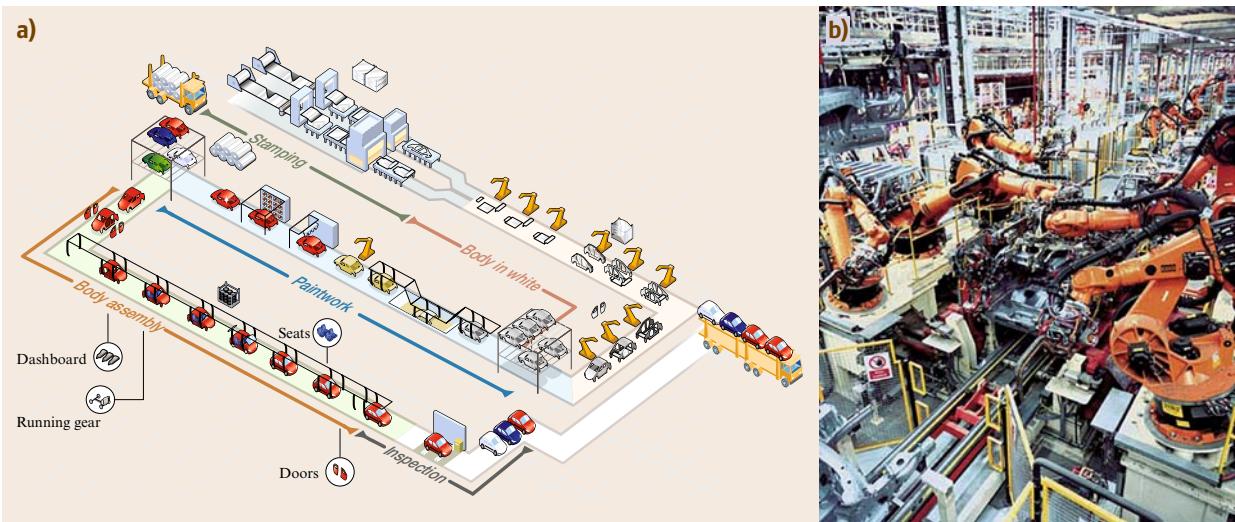

Fig. 42.9a,b Car body assembly. (a) A car body assembly usually follows the illustrated steps: Stamping of the metal sheet into plates, fixing and alignment of the plates on trays, spot welding, painting the car body, and final assembly of the car body (doors, dashboard, windscreens, power-train seats, and tires). Car factories can host well over 1000 robots working two to three shifts per day. (Courtesy PSA Peugeot Citroën, Paris and Art Movies, Paris) (b) The Mercedes A class assembly in Rastatt Germany is highly automated. The picture shows spot welding robots along the, *body in white* transfer line. Trays carrying car bodies pass through the *robot garden*

tool and cable package leads to stiff and heavy arm structures. A typical robot weight-to-payload ratio is of the order of 1500 kg:150 kg.

- Three-shift continuous operation requires highest reliability of both robot and equipment. Typical mean time between failure (MTBF) is reported to be around than 50 000 h [42.1].
- The line capacity depends on the robot's speed to place spot welds. Thus, the *point-to-point* (PTP) movement time between welding positions should be kept as short as possible. This is mainly achieved by powerful drives so that the mean power consumption of the robot drives is typically 5 kW.
- Most of the trajectories, positions, and orientations are generated using *offline programming* (OLP) systems. Accurate simulations of the robot motion depend on robot models, which incorporate both robot kinematic properties and controller characteristics. The *realistic robot simulation* (RSS) interface is the accepted standard format for robot models of offline programming systems [42.16].

42.2.3 Painting

Hazardous working conditions for human operators motivated Trallfa, a Norwegian company, to develop simple

spray-painting robots in 1969, particularly for spraying bumpers and other plastic parts in the automotive industry. Initially pneumatically driven for antiexplosion reasons, today's robot designs are fully electric with greatly improved spray guns. They also have hooks and grippers to open hoods and doors during the painting task. Hollow wrists that house gas and paint hoses allow fast and agile motions. Spray guns for robots have evolved dramatically for delivering uniform quality using as little paint and solvent as possible and also for switching between different paint colors. Originally spray-painting robots replicated movements copied from human workers. Most of the programming for robot painting today is done offline as state-of-the-art programming systems offer integrated process simulations to optimize paint deposition, thickness, and coverage (Fig. 42.10).

42.2.4 Material Transfer Automation

Generally, industrial practice in robot workcell planning aims at finding a compromise between reducing the variation of the workpiece position and the cost of sensor systems to compensate for residual variation. Nearly all parts arrive at robot workcells in a repeatable manner, either being stored in special magazines, or by being

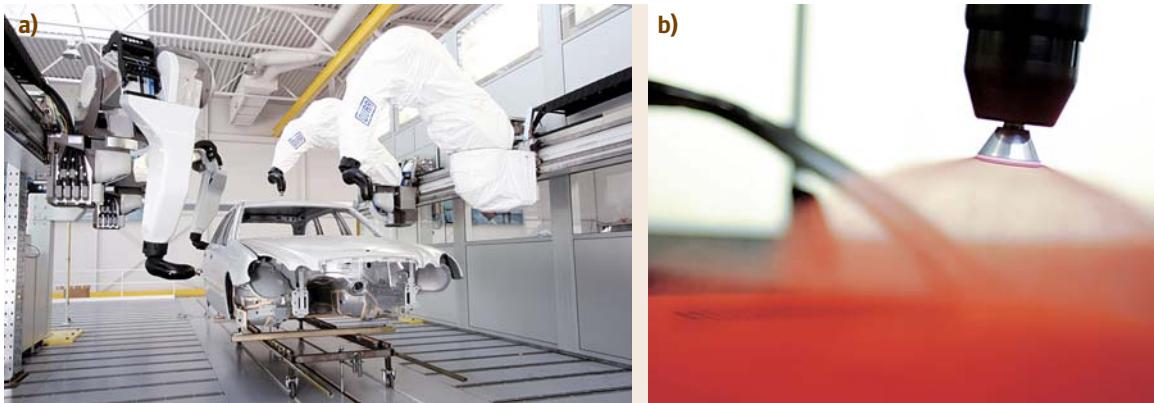

Fig. 42.10a,b Painting robots. (a) A multi-robot workcell for car body painting (b) High-speed rotating atomizer and charge. Painting robots. (a) are used for surface coating of car bodies and other parts. All current paint materials such as solvent-based paints, water-borne paints and powder can be applied. In car production, multiple robots work in parallel for optimal throughput and accessibility of the car body. Most of the programming which includes the synchronisation of the robots is performed offline. Paint guns are critical to the process quality. Figure (b) shows a Dürr EcoBell2 paint gun which atomizes the paint material at the edge of the rotating bell disk by centrifugal forces (by courtesy Dürr, Stuttgart)

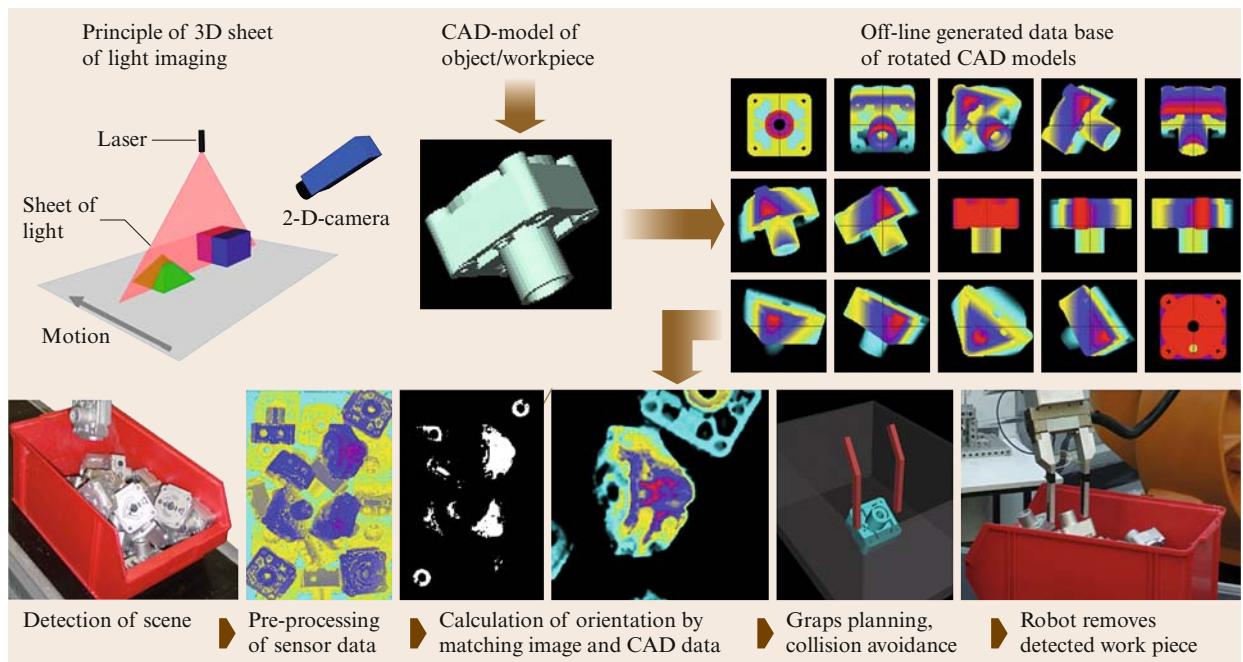

Fig. 42.11 Robot bin picking. A scene containing the objects is acquired by a 3-D sensor e.g. based on the laser triangulation principle. Beforehand this approach turns the CAD object virtually in discrete spatial angles in an off-line calculation. Feature histograms for each view are generated and stored in a database. A best match between actual feature histograms and the simulated sets of histograms determines the location of the object. A grasp has to be selected and a collision-free trajectory is generated. A typical cycle time of a location process is between 1 and 2 s

transported by vibrating devices that allow the parts to settle into a predictable orientation.

If randomly oriented in a carrier or a box, parts have to be properly located so that the robot can grasp them appropriately. This challenge in industrial robotics has been referred to as *bin-picking* and has been investigated by numerous researchers since the mid-1980s [42.17]. Even though an abundance of approaches has been presented a cost-effective standard solution has not been established yet [42.18].

Barely 10% of industrial robot installations in 2006 were sensor-equipped. However, it is expected that many

future robots will have standard embedded force-torque and vision sensors. This is a precondition for advanced vision for object identification and localization in manufacturing.

One method for determining random object locations using the object's computer-aided design (**CAD**) data starts with point clouds of a scene acquired by a three-dimensional (3-D) sensor (Fig. 42.11). A selection of 3-D sensors is described in Chap. 22. The **CAD** model has been virtually turned into discrete spatial angles in an offline calculation. Feature histograms for each view are generated and stored in a database with

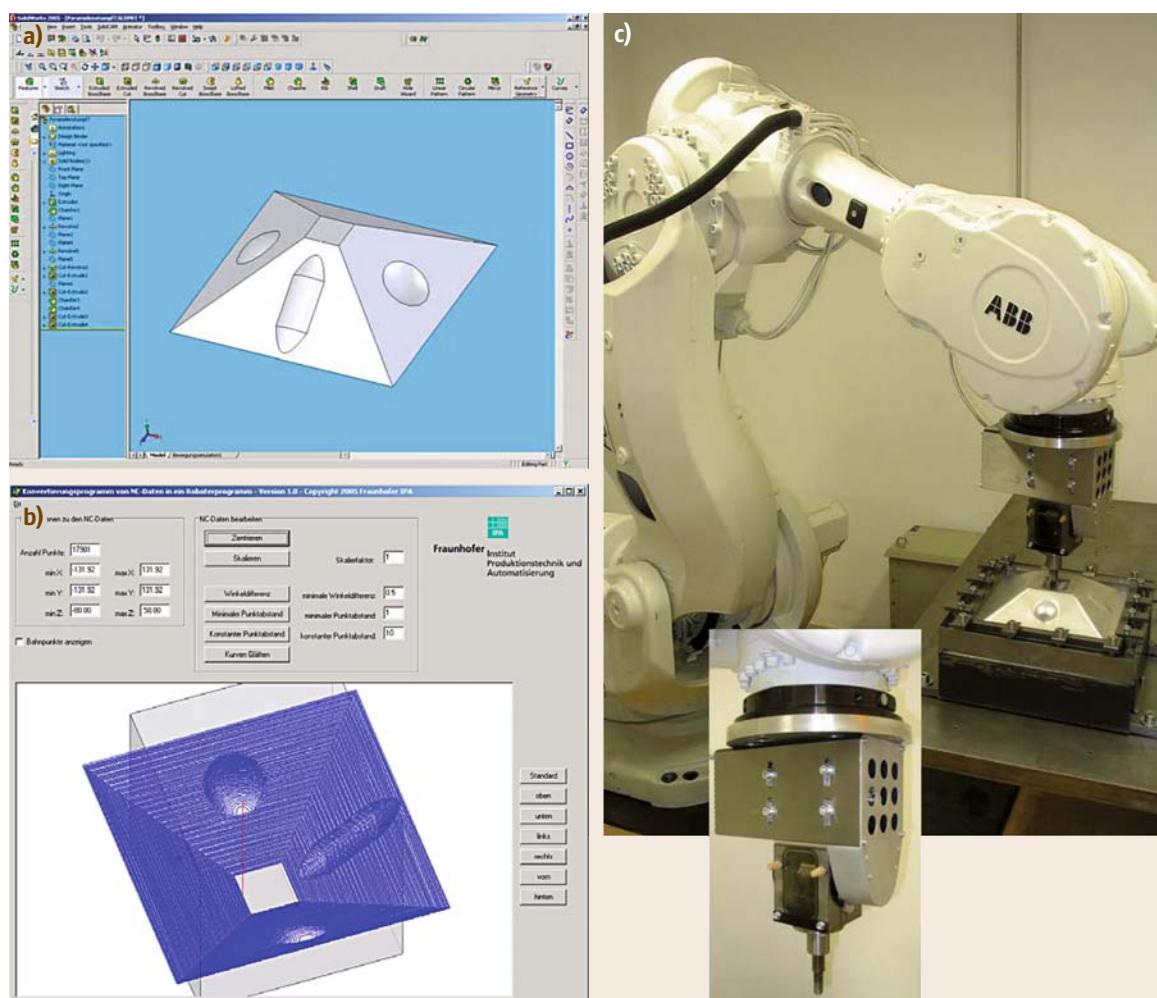

Fig. 42.12a–c Trajectory generation for incremental machining processes. In this example, the forming process of metal sheets is based on an oscillating stamp (amplitude 1 mm, 50 Hz frequency) which locally plastifies the metal in incremental steps. From the **CAD** model (a), the robot's trajectories are calculated offline on the basis of specific material models (b). Each line represents a part of the tool trajectory. (c) Shows a demonstrator robot workcell with the tool in detail

the given angular information (typically in 10° steps for all spatial angles).

A best-match process compares actual feature histograms with the simulated sets of histograms in the database. For the determined location of the object, a grasp has to be selected and a collision-free trajectory be generated. The latter steps can be quite critical as residual workpieces at the box bottom may constrain the robot's grasp and departing trajectory [42.19].

42.2.5 Machining

Compared to a milling machine or a lathe, standard robots possess much less stiffness (by a factor of 20–50 times), but much greater dexterity. A serial robot's stiffness is usually very anisotropic throughout its working space and may vary for a typical heavy duty model in the range 200–700 N/mm. Therefore, robots can machine workpieces (grinding, fettling, polishing etc.) provided that tool forces can be reduced to acceptable values for a given robot manipulator. This incremental approach to machining, particularly for cutting and forming, can produce good results. However, these sequential robot motions have to be generated automatically, which requires merging the process information with the workpiece geometry.

An example of a novel process that benefits from the robot's versatility in terms of programming, dexterity, and cost is the so-called incremental forming process of metal sheets. Without using any costly form, metal

sheets are clamped in a rigid frame and the robot produces a given 3-D contour by guiding a tool equipped with a high-frequency oscillating stamp (amplitude typically 1 mm at a frequency of 50 Hz) over the metal surface. The robot's trajectories are calculated from the CAD model on the basis of specific material models. The robot's program is generated and passed to the controller. One-off housings for machines, prototype panels or customized car panels can be economically produced using this method [42.20]. Figure 42.12 depicts the sequence of actions for automatically generating and executing the forming program.

42.2.6 Human–Robot Cooperation for Handling Tasks

Robots for human augmentation (force or precision augmentation) stretch from fully automated operation to acting as a servo-controlled balancer (see also Chap. 57). As an example: in a car drive train assembly the heavy gear box is grasped by the robot which balances it softly so the worker can insert it precisely into the housing (Fig. 42.13). Preprogrammed virtual walls give the worker a realistic feeling of constraints.

The central interface for the worker's tactile commands is a handle equipped with safety switches. These switches trigger the force-torque sensor that is attached to the robot's flange. Upon touching both safety switches (two-handed operation) the force-torque sensor is activated and the robot control is set to a safe

Fig. 42.13 Human–robot-cooperation for handling tasks. Inside a regular workcell which is secured by light curtains, the robot handles gear boxes at regular speed in fully automated mode. Upon approaching the light curtain at reduced speed, the worker grasps the safety switch which activates both the reduced-speed mode and the force-torque sensor. The worker guides the robot almost effortlessly by its handle so that the gear-box is balanced with precision into the rear axle frame for final assembly (Fraunhofer IPA, Stuttgart)

reduced end-effector speed (of some 50 mm/s). Thus, the sensor scales the applied force/torque information into a compliant robot motion. Obviously the physical human–robot cooperation has to obey safety precautions as the robot's and worker's workspaces overlap.

The ISO 10218-1:2006 standard specifies requirements and guidelines for the inherent safe design, protective measures, and information for use of industrial robots. It describes basic hazards associated with robots, and provides requirements to eliminate or adequately reduce the risks associated with these hazards. A novel element of this revised standard is the regulation of so-called collaborative operation, where the robot works in direct cooperation with a human within a defined workspace. Basically the collaborative operation depends on several criteria, which have to be met by the robot workcell [42.21]:

1. The hand-guiding equipment shall be located in the area of the end-effector.
2. The robot moves with safe reduced speed (less than 250 mm/s) and safe monitored position. This position monitoring shall be according to at least category 3 of ISO 13849, unless a risk assessment is performed and determines that a higher category is required [42.22, 23].
3. The robot must sense and keep a safe distance from the human. The distance relates to the attended

speed. The distance and speed monitoring shall be according to at least category 3 of ISO 13849, unless a risk assessment is performed and determines that another category is required.

If a robot's total power consumption can safely be limited to 80 W as well as its static impact forces to 150 N no additional sensor-based safety precautions are needed. Again, these conditions have to be secured by a risk assessment or security systems which comply with at least category 3 of ISO 13849 [42.21]. Currently, novel control algorithms, kinematic and actuator designs are being investigated to realize so-called intrinsically safe robots [42.24].

The described workcell complies with the ISO standard in such a way that the presence of the human is detected by activating both safety switches of the handle (first condition). The robot's built-in safe controller safely measures the end-effector's position and limits its velocity [42.25] (second condition). Meanwhile most of the robot manufacturers provide safe category 3 controllers. If the worker's presence in the workspace is not known (third condition, not applicable here) a safe sensor system has to detect safely the workers location according to category 3. Three-dimensional sensors meeting category 3 first appeared on the market in 2006, thus opening up a wide field of potential collaborative operations [42.26].

42.3 Kinematics and Mechanisms

The choice of mechanism, its kinematic properties, the computation methods used to determine joint motions, and the intended application of a robot manipulator are all closely related. The diagrams in Table 42.1 show several common types of robot mechanism.

With advances in the state of the art in kinematic algorithms and computer hardware processing capabilities, computation is much less of a constraint on mechanism choice than it was for early robot designers. The choice of mechanical structure of the robot depends mostly on fundamental mechanical requirements such as payload and workspace size. Considering a given level of cost, there is usually a tradeoff between workspace size and stiffness. To enable the robot to reach inside or around obstacles it is clearly advantageous to use an articulated mechanical design.

Considering also the stiffness and accuracy (in a practical sense considering what is reasonable to build), the picture is more complex. Each of the first three types in Table 42.1 we refer to as *serial kinematic machines (SKMs)*, while the last is a *parallel kinematic machine (PKM)*. To obtain maximum stiffness, again for a certain minimum level of cost, the end-effector is better supported from different directions, and here the PKM has significant advantages. On the other hand, if high stiffness (but not low weight and high dexterity) is the main concern, a typical computerized numerical control (CNC) machine (e.g., for milling) is identical in principle to the gantry mechanism. There are also modular systems with servo-controlled actuators that can be used to build both robots with purpose-designed mechanisms.

Table 42.1 Mechanical types of motions with different kinematic: Gantry is what a Cartesian coordinate robot is typically called, the **SCARA** is a *selective compliant articulated robot* (or *selective compliance assembly robot arm*, since the main application is planar assembly), the **Articulated** (all joints are rotary and placed in series after each other) robot is often referred to as an arm robot, and the **Parallel** is shown with prismatic joints, but can also have revolute joints such as the Delta robot (Fig. 42.5). Combinations are common

| Gantry | SCARA | Serial articulated | Parallel |

42.4 Task Descriptions – Teaching and Programming

We cannot instruct a robot in the same way that one would instruct a human worker how to carry out a task. With skilled workers knowing the applications, devices, processes, and the general requirements on the product to be manufactured, we would only need to summarize *what* needs to be done.

In practice, since it is difficult to encode much of the required background knowledge, we aim for programming principles that resemble instructing a (totally) unskilled worker, telling precisely *how* every aspect of the task is to be performed. That requires a much more explicit way of instructing the robot, but one which is

still human-friendly. More specifically, as a wish-list that we will come back to at the end of the chapter, we would like to teach robots by

- manually guiding the robot to the positions of interest, or even along the desired paths or trajectories if human accuracy is enough
- having simple ways to make use of CAD data whenever available
- using different complementary modalities (paths of communication between the human and the robot), such as speech and gestures
- choreographing the task movements, for instance loops and conditions, without requiring extensive programming competencies
- means of describing acceptable variation, e.g., as expected or normal deviations from the nominal path
- specification of how external sensing should be used for new types of motions or for handling unknown variations

Initially, mainly during the 1970s and 1980s, there were some painting robots that could be programmed by manual guidance. This was possible due to the following abilities

- Applications such as painting permit the use of a lightweight arm, including the end-effector, possibly balanced with respect to gravity if needed.
- The accuracy requirements were (compared to today) modest so it was possible to use back-drivable drive trains and actuators, and the definition of the motions could then be done manually by the operator moving the end-effector along the path. The recorded poses, including the timing/speed information, then define the programmed motion.
- Since no inverse kinematics was needed during programming or real-time operation, it was not a problem from a computing point of view to use arm kinematics without singularities in the workspace.
- The requirements of optimality of painting motions were also modest, compared to recent years when environmental conditions (for nature and workers) calls for minimal use of paint.

It is often referred to as an inevitable problem that there are singularities to be handled within the workspace. However, to simplify the kinematics and its inverse from a software point of view (e.g., during the 1980s considering the power of the microprocessors and algorithms available at that time), robots were actually designed to have simple (to compute) inverse kinematics. For instance, the wrist orientation was decoupled

from the translation by the arm by using wrist axes that intersected with the arm axes. The resulting singularities within the workspace could be managed by restrictions on wrist orientations, but an unfortunate implication was that robot arms were no longer back-drivable (close to the singularities) when designs were (due to engineering and repeatability requirements) adopted to standard industrial controllers. Then with the development of microprocessor-based industrial controllers and the definition of motions based on jogging (manual moves by for instance using a joystick) and CAD data, still lacking efficient and robust techniques for human-like instructions (speech, gestures, etc.), the means of robot programming became closer to computer programming (extended with motion primitives).

Robot programming languages and environments have traditionally been separated into online programming (using the actual robot in situ) and offline programming (using software tools without occupying the robot). With the increasing power of offline programming tools, their emerging ability to connect to the physical robot, and the increasing level of software functions that are embedded into the robot control system, online programming is now unusual, except to verify and manually adjust programs generated offline. Still, of course, it is economically important to minimize downtime for robot programming, and advanced sensor-based applications may be too hard to develop without access to the true dynamics of the physical workcell for fine-tuning. Nevertheless, robot languages and software tools must provide for both methods of programming.

Even though robot languages from different manufacturers look similar, there are many semantic differences that have to do with both the meaning when programs are running (the robot performing its operations) and the way the robot is instructed. The need to ensure that existing robot programs can operate with replacement robots and controllers, and also to make use of existing knowledge in robot programmers and incorporated into offline programming software, requires manufacturers to continue to support their original proprietary languages. Features such as backward execution (at least of motion statements) and interactive editing during interpretation by the robot (in combination with restrictions to make the programming simpler) also make robot languages different from conventional computer programming languages.

During the last decade and in current developments, the trend has been to focus on the tool (robot end-effector) and on the process knowledge needed for the manufacturing process, and to let the operator express

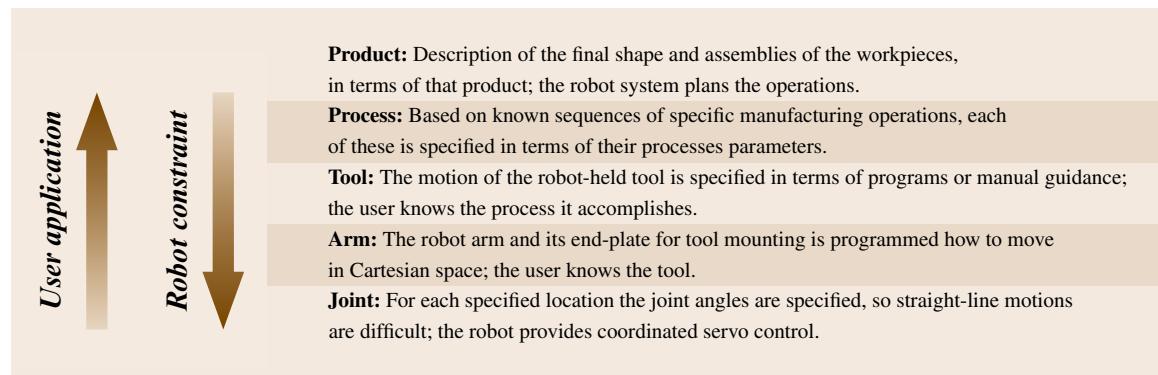

Table 42.2 Example: Simple pick-and-place operation with a typical industrial robot controller

ABB Rapid (a proprietary language) program: positions obtained from a charge-coupled device (CCD) camera; end-effector tool is pneumatic. MoveJ denotes joint-space motion and MoveL denotes linear/Cartesian motion. Basically there are four arguments for such motions: target position (here relative, by use of the offset function), the maximum motion speed (here using predefined v-constants with the number specifying the desired speed in mm/s along the path), the desired accuracy before continuing (fine referring to no corner blending at all), and the tool being used (including frames, inertia, etc., here in the tool0 data record).

```

PROC cam_pick()
MoveJ app_point, v1500, z25, tool0;           // Preposition near the working table (using a 25 mm tolerance)
MoveJ Offs(camera11,x,y,-30), v1500, fine, tool0; // Approach 30 mm above the object object, position x, y from webcam
temp1:=CRobT();                                // Acquire current position
MoveL Offs(temp1,0,0,-38), v400, fine, tool0;    // Move to object: account for suction cup flexibility (8 mm)
Set DO08;                                       // Vacuum ON, pick object
WaitTime 1.5;                                  // Wait 1.5 s
MoveL Offs(temp1,0,0,10), v400, fine, tool0;     // Move up 10 mm
MoveJ app_point, v1500, z25, tool0;             // Move "fly-by" to box with 25 mm tolerance
MoveJ place_box, v1500, fine, tool0;            // Move to box position
Reset DO08;                                     // Vacuum OFF, release object
Set DO07;                                       // Blow ON
WaitTime 0.8;                                  // Wait 0.8 s
Reset DO07;                                     // Blow OFF
ENDPROC

```

Table 42.3 Robot-related centricity, ranging from a high-level view of the work to be accomplished in terms of the product to manufacture, to a low-level robot motion view that, in practice, constraints what manufacturing operations can be performed

the robot task in such terms. This development results in a need for an increased level of abstraction to simplify the programming, reflecting the fact that the so-called robot programmer knows the production process very well, but has quite limited programming skills. To understand why such a high level of abstraction has not come into widespread usage, we may compare this with

the early days of industrial robotics when there was no kinematics software built into the controllers, and hence the robots were programmed via joint-space motions. (Kinematics here deals with the relation between robot motors/joints and the end-effector motions.)

Built-in inverse kinematics permits tool motion to be specified in Cartesian coordinates, which is clearly

a great simplification in many applications. That is, the robot user could focus more on the work to be carried out by the robot and less on the robot itself. However, robot properties such as joint limits cannot be neglected. Until the beginning of the 1990s, robots did not follow programmed trajectories very well at high speeds or accelerations, and full accuracy could only be achieved at low speed. Modern robot systems with high-performance model-based motion control perform their tasks with much greater accuracy at high speed due to model based control features, see Chap. 6 [42.27, 28].

There are increasing opportunities to raise the level of abstraction to simplify the use of robots even more by encoding more knowledge about the robot, tools, the process, and workcells into control systems.

Example 42.1:

A machine part consisting of plates and pipes of aluminium is to be manufactured, and there is robot equipment available for production of this (and other) types of workpieces.

- A *product*-centric system would generate configurations and robot programs, and instruct the operator for whatever manual assistance that might be needed (e.g., clamping and fixturing). The system would determine the welding data such as the type of welding and how many passes for each seam.
- A *process*-centric system would instead accept input in terms of the welding parameters to use, including the order of the welds. The system would select input signals to the process equipments (such as what output voltage the robot controller should set such that the welding will be done with a certain current), and robot programs specifying the motions of the weld pistol would be generated.
- A *tool*-centric way of programming would require the operator to set up the process manually by configuring the equipment in terms of their native settings, and appropriate tool data would be configured such that the robot controller can accomplish the programmed motions, which are specified by giving coordinates and motions data referring to the end-effector.
- An *arm*-centric system is similar to the tool-centric approach in that Cartesian and straight-line motions can be (and need to be) explicitly specified/programmed by the programmer, but extra work is needed since the robot does not support a general tool frame.
- A *joint*-centric style would be needed if one of the very early robot systems is being used, requiring

a straight line to be programmed by lots of joint-space poses close to each other.

Thus, the question is, are you programming robot joint servos to make the robot provide a service for you, are you programming/commanding an arm how to move a tool, is it the tool that is made programmable by means of the robot, is it manufacturing services that are ordered by specifying the desired process parameters, or is it an intelligent system that simply can produce your product?

As a final goal related to the product-centric view, so-called task-level programming is desirable. This has been a goal since the 1980s, and implicitly also since the very beginning of robotics. It would mean that the user simply tells the robot what should be done and the robot would know how to do it, but it would require extensive knowledge about the environment and so-called machine intelligence. The need for extensive modeling of the environment of the robot is well known. Sensing of the environment is costly, but in an industrial environment it should only be needed occasionally. Modeling has to encompass full component dynamics and the limitations of the manufacturing process. With these difficulties, task-level programming is not yet achievable in practice.

As indicated in the application examples, it is now common practice to generate robot programs from geometric data in **CAD** files. That is, the **CAD** application could be the environment used for specifying how the robot should perform the required operations on the specified parts. This is not quite task-level programming since human operators do the overall planning. **CAD** software packages are powerful 3-D tools and are now very common among manufacturing companies. Consequently, using those tools for robot programming is desirable since the operator may start the offline programming of the necessary manufacturing operations using the 3-D model of the product. There are two possible approaches:

1. Use the **CAD** interface to parameterize predefined robot programs, tailoring their behavior by using geometric information [42.16, 29]. This means defining motions, adding process parameters, deciding on what to do with data from devices, etc.
2. Generate the entire robot code from the information extracted from a **CAD** file, including the interface code to handle cell devices [42.30, 31].

The example presented in Fig. 42.14 was designed to run from the **CAD** package INVENTOR [42.32],

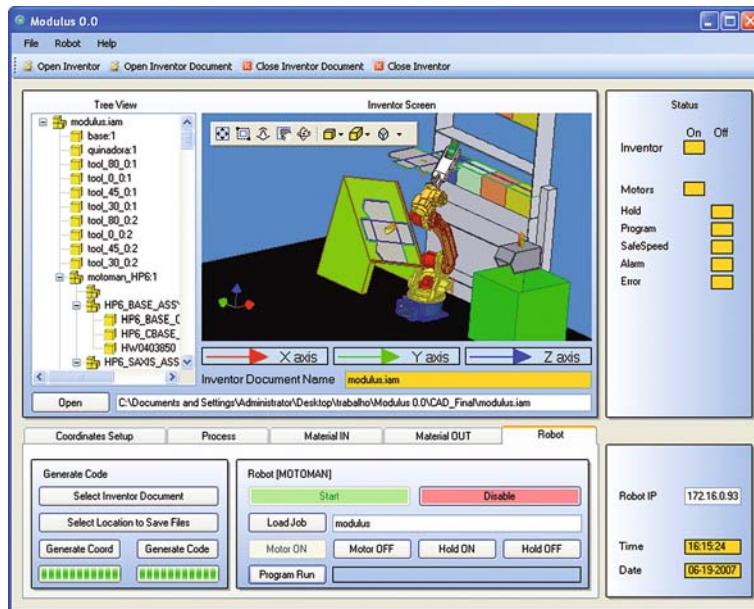

Fig. 42.14 Human-user interface for the CAD programming environment

from Autodesk. Basically it enables a user to program a workcell composed by a robot and a bending machine. The robot is used to feed and handle the sheets of metal to the bending machine, and to palletize the final product. The depicted pro-

gramming interface is an illustrative example of the possibilities, while there are a number of major vendors of CAD or offline programming system providing similar features in current and upcoming products.

42.5 End-Effectors and System Integration

It is interesting to note that connecting different workcell devices with each other, and integrating them into a working system, is hardly mentioned in the robotics literature. Nevertheless, in actual nontrivial installations, this part typically represents half of the cost of the installation. The automation scenario includes all the problems of integrating computers and their peripherals, plus additional issues that have to do with the variety of (electrically and mechanically incompatible) devices and their interaction with the physical environment (including its inaccuracies, tolerances, and unmodeled physical effects such as backlash and friction). The number of variations is enormous so it is often not possible to create reusable solutions. In total this results in a need for extensive engineering to put a robot to work. This engineering is what we call system integration.

Carrying out system integration according to current practice is not a scientific problem as such (although how to improve the situation is), but the obstacles it comprises

form a barrier to applying advanced sensor-based control for improved flexibility, as is needed in short-series production. In particular, in future types of applications using external sensing and high-performance feedback control within the workcell, system integration will be an even bigger problem since it includes tuning of the feedback too.

For long production runs, the engineering cost of system integration is less of a problem since its cost per manufactured part is small. On the other hand, the trend towards shorter series of customized products, or products with many variants that are not kept in stock, calls for high flexibility and short changeover times. Flexibility in this context refers to variable product variants, batch sizes, and process parameters. In particular this is a problem in small and medium-sized productions, but the trend is similar for larger enterprises as flexibility requirements are continuously on the rise. One may think that simply by using well standards for in-

Table 42.4 Stages of system integration, typically carried out in the order listed

| | |
|---------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Physical | Selecting equipment based on dimensioning for mechanical size, load, and stress Mechanical interfacing (locations, adapter plates, etc.) Electrical power supply (voltages and currents for robots, effectors, feeders, etc.) Connections for analog signals (shielding, scaling, currents, binary levels, etc.) |
| Communication | Interconnections for single-bit digital I/O Byte-wise data communication, including latencies and bit rates Transfer of byte sequences |
| Configuration | Configuration of messages between interacting devices Establishment of services Tuning for performance and resource utilization |
| Application | Definition of application-level functions/services |
| Task | Application programming, using the application-level services |

put/output (I/O) and well-defined interfaces, integration should be just a matter of connecting things together and run the system. Let us examine why this is not the case.

Example 42.2 Step 1 of 3:

Simple pick-and-insert (assembly) operation. As a first step let us consider only one robot performing pick-and-place from/to known locations, and assume it is a well-known object such that we can use one specific type of gripper (such as a gripper, in this case based on a vacuum cup). We then only need one digital output from the robot controller. Let us call this output GRIPPER (i. e., the name of the number of the output) and the values GRASP and RELEASE for the high and low signals depending on the sign of the hardware connection. An example of a robot program can be found in the previous section.

Of course the object-oriented software solution would be to have a gripper class with operations grasp

and release. That would be appropriate for a robot simulator in pure software, but for integration of real systems such encapsulation of data (abstract data types) would introduce practical difficulties because:

- values are explicit and accomplished by external (in this case) hardware, and for testing and debugging we need to access and measure them,
- online operator interfaces permit direct manipulation of values, including reading of output values. The use of functions of object methods (so-called set:ers and get:ers) would only complicate the picture; maintaining consistency with the external devices (such as the definitions of the constants GRIPPER, GRASP, and RELEASE) would be no simpler.

Already in this toy example we can see that the user I/O configuration depends on both connected external devices (the gripper), and also on what I/O modules (typically units on some kind of field bus) that are in-

Fig. 42.15 Force controlled robot with multiple tools: force-torque sensor (JR3), robotic hand (Barrett), CCD USB camera (uEye) and tool-changer (ATI). This type of flexible gripper is not (yet) common in industry, where simple 1 DOF grippers with fingers tailored to the product are normally used

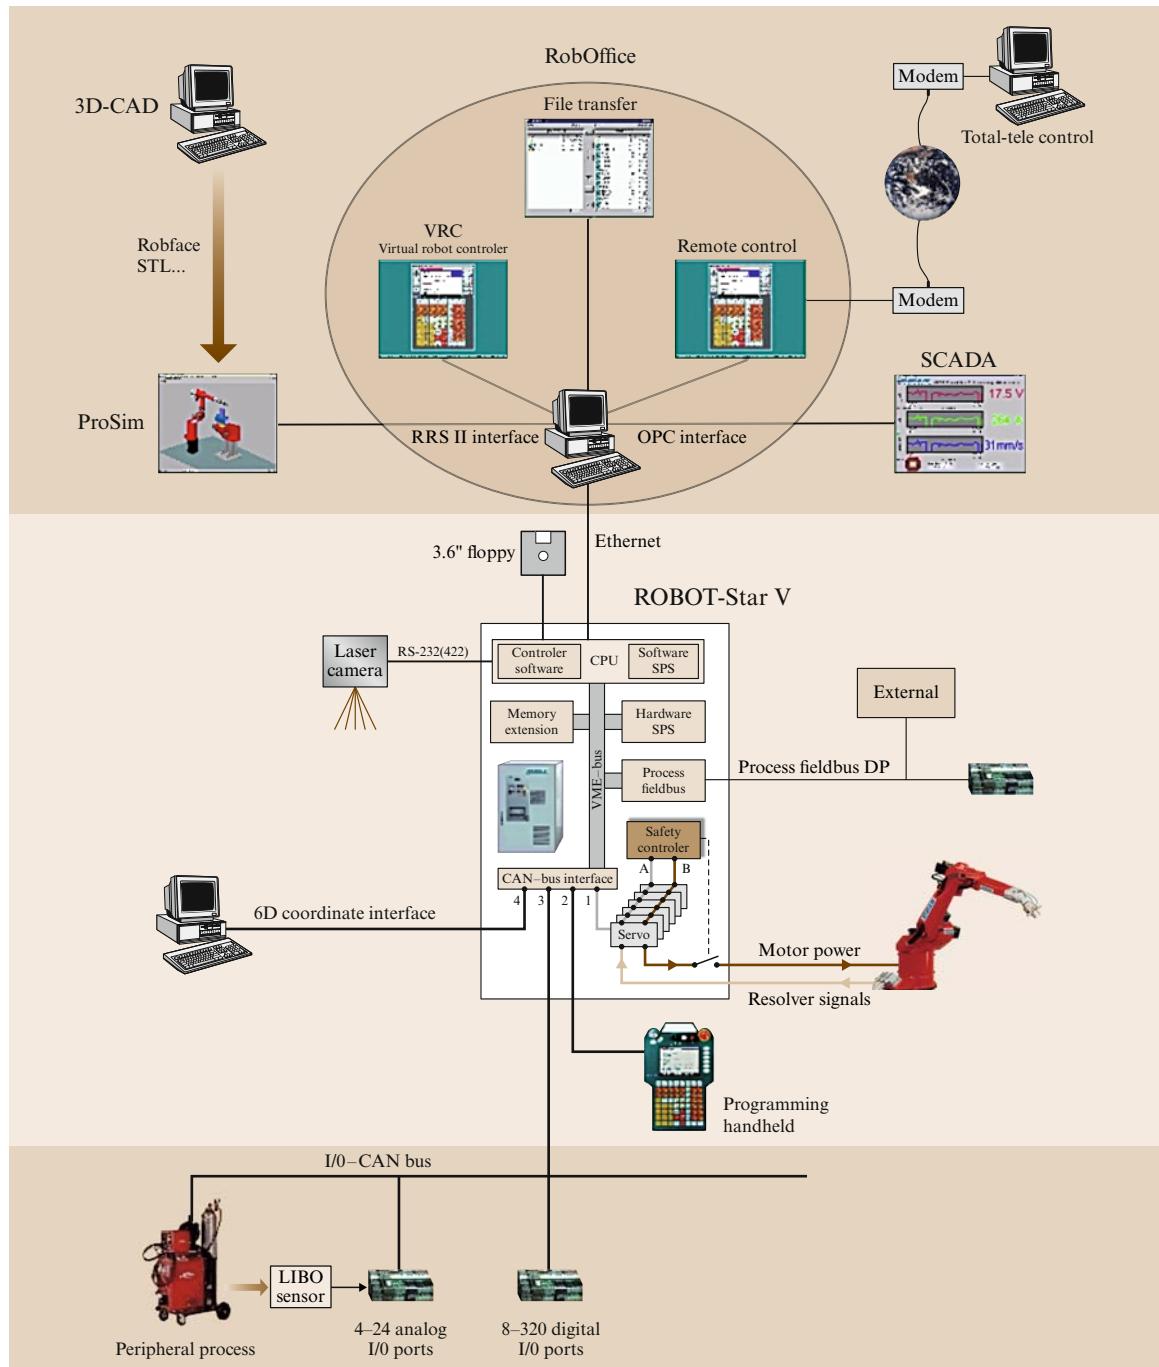

Fig. 42.16 Control modules and interfaces (Reis) on different levels, from low-level peripheral interfaces to high-level factory interfaces. The robot controller contains the middle part. The vertical integration in combination with heterogeneous hardware forms a major challenge (by courtesy Reis Robotics, Obernburg)

stalled in the robot controller (which may be subject to change when another task is given to the robot). Returning to our example, selecting modules and interfaces extends to the items of Table 42.4, where the application and task levels relate to robot programming and the research issue of how to simplify system integration, respectively.

Example 42.2 Step 2 of 3:

Simple pick-and-insert (assembly) operation. Assume we want to use a probe to detect the type and the location of the workpiece, that we need several different types of grippers depending on what object we should handle, and that the place operation needs to be a force-controlled insertion. Additionally, since we need different tools for different operations, we need a tool exchanger.

With these additional requirements we need more mechanical interfaces, the load/weight/performance considerations are more difficult (the weight of the tool exchanger and adaptor plate decreases the net payload for the grasped objects), and several more electrical interfaces need to be included.

Equipment examples are shown in Fig. 42.15, an example that extends the pick-and-insert case to include unknown positions and a gripper that can grab several types of pieces (including a wrist force sensor and force feedback in the robot fingers); details concerning robot programming and device configurations are omitted for brevity. In the presented example a three-finger robotic hand [42.33] was used to illustrate that these advanced and programmable tools are finding their way into industrial applications [42.34], for example, the hand used here has position and force-sensing capabilities. When grasping an object, the finger base and tip links move together. If a base link encounters an object it stops, while

the tip link keeps moving until it makes contact with the object as well. If the tip links encounter an object first, the whole finger assembly stops moving.

The example depicted in Fig. 42.15 shows a setup where the robot can pick the workpiece from an unknown position; the working pieces are identified using a **CCD** camera that returns the number of pieces and their position. The robot is then commanded to pick one and update its information from the cell [42.30, 35]. This example uses two tasks: one to receive remote commands, and the other to implement the gripper and camera services.

Example 42.2 Step 3 of 3:

Simple pick-and-insert (assembly) operation. As a final requirement, to monitor the quality of the assembly operation, assume that we want to have slip detection embedded into the gripper and that we need logging of the force control signal. The production statistics should be provided on the overall plant level of the factory.

These additional requirements call for integration of low-level devices with high-level factory control system, and is hence called *vertical integration*, whereas integration within (for instance) the workcell level is called *horizontal integration*.

Lack of self-descriptive and self-contained data descriptions that are also useful at the real-time level further increases the integration effort since data interfaces/conversions typically have to be manually written. In some cases, as illustrated in Fig. 42.16, there are powerful software tools available for the integration of the robot user level and the engineering level [42.36, 37]. The fully (on all levels) integrated and nonproprietary system, sometimes referred to as a *digital factory*, still is a challenge, particularly for small and medium-sized productions [42.38, 39].

42.6 Conclusions and Long-Term Challenges

The widespread use of robots in standard, large-scale production such as the automotive industry, where robots (even with impressive performance, quality, and semiautomatic programming) perform repetitive tasks in very well-known environments, for some time resulted in the common opinion that *industrial robotics is a solved problem*. However, these applications comprise only a minor part of the industrial work needed in any wealthy society, especially considering the number of companies

and the variety of applications. The use of robots in small and medium-sized manufacturing is still tiny.

Global prosperity and wealth requires resource-efficient and human-assistive robots. The challenges today are to recognize and overcome the barriers that are currently preventing robots from being more widely used.

Taking a closer look at the scientific and technological barriers, we find the following challenges:

- *Human-friendly task specification*, including intuitive ways of expressing permitted/normal/expected variations. That is, there are many upcoming and promising techniques for user-friendly human–robot interaction (such as speech, gestures, manual guidance, and so on), but the focus is still on specification of the nominal task (see Chaps. 58 and 59). The foreseen variations, and the unforeseen variations experienced during robot work, are more difficult to manage. When instructing a human he/she has an extensive and typically implicit knowledge about the work and the involved processes. To teach a robot, it is an issue both how to realize what the robot does not know, and how to convey the missing information efficiently.
- *Efficient mobile manipulation*. Successful implementations and systems are available for both mobility and for manipulation, but accomplished in different systems and using different types of (typically incompatible) platforms. A first step would be to accomplish mobile manipulation at all, including the *combination* of legged locomotion see Chap. 56 (for stairs and rough terrain), autonomous navigation (with adaptive but predictable understanding of constraints), dexterous manipulation, and robust force/torque interaction with environments (that have unknown stiffness). As a second step, all this needs to be done with decent performance using reasonably priced hardware, and with interfaces according to the previous item. Thus, we are far from useful mobile manipulation.
- *Low-cost components including low-cost actuation*. Actuation of high-performance robots represent about a third of the overall robot cost, and improved modularity often results in a higher total hardware cost (due to less opportunities for mechatronic optimization). On the other hand, cost-optimized (with respect to certain applications) systems result in more-specialized components and smaller volumes, with higher costs for short-series production of those components. Since future robotics and automation solutions might provide the needed cost efficiency for short-series customized components, we can interpret this as a boot-strapping problem, involving both technical and business aspects. The starting point is probably new core components that can fit into many types of systems and applications, calling for more mechatronics research and synergies with other products.
- *Composition of subsystems*. In most successful fields of engineering, the principle of superposition holds,

meaning that problems can be divided into subproblems and that the solutions can then be superimposed (added/combined) onto each other such that the total solution comprises a solution to the overall problem. These principles are of key importance in physics and mathematics, and within engineering some examples are solid-state mechanics, thermal dynamics, civil engineering, and electronics. However, there is no such thing for software, and therefore not for mechatronics (which includes software) or robotics (programmable mechatronics) either. Thus, composition of unencapsulated subsystems is costly in terms of engineering effort.

Even worse, the same applies to encapsulated software modules and subsystems. For efficiency, system interconnections should go directly to known (and hopefully standardized) interfaces, to avoid the indirections and extra load (weight, maintenance, etc.) of intermediate adapters (applying to both mechanics for end-effector mounting and to software). Interfaces can be agreed upon, but the development of new versions typically maintains backward compatibility (newer devices can be connected to old controller), while including the reuse of devices calls for mechanisms for forward compatibility (automatic upgrade based on meta information of new interfaces) to cover the case that a device is connected to a robot that is not equipped with all the legacy or vendor-specific code.

- *Embodiment of engineering and research results*. Use or deployment of new technical solutions today still starts from scratch, including analysis, understanding, implementation, testing, and so on. This is the same as for many other technical areas, but the exceptional wide variety of technologies involved with robotics and the need for flexibility and upgrading makes it especially important in this field. Embodiment into components is one approach, but knowledge can be applicable to engineering, deployment, and operation, so the representation and the principle of usage are two important issues. Improved methods are less useful if they are overly domain specific or if engineering is experienced to be significantly more complicated. Software is imperative, as well as platform and context dependent, while know-how is more declarative and symbolic. Thus, there is still a long way to go for efficient robotics engineering and reuse of know-how.
- *Open dependable systems*. Systems need to be open to permit extensions by third parties, since there is no way for system providers to foresee all upcom-

ing needs in a variety of new application areas. On the other hand, systems need to be closed such that the correctness of certain functions can be ensured. Extensive modularization in terms of hardware and supervisory software makes systems more expensive and less flexible (contrary to the needs of openness). Highly restrictive frameworks and means of programming will not be accepted for widespread use within short-time-to-market development. Most software modules do not come with formal specification, and there is less understanding of such needs. Thus, systems engineering is a key problem.

- *Sustainable manufacturing.* Manufacturing is about transformation of resources into products, and productivity (low cost and high performance) is a must.

For long-term sustainability, however, those resources in terms of materials and the like must be recycled. In most cases this can be achieved by crushing the product and sorting the materials, but in some cases disassembly and automatic sorting of specific parts are needed. There is therefore a need for robots in recycling and demanufacturing. Based on future solutions to the above items, this is then a robot application challenge.

An overall issue is how both industry and academia can combine their efforts such that sound business can be combined with scientific research so that future development overcomes the barriers that are formed by the above challenges.

Underwater

43. Underwater Robotics

Gianluca Antonelli, Thor I. Fossen, Dana R. Yoerger

This chapter deals with the main underwater robotic topics. First, a brief introduction showing the constantly expanding role of marine robotics in oceanic engineering is given; this section also contains some historical backgrounds. Most of the following sections strongly overlap with the corresponding chapters presented in this handbook; hence, to avoid useless repetitions, only those aspects peculiar to the underwater environment are discussed, assuming that the reader is already familiar with concepts such as fault detection systems when discussing the corresponding underwater implementation. The modeling section is presented by focusing on a coefficient-based approach capturing the most relevant underwater dynamic effects. Two sections dealing with the description of the sensor and the actuating systems are then given. Autonomous underwater vehicles require the implementation of mission control system as well as guidance and control algorithms. Underwater localization is also discussed. Underwater manipulation is then briefly approached. Fault detection and fault tolerance, together with the

coordination control of multiple underwater vehicles, conclude the theoretical part of the chapter. Two final sections, reporting some successful applications and discussing future perspectives, conclude the chapter.

43.1 The Expanding Role of Marine Robotics in Oceanic Engineering

The world's oceans cover 2/3 of the Earth's surface and have been critical to human welfare throughout history. As in ancient times, they enable the transport of goods between nations. Presently, the seas represent critical sources of food and other resources such as oil and gas. In the near term, we may soon see the emergence of offshore mining for metals as well as the exploitation of gas hydrates. Conversely, the ocean can also threaten human safety and damage infrastructure through natural phenomena such as hurricanes and tsunamis.

Our scientific understanding of the deep sea is expanding rapidly through the use of a variety of

technologies. The first scientific explorations were conducted primarily through the use of diving and human-occupied submersibles, complemented by a variety of other technologies such as towed or lowered instruments, trawls, dredges, autonomous seafloor instruments, and deep-sea drilling. More recently remotely operated and autonomous vehicles have begun to revolutionize seafloor exploration, often returning superior data at reduced costs. In the near future, seafloor observatories linked by fiber-optic cables and satellites will return massive amounts of data from coastal and deep-sea sites. These observations will complement those

Fig. 43.1 The ROV Jason 2 (courtesy of the Woods Hole Oceanographic Institute, <http://www.whoi.edu>)

from conventional expeditionary investigations, and will require teleoperated or robotic intervention during installation and for service. An example of a remotely operated vehicle developed for the scientific study of the seafloor is the Jason 2 vehicle developed at the Woods Hole Oceanographic Institution (shown in Fig. 43.1), and a list of remotely operated vehicles for scientific exploration appears in Table 43.1 (the last vehicle in the table, Kaiko, was lost several years ago).

Offshore oil and gas installations are presently serviced almost exclusively by remotely operated vehicles (ROVs), physically connected via a tether to receive power and data, with human divers used only for the shallowest installations. Subsea systems require extensive work capability during installation, and need frequent inspection and intervention to support drilling operations, actuate valves, repair or replace subsea components, and to accomplish a variety of tasks required to maintain production rates and product quality. The trend toward robotic and teleoperated subsea intervention is certain to continue as offshore oil and gas production moves into deeper waters, and economic considerations push key production steps from surface platforms to the seafloor. Remotely operated manipulators enable these systems to perform complex tasks such as debris removal, cleaning using abrasive tools, and to operate a variety of nondestructive testing tools. The effectiveness of using ROVs decreases with depth mainly due to the cost increase and the difficulties of handling the long tether.

Autonomous underwater vehicles (AUVs) are free-swimming unoccupied underwater vehicles that can overcome the limitations imposed by ROV tethers for some tasks. Such vehicles carry their own energy supplies (presently batteries, perhaps fuel cells in the future) and communicate only through acoustics and perhaps optical links in the near future. Limited communications require these vehicles to operate independently of continuous human control, in many cases the vehicles operate completely autonomously. AUVs are currently used for scientific survey tasks, oceanographic sampling, underwater archeology and under-ice survey. Military applications, such as mine detection and landing site survey, are presently operational, and more ambitious applications such as long-term undersea surveillance are in engineering development. Presently, AUVs are incapable of sampling or manipulations tasks like those done routinely by ROVs, as typical work environments tend to be complex and challenging even to skilled human pilots.

Today, approximately 200 AUVs are operational, many of them experimental. However, they are maturing rapidly. Recently several companies now offer commercial services with AUVs. As an example, for the oil and gas industry the cost reduction of a survey performed with an AUV instead of a towed vehicle is up to 30% and the data quality is generally higher. Likewise, commercial manufacturers in several countries now offer turnkey AUV systems for specific, well-defined tasks. Currently, remotely operated manipulators are standard

equipment for most ROVs, while on the contrary autonomous manipulation is still a research challenge; the two projects SAUVIM [43.1] and ALIVE [43.2] were devoted to studying this control problem.

43.1.1 Historical Background

Boats have been used by humans since the start of recorded history, but vehicles able to go under water are more recent. Perhaps the first recorded idea of an underwater machine came from Aristotle; according to legend he built the: *skaphe andros* (boat-man) that allowed Alexander the Great (Alexander III of Macedonia, 356–323 BC) to stay submerged for at least half a day during the war of Tiro in 325 BC. This is probably unrealistic; if true it would precede Archimedes' law, which was first articulated in approximately 250 BC. Leonardo Da Vinci may have been the first to design an underwater vehicle. His efforts were recorded in the *Codice Atlantico (Codex Atlanticus)*, written between 1480 and 1518. Legends say that Leonardo worked on the idea of an underwater military machine but he de-

stroyed the results as he judged them to be too dangerous. The first use of feedback theory for marine control was probably the Northseeking device, patented in 1908, that used gyroscopic principals to develop the first autopilot [43.3]. From that point on, the use of feedback theory in marine control grew continuously; it is interesting to notice that the proportional–integral–derivative (PID) control commonly used today in numerous industrial applications was first formally analyzed in 1929 by Minorsky [43.4]. The first remotely operated underwater vehicle, POODLE, was built in 1953, and the ROV evolved through the 1960s and 1970s, mostly for military purposes. In the 1980s ROVs became established for use in the commercial offshore industry and began to emerge for scientific applications. The first tetherless, autonomous vehicles were built for experimental purposes in the 1970s. Currently, AUVs are becoming increasingly commonplace for scientific, military, and commercial applications. Turnkey AUV systems for a range of tasks are available from commercial vendors, and AUV services can be acquired from a number of companies [43.5].

43.2 Underwater Robotics

43.2.1 Modeling

A rigid body is completely described by its position and orientation with respect to a reference frame Σ_i , $O_i - xyz$ that is supposed to be Earth-fixed and inertial. Let us define $\eta_1 \in \mathbb{R}^3$ as

$$\eta_1 = (x \ y \ z)^\top,$$

the vector of the body position coordinates in an Earth-fixed reference frame. The vector $\dot{\eta}_1$ is the corresponding time derivative (expressed in the Earth-fixed frame). If one defines

$$v_1 = (u \ v \ w)^\top$$

as the linear velocity of the origin of the body-fixed frame Σ_b , $O_b - x_b \ y_b \ z_b$ with respect to the origin of the Earth-fixed frame expressed in the body-fixed frame (from now on: body-fixed linear velocity) the following relation between the defined linear velocities holds

$$v_1 = R_I^B \dot{\eta}_1, \quad (43.1)$$

where R_I^B is the rotation matrix expressing the transformation from the inertial frame to the body-fixed frame.

Let us define $\eta_2 \in \mathbb{R}^3$ as

$$\eta_2 = (\phi \ \theta \ \psi)^\top$$

the vector of body Euler angle coordinates in a Earth-fixed reference frame. In the nautical field those are commonly named roll, pitch, and yaw. Yaw is defined as rotation around the z axis of the fixed frame; pitch is defined as rotation around the y axis resulting after the yaw movement; and roll is defined as rotation around the x axis resulting after both yaw and pitch movements. The vector $\dot{\eta}_2$ is the corresponding time derivative (expressed in the inertial frame). Let us define

$$v_2 = (p \ q \ r)^\top$$

as the angular velocity of the body-fixed frame with respect to the Earth-fixed frame expressed in the body-fixed frame (from now on: body-fixed angular velocity). The vector $\dot{\eta}_2$ does not have a physical interpretation and it is related to the body-fixed angular velocity by a proper Jacobian matrix

$$v_2 = J_{k,o}(\eta_2) \dot{\eta}_2. \quad (43.2)$$

Table 43.2 Common notation for the motion of a marine vehicle

| | | Forces and moments | v_1, v_2 | η_1, η_2 |
|------------------------------|-------|--------------------|------------|------------------|
| Motion in the x -direction | Surge | X | u | x |
| Motion in the y -direction | Sway | Y | v | y |
| Motion in the z -direction | Heave | Z | w | z |
| Rotation about the x -axis | Roll | K | p | ϕ |
| Rotation about the y -axis | Pitch | M | q | θ |
| Rotation about the z -axis | Yaw | N | r | ψ |

The matrix $\mathbf{J}_{k,o} \in \mathbb{R}^{3 \times 3}$ can be expressed in terms of the Euler angles as

$$\mathbf{J}_{k,o}(\eta_2) = \begin{pmatrix} 1 & 0 & -s_\theta \\ 0 & c_\phi & c_\theta s_\phi \\ 0 & -s_\phi & c_\theta c_\phi \end{pmatrix}, \quad (43.3)$$

where c_α and s_α are abbreviations for $\cos(\alpha)$ and $\sin(\alpha)$, respectively. The matrix $\mathbf{J}_{k,o}(\eta_2)$ is not invertible for every value of η_2 . In detail, it is

$$\mathbf{J}_{k,o}^{-1}(\eta_2) = \frac{1}{c_\theta} \begin{pmatrix} 1 & s_\phi s_\theta & c_\phi s_\theta \\ 0 & c_\phi c_\theta & -c_\theta s_\phi \\ 0 & s_\phi & c_\phi \end{pmatrix}, \quad (43.4)$$

that it is singular for $\theta = (2l+1)\pi/2$ rad, with $l \in \mathbb{N}$, i.e., for a pitch angle of $\pm\pi/2$ rad.

The rotation matrix \mathbf{R}_I^B , needed in (43.1) to transform the linear velocities, is expressed in terms of the Euler angles by

$$\mathbf{R}_I^B(\eta_2) = \begin{pmatrix} c_\psi c_\theta & s_\psi c_\theta & -s_\theta \\ -s_\psi c_\phi + c_\psi s_\theta s_\phi & c_\psi c_\phi + s_\psi s_\theta s_\phi & s_\phi c_\theta \\ s_\psi s_\phi + c_\psi s_\theta c_\phi & -c_\psi s_\phi + s_\psi s_\theta c_\phi & c_\phi c_\theta \end{pmatrix}. \quad (43.5)$$

Table 43.2 shows the common notation used for marine vehicles according to the Society of Naval Architects and Marine Engineers (SNAME) notation [43.6]; a sketch is shown in Fig. 43.2.

As for any representation of a rigid body's orientation several possibilities arise, among them, the use

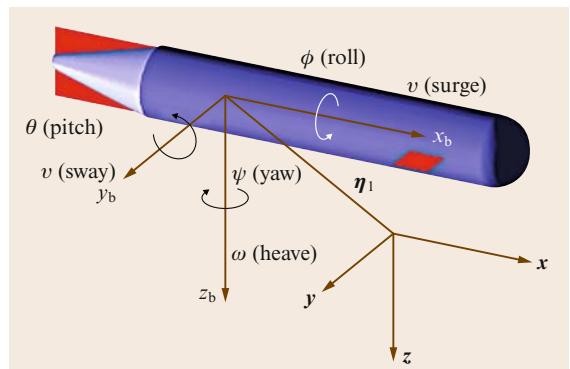

Fig. 43.2 Motion variables for an underwater vehicle

of a four-parameter description given by quaternions. The term *quaternion* was introduced by Hamilton in 1840, 70 years after the introduction of a four-parameter rigid-body attitude representation by Euler. An introduction to alternative orientation representations can be found in Chap. 1 and concerning the marine environment in [43.7].

It is useful to collect the kinematic equations in six-dimensional matrix forms. Let us define the vector $\eta \in \mathbb{R}^6$ as

$$\eta = \begin{pmatrix} \eta_1 \\ \eta_2 \end{pmatrix} \quad (43.6)$$

and the vector $\mathbf{v} \in \mathbb{R}^6$ as

$$\mathbf{v} = \begin{pmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{pmatrix}, \quad (43.7)$$

and, defining the matrix $\mathbf{J}_e(\mathbf{R}_B^I) \in \mathbb{R}^{6 \times 6}$

$$\mathbf{J}_e(\mathbf{R}_B^I) = \begin{pmatrix} \mathbf{R}_B^I & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{J}_{k,o} \end{pmatrix}, \quad (43.8)$$

where the rotation matrix \mathbf{R}_B^I is given in (43.5) and $\mathbf{J}_{k,o}$ is given in (43.3),

$$\dot{\mathbf{v}} = \mathbf{J}_e(\mathbf{R}_B^I) \dot{\eta}. \quad (43.9)$$

The inverse mapping, given the block-diagonal structure of \mathbf{J}_e , is given by

$$\dot{\eta} = \mathbf{J}_e^{-1}(\mathbf{R}_B^I) \mathbf{v} = \begin{pmatrix} \mathbf{R}_B^I & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{J}_{k,o}^{-1} \end{pmatrix} \mathbf{v}, \quad (43.10)$$

where $\mathbf{J}_{k,o}^{-1}$ is given in (43.4).

Defining as

$$\boldsymbol{\tau}_v = \begin{pmatrix} \boldsymbol{\tau}_1 \\ \boldsymbol{\tau}_2 \end{pmatrix},$$

the vector of generalized forces, where

$$\boldsymbol{\tau}_1 = (X \ Y \ Z)^\top, \quad (43.11)$$

the resultant forces acting on the rigid body expressed in a body-fixed frame, and

$$\boldsymbol{\tau}_2 = (K \ M \ N)^\top, \quad (43.12)$$

the corresponding resultant moment to the pole O_b , it is possible to rewrite the Newton–Euler equations of motion of a rigid body moving in the space as:

$$\mathbf{M}_{RB}\dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} = \boldsymbol{\tau}_v. \quad (43.13)$$

The derivation of (43.13) can be found in Chap. 2.

The matrix \mathbf{M}_{RB} is constant, symmetric, and positive definite, i.e., $\dot{\mathbf{M}}_{RB} = \mathbf{0}$ and $\mathbf{M}_{RB} = \mathbf{M}_{RB}^\top > \mathbf{0}$. Its unique parametrization is of the form

$$\mathbf{M}_{RB} = \begin{pmatrix} m\mathbf{I}_3 & -m\mathbf{S}(\mathbf{r}_C^b) \\ m\mathbf{S}(\mathbf{r}_C^b) & \mathbf{I}_{O_b} \end{pmatrix}, \quad (43.14)$$

where \mathbf{r}_C^b is the 3×1 distance vector to the center of gravity (CG) expressed in the body-fixed frame, \mathbf{I}_3 is the 3×3 identity matrix, and \mathbf{I}_{O_b} is the inertia tensor expressed in the body-fixed frame $\mathbf{S}(\mathbf{x})$ is the matrix operator performing the cross product between two (3×1) vectors

$$\mathbf{S}(\mathbf{x}) = \begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}.$$

On the other hand, there does not exist a unique parametrization of the matrix \mathbf{C}_{RB} , which represents the Coriolis and centripetal terms. It can be demonstrated that the matrix \mathbf{C}_{RB} can always be parameterized such that it is skew symmetric, i.e.,

$$\mathbf{C}_{RB}(\mathbf{v}) = -\mathbf{C}_{RB}^\top(\mathbf{v}) \quad \forall \mathbf{v} \in \mathbb{R}^6; \quad (43.15)$$

explicit expressions for \mathbf{C}_{RB} can be found in [43.7].

Notice that (43.13) can be greatly simplified if the origin of the body-fixed frame is chosen to be coincident with the central frame, i.e., $\mathbf{r}_C^b = \mathbf{0}$.

Hydrodynamic Generalized Forces

Equation (43.13) represents the motion of a rigid body in an empty space, while dealing with ships or underwater vehicles requires the consideration of the presence of

the hydrodynamics generalized forces, i.e., the forces and moments caused by the presence of the fluid. In hydrodynamics it is common to assume that the generalized hydrodynamics forces on a rigid body can be linearly superimposed [43.8]; in particular, those are separated into radiation-induced forces, environmental disturbances, and restoring forces due to gravity and buoyancy.

Radiation-induced forces are defined as the *forces on the body when the body is forced to oscillate with the wave excitation frequency and there are no incident waves*; these can be identified as the sum of the *added mass* due to the inertia of the surrounding fluid and the *radiation-induced potential damping* due to the energy dissipated by generated surface waves.

Environmental disturbances can be identified as the generalized forces caused by the wind, the waves, and the ocean current.

The overall equations of motions can therefore be written in matrix form as [43.7, 9, 10]:

$$\mathbf{M}_v\dot{\mathbf{v}} + \mathbf{C}_v(\mathbf{v})\mathbf{v} + \mathbf{D}_v(\mathbf{v})\mathbf{v} + \mathbf{g}_v(\mathbf{R}_B^I) = \boldsymbol{\tau}_v, \quad (43.16)$$

where $\mathbf{M}_v = \mathbf{M}_{RB} + \mathbf{M}_A$ and $\mathbf{C}_v = \mathbf{C}_{RB} + \mathbf{C}_A$ also include the added mass terms.

In the following subsections these generalized forces, specific to the marine environment, will be briefly discussed.

Added Mass and Inertia

When a rigid body is moving in a fluid, the additional inertia of the fluid surrounding the body that is accelerated by the movement of the body has to be considered. This effect can be neglected in industrial robotics since the density of the air is much lower than the density of a moving mechanical system. In underwater applications, however, the density of the water, $\rho \approx 1000 \text{ kg/m}^3$, is comparable with the density of the vehicles. In particular, at 0°C , the density of freshwater is 1002.68 kg/m^3 ; for sea water with 3.5% salinity it is $\rho = 1028.48 \text{ kg/m}^3$.

The fluid surrounding the body is accelerated with the body, so a force is necessary to achieve this acceleration, while the fluid exerts a reaction force which is equal in magnitude and opposite in direction. This reaction force is the added mass contribution. The added mass is not a quantity of fluid to add to the system such that it has an increased mass. Different properties hold with respect to the 6×6 inertia matrix of a rigid body due to the fact that the added mass is a function of the body's surface geometry.

The hydrodynamic force along \mathbf{x}_b due to the linear acceleration in the \mathbf{x}_b -direction is defined as:

$$\mathbf{X}_A := -X_{\dot{u}}\dot{u}, \quad \text{where} \quad X_{\dot{u}} := \frac{\partial X}{\partial \dot{u}},$$

where the symbol ∂ denotes the partial derivative. In the same way it is possible to define all the remaining 35 elements that relate the six force/moment components $(X \ Y \ Z \ K \ M \ N)^\top$ to the six linear/angular accelerations $(\dot{u} \ \dot{v} \ \dot{w} \ \dot{p} \ \dot{q} \ \dot{r})^\top$. These elements can be grouped into the added mass matrix $\mathbf{M}_A \in \mathbb{R}^{6 \times 6}$. Usually, all the elements of the matrix are nonzero.

In general, added mass and potential damping will be frequency dependent and depend on the forward speed. This is also the case for certain viscous damping terms (skin friction, roll damping, etc.). This gives a pseudo differential equation describing the frequency response of the vehicle. Since some of the coefficients depend on the frequency this is not an ordinary differential equation (ODE). The frequency equation, however, can be transformed to the time domain using the concepts described in [43.11] and [43.12], and recently in [43.13]. The resulting equation is an ODE where the added inertia matrix \mathbf{M}_A is constant, speed independent, and positive definite:

$$\mathbf{M}_A = \mathbf{M}_A^\top > \mathbf{0}, \quad \dot{\mathbf{M}}_A = \mathbf{0}. \quad (43.17)$$

This result is well known from ship hydrodynamics; see [43.14] for instance. The matrix \mathbf{M}_A can be computed using numerical programs such as WAMIT or Matlab, based on the US Air Force Digital Datcom [43.15]; in this case, the infinity-frequency result should be used, that is, $\mathbf{M}_A = A(\infty)$ where $A(\omega)$ is the frequency-dependent added mass matrix. The potential damping matrix will be small compared to the viscous effects and drag/lift terms. Hence, this term can be set to zero for underwater vehicles. If the added mass is computed experimentally, it is common practice to symmetrize the results such that

$$\mathbf{M}_A = \frac{1}{2} (A_{\text{exp}} + A_{\text{exp}}^\top),$$

where A_{exp} denotes the experimentally obtained added mass terms.

If the body is completely submerged in the water and is designed with port/starboard symmetry (xz -plane) as is common for underwater vehicles in six degrees-of-freedom (DOFs), the following structure of

the matrices \mathbf{M}_A can be considered:

$$\mathbf{M}_A = - \begin{pmatrix} X_{\dot{u}} & 0 & X_{\dot{w}} & 0 & X_{\dot{q}} & 0 \\ 0 & Y_{\dot{v}} & 0 & Y_{\dot{p}} & 0 & Y_{\dot{r}} \\ Z_{\dot{u}} & 0 & Z_{\dot{w}} & 0 & Z_{\dot{q}} & 0 \\ 0 & K_{\dot{v}} & 0 & K_{\dot{p}} & 0 & K_{\dot{r}} \\ M_{\dot{u}} & 0 & M_{\dot{w}} & 0 & M_{\dot{q}} & 0 \\ 0 & N_{\dot{v}} & 0 & N_{\dot{p}} & 0 & N_{\dot{r}} \end{pmatrix}. \quad (43.18)$$

The added mass coefficients can theoretically be derived by exploiting the geometry of the rigid body or numerically by strip theory [43.16].

In [43.17] the coefficients for the experimental AUV Phoenix of the Naval Postgraduate School (NPS) are reported. These coefficients have been derived experimentally, and the geometry gives a nondiagonal \mathbf{M}_A matrix. To provide an order of magnitude for the added mass terms, for the vehicle mass of about 5000 kg, the $X_{\dot{u}}$ is approximately -500 kg.

The added mass also makes an *added* Coriolis and centripetal contribution. It can be demonstrated that the matrix expression can always be parameterized such that

$$\mathbf{C}_A(\mathbf{v}) = -\mathbf{C}_A^\top(\mathbf{v}), \quad \forall \mathbf{v} \in \mathbb{R}^6,$$

whose symbolic expressions can be found in [43.3].

Hydrodynamic Damping

The hydrodynamic damping for marine vehicles is mainly caused by

- potential damping
- skin friction
- wave drift damping
- vortex shedding damping
- viscous damping

The radiation-induced potential damping due to forced body oscillations is commonly known as potential damping; its dynamic contribution is usually negligible with respect to, e.g., the viscous friction for underwater vehicles while it may be significant for surface vessels.

Linear skin friction is due to laminar boundary layers and can affect the low-frequency motion of the vehicle. Together with this effect, at high frequencies it is possible to observe a quadratic, or nonlinear, skin friction phenomenon caused by turbulent boundary layers.

Wave drift damping is the dominant dynamic damping effect in surge motion of surface vessels in high sea. It can be considered as an added resistance for boats advancing in waves; its drift is proportional to the square of the significant wave height. In the sway and yaw di-

Table 43.3 Lift and drag coefficient for a cylinder

| Reynolds number | Regime motion | C_d | C_l |
|---------------------------------------|--------------------|-------|-------|
| $R_n < 2 \times 10^5$ | Subcritical flow | 1 | 3–0.6 |
| $2 \times 10^5 < R_n < 5 \times 10^5$ | Critical flow | 1–0.4 | 0.6 |
| $5 \times 10^5 < R_n < 3 \times 10^6$ | Transcritical flow | 0.4 | 0.6 |

rections, however, its dynamic contribution is negligible with respect to the effect of vortex shedding.

A body moving in a fluid causes a separation of the flow; this can still be considered as laminar in the upstream while two antisymmetric vortices can be observed in the downstream. In case that the body is a cylinder moving in a direction normal to its axis, the result is a periodic force normal to both the velocity and the axis. This effect may cause the oscillation of cables and other underwater structures. However, concerning underwater vehicles, this effect is negligible for ROVs and may be counteracted by designing proper small control surfaces for torpedo-like AUVs.

Vortex shedding is an unsteady flow that takes place at special flow velocities (according to the size and shape of the cylindrical body). In this flow vortices are created at the back of the body, periodically from each side.

The viscosity of the fluid also causes dissipative forces. These are composed of drag and lift forces, the former being parallel to the relative velocity of the vehicle with respect to the water while the latter are normal to it. For a sphere moving in a fluid, the drag force can be modeled as [43.8]

$$F_{\text{drag}} = \frac{1}{2} \rho U^2 S C_d (R_n), \quad (43.19)$$

where ρ is the fluid density, U is the velocity of the sphere, S is the frontal area of the sphere, C_d is the nondimensional drag coefficient, and R_n is the Reynolds number. For a generic body, S is the projection of the frontal area along the flow direction. The drag force can be considered as the sum of two physical effects: the frictional contribution of the surface whose normal is perpendicular to the flow velocity, and the pressure contribution of the surface whose normal is parallel to the flow velocity. For a hydrofoil moving in a fluid, the lift force can be modeled as [43.8]

$$F_{\text{lift}} = \frac{1}{2} \rho U^2 S C_l (R_n, \alpha), \quad (43.20)$$

where S is now the area, C_l is the nondimensional lift coefficient, and α is the angle of attack, i.e., the angle between the relative velocity and the tangent to the surface. For small angles of attack, i.e., $|\alpha| < 10^\circ$, the

lift coefficient is approximatively proportional to α and rapidly decays to zero as α increases [43.18].

The drag and lift coefficients are therefore dependent on the Reynolds number, i.e., on the laminar/turbulent fluid motion

$$R_n = \frac{\rho |U| D}{\mu},$$

where D is the characteristic dimension of the body perpendicular to the direction of U and μ is the dynamic viscosity of the fluid. Table 43.3 reports the drag coefficients as a function of the Reynolds number for a cylinder [43.19].

A common simplification considers only linear and quadratic damping terms and group these into a matrix D_v as in (43.16) such that

$$D_v(v) > 0, \quad \forall v \in \mathbb{R}^6.$$

Gravity and Buoyancy

When a rigid body is completely or partially submerged in a fluid under the effect of the gravity two more forces have to be considered: the gravitational force and buoyancy. The latter is the only hydrostatic effect, i.e., it is not a function of the relative movement between the body and fluid.

Let us define as

$$\mathbf{g}^I = (0 \ 0 \ 9.81)^\top \text{m/s}^2$$

the acceleration of gravity. This effect is not constant but varies with depth, longitude, and latitude; however, this value is usually accurate enough for most applications except for inertial navigation systems.

For a completely submerged body the computation of these dynamic effects is straightforward. The submerged weight of the body is defined as $W = m \|\mathbf{g}^I\|$, while its buoyancy $B = \rho \nabla \|\mathbf{g}^I\|$, where ∇ is the volume of the body and m is its mass. The gravity force, which acts at the center of mass \mathbf{r}_C^B , is represented in the body-fixed frame by

$$\mathbf{f}_G(\mathbf{R}_I^B) = \mathbf{R}_I^B \begin{pmatrix} 0 \\ 0 \\ W \end{pmatrix},$$

while the buoyancy force, acting at the center of buoyancy \mathbf{r}_B^B , is represented in the body-fixed frame by

$$\mathbf{f}_B(\mathbf{R}_I^B) = -\mathbf{R}_I^B \begin{pmatrix} 0 \\ 0 \\ B \end{pmatrix}.$$

The 6×1 vector of force/moment due to gravity and buoyancy in the body-fixed frame, included in the left-hand side of the equations of motion, is represented by

$$\mathbf{g}_v(\mathbf{R}_I^B) = - \begin{pmatrix} f_G(\mathbf{R}_I^B) + f_B(\mathbf{R}_I^B) \\ \mathbf{r}_G^B \times f_G(\mathbf{R}_I^B) + \mathbf{r}_B^B \times f_B(\mathbf{R}_I^B) \end{pmatrix}.$$

In the following, the symbol $\mathbf{r}_G^B = (x_G \ y_G \ z_G)^\top$ (with $\mathbf{r}_G^B = \mathbf{r}_C^B$) will be used for the center of gravity. The expression for \mathbf{g}_v in terms of the Euler angles is

$$\mathbf{g}_v(\eta_2) = \begin{pmatrix} (W - B)s_\theta \\ -(W - B)c_\theta s_\phi \\ -(W - B)c_\theta c_\phi \\ -(y_G W - y_B B)c_\theta c_\phi + (z_G W - z_B B)c_\theta s_\phi \\ (z_G W - z_B B)s_\theta + (x_G W - x_B B)c_\theta c_\phi \\ -(x_G W - x_B B)c_\theta s_\phi - (y_G W - y_B B)s_\theta \end{pmatrix}. \quad (43.21)$$

Current

Ocean currents are mainly caused by tidal movement, the atmospheric wind system over the sea surface, heat exchange at the sea surface, salinity changes, the Coriolis force due to the Earth's rotation, nonlinear waves, the major ocean circulations such as the Gulf Stream, the effect of setup phenomena or storm surges, and strong density gradients in the upper ocean. Currents can be very different due to local climatic and/or geographic characteristics; as an example, in fjords, the tidal effect can cause currents of up to 3 m/s, moreover, specific mathematical models exist for the various components [43.7].

Let us assume that the ocean current, expressed in the inertial frame, \mathbf{v}_c^I , is constant and irrotational, i. e.,

$$\mathbf{v}_c^I = (v_{c,x} \ v_{c,y} \ v_{c,z} \ 0 \ 0 \ 0)^\top$$

and $\dot{\mathbf{v}}_c^I = \mathbf{0}$; its effects can be added to the dynamics of a rigid body moving in a fluid simply by considering the relative velocity in the body-fixed frame

$$\mathbf{v}_r = \mathbf{v} - \mathbf{R}_I^B \mathbf{v}_c^I \quad (43.22)$$

in the derivation of the added Coriolis and centripetal and the damping terms.

$$\begin{aligned} \mathbf{M}_v \dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} + \mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}_v(\mathbf{v}_r)\mathbf{v}_r + \mathbf{g}_v(\mathbf{R}_B^I) \\ = \boldsymbol{\tau}_v. \end{aligned} \quad (43.23)$$

Notice that the term $\mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r$ includes the important destabilizing effect known as the Munk moment [43.8].

If $\mathbf{D}_v(\mathbf{v}_r)$ is unknown, quadratic surge resistance and the cross-flow drag principle can be used to describe the dissipative forces and moments in surge, sway, and yaw [43.8]. Moreover:

$$\mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}_v(\mathbf{v}_r)\mathbf{v}_r \approx (X_c \ Y_c \ 0 \ 0 \ 0 \ N_c)^\top; \quad (43.24)$$

for large relative current angles $|\beta_c - \psi|$, where β_c is the current direction, the cross-flow principles models the sway force Y_c and yaw moment N_c as

$$Y_c = \frac{\rho}{2} \int_L H(x) C_D(x) v_r^x(x) |v_r^x(x)| dx \quad (43.25)$$

$$N_c = \frac{\rho}{2} \int_L x H(x) C_D(x) v_r^x(x) |v_r^x(x)| dx, \quad (43.26)$$

where L is the vehicle length, $H(x)$ is the vehicle height, $C_D(x)$ is the two-dimensional drag coefficient, and $v_r^x(x) = v_r + rx$ is the relative cross-flow velocity at x . In practice $C_D(x)$ can be chosen as a constant between 0 and 1. The proper value can be determined by curve fitting of experimental data. Along the surge direction, however, the quadratic damping contribution X_c is still well represented by a term proportional to the square of the relative velocity, whose symbolic expression can be written as

$$X_c = -X_{u|u|} u_r |u_r|, \quad (43.27)$$

where $-X_{u|u|} > 0$ is the quadratic surge damping coefficient, which can be found by curve fitting of experimental data or relating it to the drag coefficient C_d as in (43.19).

Alternatively, the computation of the quadratic surge resistance, nonlinear roll damping, and the cross-flow drag effect can be made by resorting to the Datcom database for aircraft, as shown in [43.20].

Model Properties

For completely submerged bodies in an ideal fluid moving at low velocity where there are no currents or waves, (43.16) satisfies the following properties:

- the inertia matrix is symmetric and positive definite, i. e.,

$$\mathbf{M}_v = \mathbf{M}_v^\top > \mathbf{0};$$
- the damping matrix is positive definite, i. e.,

$$\mathbf{D}_v(\mathbf{v}) > \mathbf{0};$$

- the matrix $C_v(v)$ is skew symmetric, i.e.,

$$C_v(v) = -C_v^\top(v), \forall v \in \mathbb{R}^6.$$

Hydrodynamic Modeling

The mathematical model of an underwater robot as expressed in (43.16) is of great importance; even when simplified it captures the most important part of the dynamics. Moreover, it is in a form appropriate for control design. A wide literature exists on **AUV/ROV** controllers whose stability relies on the properties reported above. On the other hand, there are working conditions in which these assumptions are no longer valid, i.e., when the **AUV** is traveling at high speed, or close to the surface, or when its shape does not allow geometric simplifications. The latter is the case of, e.g., several **ROVs**. In addition, it is still common to design the controllers for **AUVs** based on linearized models and to control **ROVs** with simple **PID** controllers.

These considerations justify a modeling effort to calculate the hydrodynamic terms more accurately with the aim of prediction, simulation, and performance analysis rather than control design. This can be done by switching from a coefficient-based approach, such as that presented above, to a component modeling method, the latter being based on computational fluid dynamics theory. In detail, each vehicle geometry, with its specific angle of attack and sideslip, is taken into consideration when computing the hydrodynamic forces/moments. This increased computational effort makes it possible to capture some dynamic effects, such as the vortex-induced roll moment, not justifiable with the coefficient-based approach.

Table 43.4 UUVs: possible instrumentation

| Sensor | Measured variable |
|-----------------------------------|------------------------------------------|
| Inertial system | Linear acceleration and angular velocity |
| Pressure meter | Vehicle depth |
| Frontal sonar | Distance from obstacles |
| Vertical sonar | Distance from the bottom |
| Ground speed sonar | Relative velocity vehicle/bottom |
| Current meter | Relative velocity vehicle/current |
| Global positioning system | Absolute position at the surface |
| Compass | Orientation |
| Acoustic baseline | Absolute position in known area |
| Vision systems | Relative position/velocity |
| Acoustic Doppler current profiler | Water current at several positions |

The control plant model is usually a simplified model that captures the most important parts of the dynamics. The most accurate model of the vehicle should be used for prediction and motion simulation.

43.2.2 Sensor Systems

Underwater vehicles are equipped with a sensor system devoted to enabling motion control as well as accomplishing the specific mission it has been commanded to complete. In the latter case, sensors developed for chemical/biological measurements or mapping may be installed, which is beyond the scope of this chapter.

AUVs need to operate underwater most of the time; one of the major problems with underwater robotics is in the localization task due to the absence of a single, proprioceptive sensor to measure the vehicle position. The global position system (**GPS**) cannot be used underwater. Redundant multisensor systems are commonly combined using state estimation or sensor fusion techniques to provide fault detection and tolerance capability to the vehicle. Table 43.4 lists the types of sensors and the corresponding variable measured commonly available for unmanned underwater vehicles (**UUVs**).

The sensors that can be found on an underwater vehicle are:

- Compass. A gyrocompass can provide an estimate of geodetic north accurate to a fraction of a degree. Magnetic compasses can provide estimates of magnetic north with an accuracy of less than 1° if carefully calibrated to compensate for magnetic disturbances from the vehicle itself. Tables or models can be used to convert from magnetic north to geodetic north.
- Inertial measurement unit (**IMU**). An **IMU** provides information about the vehicle's linear acceleration and angular velocity. These measurements are combined to form estimates of the vehicle's attitude including an estimate of geodetic (true) north from the most complex units. In most cases, for slow-moving underwater vehicles, an independent measurement of the vehicle's velocity is also required to produce accurate estimates of the translational velocity or relative displacement.
- Depth sensor. Measuring the water pressure gives the vehicle's depth. At depths beyond a few hundred meters, the equation of state of seawater must be invoked to produce an accurate depth estimate based on the ambient pressure [43.21]. With a high-quality

Table 43.5 JHUROV instrumentation

| Measured variable | Sensor | Precision | Update rate |
|------------------------|----------------------------|-----------|-------------|
| 3-DOF vehicle position | SHARP acoustic transponder | 0.5 cm | 10 Hz |
| Depth | Foxboro/ICT model n. 15 | 2.5 cm | 20 Hz |
| Heading | Litton LN200 IMU Gyro | 0.01° | 20 Hz |
| Roll and pitch | KVH ADGC | 0.1° | 10 Hz |
| Heading | KVH ADGC | 1° | 10 Hz |

Table 43.6 ODIN III sensors summary

| Measured variable | Sensor | Update rate |
|----------------------|-----------------|-------------|
| xy vehicle position | 8 sonars | 3 Hz |
| Depth | Pressure sensor | 30 Hz |
| Roll, pitch, and yaw | IMU | 30 Hz |

sensor, these estimates are reliable and accurate, giving a small error of order 0.01%.

- Altitude and forward-looking sonar. These are used to detect the presence of obstacles and distance from the seafloor.
- Doppler velocity log (DVL). By processing reflected acoustic energy from the seafloor and the water column from three or more beams, estimates of vehicle velocity relative to the seafloor and relative water motion can be obtained. Bottom-tracking velocity estimates can be accurate to $\approx 1 \text{ mm/s}$.
- Global positioning system (GPS). This is used to localize the vehicle while on the surface to initialize or reduce drift of estimates from an IMU/DVL combination. GPS only works at the surface.
- Acoustic positioning. A variety of schemes exist for determining vehicle position using acoustics. Long-baseline navigation can determine the position of the vehicle relative to a set of acoustic beacons anchored to the seafloor or on the surface through range estimates obtained from acoustic travel times. Ultrashort-baseline navigation uses phase information to determine direction from a cluster of hydrophones; this is most often used to determine the direction of the vehicle (in two dimensions) from a surface support vessel, which is then combined with an acoustic travel-time measurement to produce an estimate of relative vehicle position in spherical coordinates. These techniques will be discussed later in the localization section.

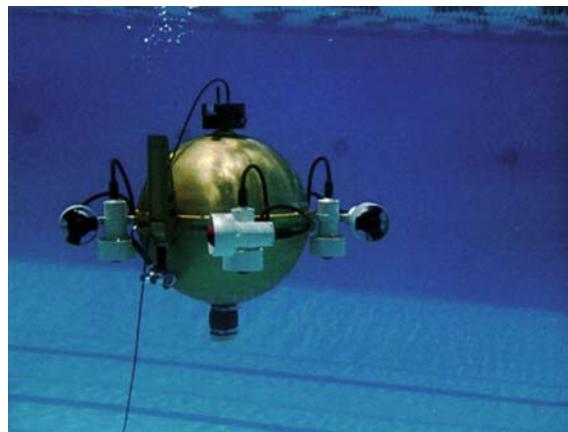

Fig. 43.3 The fully actuated AUV ODIN (courtesy of the Autonomous Systems Laboratory, University of Hawaii, <http://www.eng.hawaii.edu/~asl/>)

- Vision systems. Cameras can be used to obtain estimates of relative, and in some cases absolute, motion using a type of simultaneous localization and mapping (SLAM) algorithm [43.22] and used to perform tasks such as visual tracking of pipelines, station keeping, visual servoing or image mosaicking.

As an example, Table 43.5 reports some data from the instrumentation of the ROV developed at the John Hopkins University [43.23], and Table 43.6 some data from the AUV ODIN III [43.24]. Reference [43.25] shows some data fusion results with a redundant sensorial system mounted on the AUV Oberon, while reference [43.26] reviews advances in navigation technology.

43.2.3 Actuating Systems

Marine vehicle are generally propelled by means of thrusters or hydrojets. In the case of ROVs with structural pitch-roll stability, there are usually four thrusters that provide holonomic mobility to the four remained DOFs, in particular, the depth is often decoupled and the vehicle is controlled on a plane in the surge, sway, and yaw DOFs. Those vehicles, being underactuated, cannot easily be used for interactive control by means of a manipulator due to the impossibility of counteracting the generalized forces exchanged with the manipulator's base; in such case, six or more thrusters are required. AUVs generally have a torpedo-like shape and are used for mapping/exploration. They are propelled using one or two thrusters parallel to the fore-aft direction and

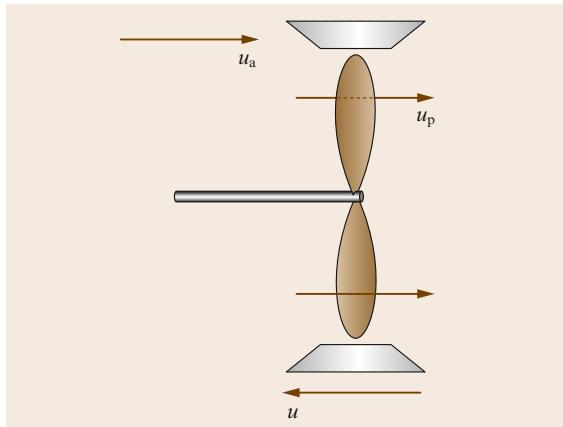

Fig. 43.4 Ambient water and axial flow velocities affecting thruster behavior

a fin and a rudder; this kind of propulsion is obviously nonholonomic and experiences a loss of mobility at low velocities. Hydrojets, also known as pump jets or water jets, are systems that create a jet of water for propulsion; they have certain advantages over thrusters such as a higher power density and usability in shallow water, but can provide thrust in one direction only.

Several efforts have been made to accurately and efficiently describe the mathematical model of a thruster; [43.28] reports a *one-state* model where the state is n , the propeller shaft speed. In [43.29] a *two-state* model is proposed to take into account the experimentally observed overshoot in the thrust; together with n , the additional state variable is u_p , the axial flow velocity in the propeller disc. In [43.30] a thruster model incorporating the effects of rotational fluid velocity and inertia on thruster responses is presented together with a method for experimentally determining nonsinusoidal lift/drag curves. A *three-state* model is described in [43.31]:

$$\begin{aligned} J_m \dot{n} + K_n n &= \tau - Q, \\ m_f \dot{u}_p + d_{f0} u_p + d_f |u_p| (u_p - u_a) &= T, \\ (m - X_u) \dot{u} - X_u u - X_{u|u|} u |u| &= (1-t)T, \end{aligned}$$

where J_m is the moment of inertia for the dc-motor/propeller, K_n is the linear motor damping coefficient, τ is the motor control input, Q is the propeller torque, m_f is the mass of water in the propeller control volume, u_p is the axial flow velocity in the propeller disc, d_{f0} and d_f are the linear and quadratic damping coefficients for control volume, respectively, u_a is the ambient water velocity, T is the propeller thrust, and t is the thrust deduction number (Fig. 43.4). In the

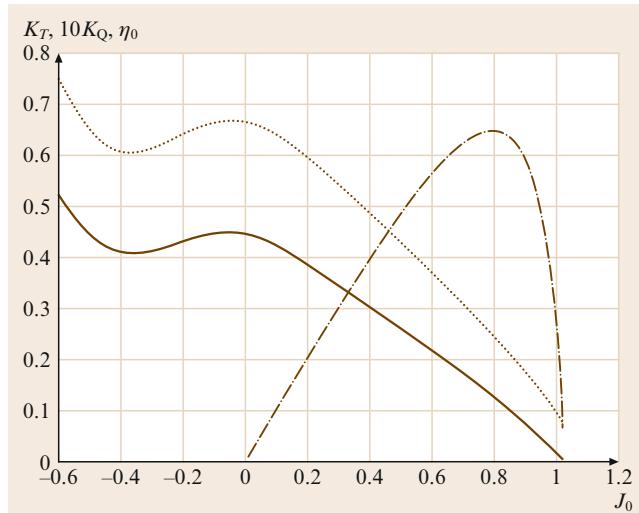

Fig. 43.5 Values of K_T (solid), $10K_Q$ (dotted), and η_0 (dash-dotted) as a function of J_0 [43.27]

case of steady-state motion, i. e., $\dot{u} = 0$, the ambient water velocity u_a is related to the surge by the *wake fraction number* w as:

$$u_a = (1-w)u. \quad (43.28)$$

Notice also that the unmeasured variable u_p can be estimated using a nonlinear observer [43.31].

The *outputs* of the nonlinear three-state dynamic systems are the thrust T and the torque Q , which are functions of several variables; in the following, unsteady flow effects such as air suction, cavitation, the in-and-out-of-water (Wagner), boundary layer, and gust (Kulessner) effects will be neglected. This leads to a quasi-steady representation of the model:

$$T = \rho D^4 K_T(J_0) n |n|, \quad (43.29)$$

$$Q = \rho D^5 K_Q(J_0) n |n|, \quad (43.30)$$

where D is the propeller diameter and $K_T(J_0)$ and $K_Q(J_0)$ are the thrust and torque coefficients, respectively. The latter are function of the advance ratio J_0

$$J_0 = \frac{u_a}{nD}. \quad (43.31)$$

The open-water propeller efficiency in undisturbed water is given as the ratio of the work done by the propeller in producing a thrust force divided by the work required to overcome the shaft torque:

$$\eta_0 = \frac{u_a T}{2\pi n Q} = \frac{J_0}{2\pi} \cdot \frac{K_T}{K_Q}. \quad (43.32)$$

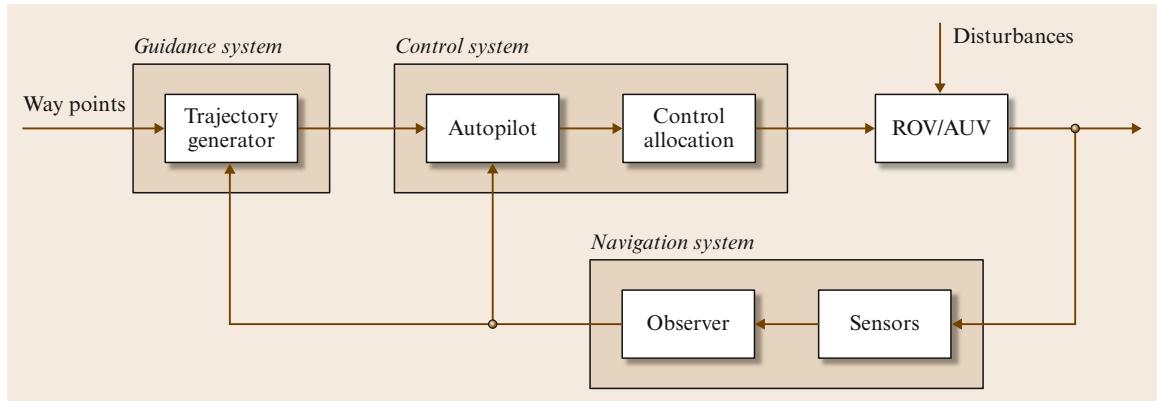

Fig. 43.6 Guidance, navigation, and control for an autonomous marine vehicle

Figure 43.5 shows the values of K_T , K_Q , and η_0 as functions of the advance ratio for the Wageningen B4-70 propeller [43.27].

Controlling a marine vehicle usually requires that desired forces/moment act on the vehicle's body; these generalized forces are mapped into desired thrusts to be provided by the propellers. There is, thus, a nontrivial control problem in that the motors are required to provide the appropriate propeller shaft speed n that satisfies the nonlinear relationship with the thrust T presented above.

To enable robustness with respect to possible failures, the actuating system is often redundant. In this case, the problem of allocation of the desired force/moment acting on the vehicle among the thrusters must also be solved. Reference [43.32] reports a survey of control allocation methods of ships and underwater vehicles.

43.2.4 Mission Control System

The mission control system (MCS) can be considered as the highest-level process running during an AUV's mission; it is responsible for achieving several control objectives. At the highest level it works as an interface between the operator, accepting his instructions in a higher-level language and decomposing those instructions into mission tasks according to the implemented software architecture. The mission tasks are generally concurrent and their handling depends on the vehicle state and environmental conditions; it is therefore the MCS that handles the tasks, eventually suppressing, sequencing, modifying, and prioritizing them. An MCS is also usually equipped with a graphical user interface (GUI) to report the mission state to the operator.

As for most advanced robotics applications, an efficient MCS should allow the use of complex robotic systems by users that do not necessarily know all of their technical details. An overview relevant to underwater mission control is given in [43.33], which includes an interesting classification of the MSCs in use in several laboratories according to which four major AUV control architectures were identified: the hierarchical, heterarchical, subsumption, and hybrid.

From a mathematical point of view, the MCS generally needs to be designed in order to be able to address hybrid dynamical systems, i.e., handling both event-driven and time-driven processes. In [43.34], e.g., the MSC developed at the Portuguese Instituto Superior Técnico (IST), named CORAL, is implemented by resorting to a Petri-net-based architecture that properly handles all the necessary tasks in order to manage navigation, guidance and control, sensing, communications, etc.

The motion-oriented operating system (MOOS), designed at the Massachusetts Institute of Technology, is a software tool capable of executing and coordinating a multitude of subsea operations. The MSC developed at the Naval Postgraduate School is in the framework of the behavioral control organized in three layers [43.35]; it is based on PROLOG, an artificial intelligence language for predicate logic.

43.2.5 Guidance and Control

The terms guidance and control can be defined as [43.7]:

Guidance is the action of determining the course, attitude, and speed of the vehicle, relative to

| | |
|---------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Control | <p>some reference frame (usually the Earth), to be followed by the vehicle,</p> <p>is the development and application to a vehicle of appropriate forces and moments for operating point control, tracking, and stabilization. This involves designing the feedforward and feedback control laws.</p> |
|---------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

Figure 43.6 shows the corresponding block diagram, in which the navigation component is also outlined.

Guidance of Underwater Vehicles

Guidance algorithms may benefit from a wide range of inputs, overall mission information, real-time operator input, environmental measured data such as the ocean current, environmental topological information such as a bathymetric map, exteroceptive sensors for obstacle avoidance, and obviously the vehicle state as output from the navigation system.

The vehicle may be required to follow a path, i.e., a curve geometrically represented in two or three dimensions, or a trajectory, i.e., a path with a specific time law assigned. Moreover, when the desired position is constant, the problem is called set-point regulation or maneuvering. The guidance problem is commonly decomposed into simple subtasks of lower dimension: an attitude control problem and a path control. Moreover, attitude is usually considered as a simple depth set-point with null roll and pitch and the path is usually a line in the horizontal plane.

One of the most common guidance approaches is based on the generations of way-points. Those are usually stored in a database and are used to generate the vehicle path/trajectory; a *passing* velocity, in fact, may be defined together with the Cartesian coordinates of the points. The simplest way to connect the way-points is to use the segments connecting two successive way-points. Efficient way-point-based guidance approaches need to take into account the presence of the current and the eventual nonholonomicity of the vehicle [43.36]. A technique for adaptively tracking bathymetric contours by proper generation of way-points is presented in [43.37]; environment information is acquired by mean of a single vertical sonar. An alternative method is based on *line-of-sight* guidance [43.38–40]. In this case, the heading control is computed by considering as input the angle formed by the vector from the vehicle to the next way-point rather than requiring the vehicle to exactly follow the line segment between the current and the following way-point. Special care needs to be paid to

the docking maneuver with algorithms designed on the scope [43.41].

By combining vision-based guidance with a neuro-controller trained by reinforcement learning, in [43.42], an algorithm aimed at a hold station on a reef or swimming along a pipe has been presented. In [43.43] guidance for **AUVs** specifically involved in a pre-deployment survey of the sea bottom and visual inspection of pipelines is given. Reference [43.44] reports a specific guidance system aimed at mine avoidance for **AUVs**. Based on a three-dimensional discretization of the environment, the path-planning technique consists of computing a safe path avoiding the unsafe cells of the map. Due to the poor manoeuvrability at low speed under some conditions, the vehicle has to make a 360° turn to avoid stopping and to map the environment close to it before generating a safe path.

A deep discussion on guidance for surface and underwater vehicles can be found in [43.3, 7].

Control of Underwater Vehicles

Control of underwater vehicles needs to consider the different operating conditions and actuating configurations in which a submerged vehicle is required to operate. In particular, there are three main control problems.

- An **AUV** traveling at high speed ($> 1 \text{ m/s}$) generally equipped with at least one thruster aligned in the fore-aft direction and at least two control surfaces (stern and rudder).
- An underactuated **ROV**, with high metacentric stability, i.e., structurally stable in roll and pitch, and equipped with at least four thrusters.
- A fully actuated **AUV** equipped with at least six thrusters.

AUVs equipped with control surfaces are underactuated vehicles mainly used for survey/exploration missions. Inheriting the common practice of submarine control, they are not allowed to perform arbitrary motions in six **DOFs** but are rather designed to perform specific movements such as: cruising along a given direction at constant depth, steering at constant depth, or diving. Marine experience and mathematical insight, in fact, demonstrate that these movements are lightly coupled in dynamic terms. For these vehicles, moreover, specific manoeuvres such as homing or docking require special capabilities [43.41]. This requires the design of vehicles that are structurally stable in the roll **DOF**. Cruising requires control of the surge velocity $u(t)$; steering requires control of the sway velocity $v(t)$ and the yaw **DOF** $r(t)$, $\psi(t)$, diving requires control of the

heave **DOF** $\omega(t)$, $z(t)$ and the pitch **DOF** $q(t)$, $\theta(t)$. The simplest configuration of actuators that can control an **AUV** through these movements is composed of one thruster aligned along the fore-aft direction, one stern, and one rudder; the control variables, thus, are the propeller speed and the deflection of the fins. Several approaches can then be considered to solve this control problem, among them, in [43.45] the sliding mode control is proposed, while [43.46] presents an adaptive sliding mode control for the diving manoeuvre. Reference [43.17] reports a successful implementation of multivariable sliding mode control on the **NPS AUV II**, later also implemented on the **NPS ARIES AUV** [43.47]. As the model of an **AUV** traveling at high speed is nonlinear and coupled, the tuning of the parameters is mainly based on a linearized model around the working conditions.

From a descriptive point of view, an **ROV** is mainly a box-shaped underwater vehicle equipped with tools such as a video camera or robot manipulator, while its payload is often variable depending on the task. It is remotely operated and physically connected to another vehicle, either an underwater or a surface vessel. It is mainly designed to travel at low speed and it is structurally stable in roll and pitch, while its depth, surge, sway, and yaw are independently controllable. Due to the absence of a specific shape, the varying payload, and the relatively low required performances, it is common to control a **ROV** by means of single-input single-output (**SISO**) controllers. Moreover, the **PID** approach is often used due to its simplicity. A two-layer guidance and control architecture for the **ROV Romeo** is given in [43.48].

Control of a fully actuated **AUV** in six **DOFs** is needed in the case of, e.g., an interaction task performed by a manipulator mounted on a vehicle; the latter, in fact, needs to provide all the force/moment components in order to counteract the presence of the manipulator dynamically. This problem is kinematically similar to the problem of controlling a satellite in six **DOFs**; the underwater environment, however, makes it significantly different from the dynamic point of view. In kinematic terms the main issue is in implementing a suitable policy for orientation control; any three-parameter representation of orientation, in fact, experiences representation singularities (Chap. 1). This problem may be overcome by resorting to a redundant representation of the orientation such as the quaternion. Most of the six-**DOF** controllers proposed in the literature are based on (43.16), which model the simplified effect of the hydrodynamic terms and which have very

similar properties as the equations of motion of an industrial manipulator. Based on this, it is obviously possible to find a collection of approaches inherited from classical robotics, see, e.g., [43.3, 7] for some examples. In [43.49], some specific considerations for the underwater environment lead to a quaternion-based, adaptive controller; it is worth noticing that adaptive control requires a suitable, and simplified, expression for the hydrodynamic terms. In [43.50] a comparison among several 6-**DOF** controllers is made.

43.2.6 Localization

Localization in the underwater environment can be a complex task, mainly due to the absence of a single external sensor that gives the vehicle position such as, e.g., the **GPS** for outdoor ground vehicles; moreover, the environment is often poorly structured.

One of the most reliable methods is based on the use of acoustic systems such as the baseline systems: the long-baseline system (**LBL**), the short-baseline system (**SBL**), and the ultrashort-baseline system (**USBL**). These systems are based on the presence of a transceiver mounted on the vehicle and a variable number of transponders located in known positions. The transceiver's distance from each transponder can be measured via the measurement of an echo delay; from this information the position of the vehicle can be calculated by basic triangulation operations. The **USBL** can be used with a single transponder, which is usually mounted on a surface ship whose position is measured by **GPS**.

Another localization system is called terrain-aided navigation and is based on the use of terrain elevation maps; bathymetric maps are available, especially in the case of well-known locations such as harbors where they usually have a resolution of ≈ 1 m. In this case, the vehicle position is obtained by filtering the information coming from a downward-looking sonar. In [43.51], a particle filter approach was used to localize an **AUV** in Sydney harbor.

Moving vehicles may be equipped with an **IMU** or **DVL** in order to measure its velocity and/or acceleration. This data can then be integrated to estimate the vehicle position. This kind of information is subject to the drift phenomenon and may not be reliable for long-duration runs or may become cost ineffective if accurate **IMU** devices are needed.

Relative localization can be obtained by resorting to any device that provides information about the relative position of the vehicle with respect to the environment,

even in the absence of a map. In this case, by filtering the distance measurements taken along the motion, the vehicle's position can be measured. This is the case, e.g., of sonar or vision-based localization techniques [43.52].

Often, the techniques presented above are used together in a redundant system and the effective position is obtained by resorting to sensor fusion techniques such as the Kalman filtering approach.

Simultaneous Localization and Mapping

Simultaneous localization and mapping (**SLAM**), also known as concurrent mapping and localization (**CML**), is a wide topic in mobile robotics. The problem can be formulated as the requirement for a mobile robot to be placed in an unknown environment and progressively build a map while locating itself inside the map. Chapter 37 discusses this topic in detail. For the marine environment an additional issue arises due by the large-scale map that needs to be used for long-duration missions; [43.53] implements a decoupled stochastic mapping to handle this computational problem in an extended Kalman filter. Terrain-aided navigation with the use of a scanning sonar is implemented in [43.54]. Reference [43.55] uses long-baseline range measurements as the input for a nonlinear least-squares approach solved by the Gauss–Newton method; both the initially unknown position of the transponders and the vehicle position are estimated. An interesting survey on navigation and **SLAM** for underwater vehicles is given in [43.26].

43.2.7 Underwater Manipulation

A manipulator may be mounted on an **AUV** or a **ROV** in order to accomplish interaction operations. In this

case, the vehicle needs to be fully actuated to counteract the forces and moments generated by the manipulator's base. By considering a manipulator with n links, thus six **DOFs**, the underwater vehicle manipulator system (**UVMS**) is a $(6+n)$ -**DOF** robotic system whose velocity vector is

$$\boldsymbol{\xi} = (\boldsymbol{v}_1^\top \ \boldsymbol{v}_2^\top \ \dot{\boldsymbol{q}}^\top)^\top, \quad (43.33)$$

where $\boldsymbol{q} \in \mathbb{R}^n$ is the vector collecting the manipulator joints positions.

Repeating the same considerations as for an underwater vehicle, it is possible to write the equations of motions of an **UVMS** in matrix form as

$$\boldsymbol{M}(\boldsymbol{q})\ddot{\boldsymbol{q}} + \boldsymbol{C}(\boldsymbol{q}, \boldsymbol{\xi})\dot{\boldsymbol{q}} + \boldsymbol{D}(\boldsymbol{q}, \boldsymbol{\xi})\boldsymbol{\xi} + \boldsymbol{g}(\boldsymbol{q}, \boldsymbol{R}_B^I) = \boldsymbol{\tau}, \quad (43.34)$$

where $\boldsymbol{M} \in \mathbb{R}^{(6+n) \times (6+n)}$ is the inertia matrix, including added mass terms, $\boldsymbol{C}(\boldsymbol{q}, \boldsymbol{\xi})\dot{\boldsymbol{q}} \in \mathbb{R}^{6+n}$ is the vector of the Coriolis and centripetal terms, $\boldsymbol{D}(\boldsymbol{q}, \boldsymbol{\xi})\boldsymbol{\xi} \in \mathbb{R}^{6+n}$ is the vector of dissipative effects, and $\boldsymbol{g}(\boldsymbol{q}, \boldsymbol{R}_B^I) \in \mathbb{R}^{6+n}$ is the vector of gravity and buoyancy effects. The relationship between the generalized forces $\boldsymbol{\tau}$ and the control input is given by:

$$\boldsymbol{\tau} = \begin{pmatrix} \boldsymbol{\tau}_v \\ \boldsymbol{\tau}_q \end{pmatrix} = \begin{pmatrix} \boldsymbol{B}_v & \boldsymbol{0}_{6 \times n} \\ \boldsymbol{0}_{n \times 6} & \boldsymbol{I}_n \end{pmatrix} \boldsymbol{u} = \boldsymbol{B}\boldsymbol{u}, \quad (43.35)$$

where $\boldsymbol{u} \in \mathbb{R}^{p_v+n}$ is the vector of the control input. Notice that, while for the vehicle a generic number $p_v \geq 6$ of control inputs is assumed, for the manipulator it is supposed that n joint motors are available.

Under this hypothesis, which can be considered as reasonable at low velocity, it holds that:

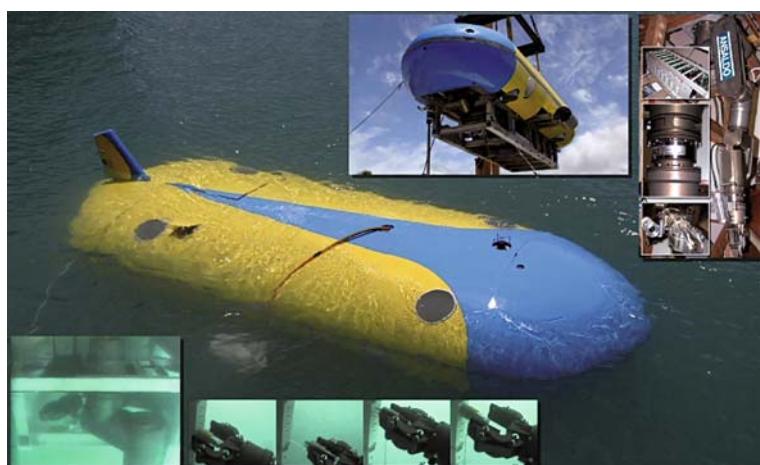

Fig. 43.7 An underwater vehicle–manipulator system: SAUVIM (courtesy of Autonomous Systems Laboratory, University of Hawaii, <http://www.eng.hawaii.edu/~asl/>)

- the inertia matrix \mathbf{M} of the system is symmetric and positive definite;
- for a suitable choice of the parametrization of \mathbf{C} and if all the single bodies of the system are symmetric, $\dot{\mathbf{M}} - 2\mathbf{C}$ is skew symmetric;
- the matrix \mathbf{D} is positive definite.

In [43.19] the mathematical model written with respect to the Earth-fixed-frame vehicle position and the manipulator end-effector can be found. However, it must be noted that, in this case, a six-dimensional manipulator is considered in order to have a square Jacobian to work with; moreover, kinematic singularities need to be avoided.

The equations of motion of UVMSs in matrix form presented in (43.34) are formally similar to the equations of motion of ground fixed manipulators (Chap. 2) for which a wide control literature exists. This has suggested a suitable translation/implementation of existing control algorithms. However, some differences, crucial from the control aspect, need to be underlined. UVMSs are complex systems characterized by several strong constraints:

- uncertainty in the model knowledge, mainly due to the poor knowledge about the hydrodynamic effects
- the complexity of the mathematical model
- the kinematic redundancy of the system
- the difficulty in controlling the vehicle in hovering, mainly due to poor thruster performance
- the dynamic coupling between the vehicle and the manipulator
- the low bandwidth of the sensor readings

In 1996 McLain et al. [43.56] presented a control law for UVMSs with some interesting experimental results conducted at the Monterey Bay Aquarium Research Institute (MBARI). A one-link manipulator was mounted on the OTTER vehicle controlled in all six DOFs by means of eight thrusters. A coordinated control system was then implemented to improve the tracking errors of the end effector.

The monograph [43.50] is focused on the modeling and control issues of such systems, and can be considered as a reference for further reading. Moreover, interaction with the environment is also discussed.

Currently, remotely operated manipulator are standard equipment for several underwater ROVs. However, autonomous manipulation is still a research challenge. Figure 43.7 shows the SAUVIM vehicle, one of the first semiautonomous underwater vehicle manipulator systems, developed at the Autonomous Systems Laboratory, University of Hawaii. A similar research project, ALIVE, was funded by the Fifth Framework Program of the European Community [43.2].

43.2.8 Fault Detection/Tolerance

Generally, AUVs must operate over long periods of time in unstructured environments in which an undetected failure could cause the loss of the vehicle. Failure detection and a fault-tolerant strategy are required to determine whether a mission must be terminated in the safest manner possible or if the vehicle can continue in a diminished capacity. An example is the case of the arctic mission of Theseus [43.57].

In the case of the use of ROVs, a skilled human operator is in charge of commanding the vehicle; a failure detection strategy is then of help in the human decision-making process. Based on the information detected, the operator can decide on vehicle rescue or to terminate the mission by, e.g., turning off a thruster.

Fault detection is the process of monitoring a system in order to recognize the presence of a failure; fault isolation or diagnosis is the capability to determine which specific subsystem is subject to failure. Often in the literature there is a certain overlap in the use of these terms. Fault tolerance is the capability to complete the mission in the case of the failure of one or more subsystems; it is also known as fault control, fault accommodation, or control reconfiguration. In the following the terms fault detection/tolerance will be used.

The characteristics of a fault detection scheme are the capability to isolate the detected failure, sensitivity in terms of the magnitude of the failure that can be detected, and robustness in the sense of the capability to continue working properly in non-nominal conditions. The requirements of a fault-tolerant scheme are reliability, maintainability, and survival. The common concept is that, to overcome the loss of capability due to a failure, a kind of redundancy is required in the system.

In this section, a survey of existing fault-detection and fault-tolerant schemes for underwater vehicles is presented. For these specific systems, if proper strategies are applied, a hardware/software (HW/SW) sensor or thruster failure can be successfully handled. In some conditions, the fault-detection scheme must also be able to diagnose some external abnormal working conditions such as a multipath phenomena affecting the echo-sounder system. It is worth noticing that, for autonomous systems such as AUVs, space systems or aircraft, a fault-tolerant strategy is necessary to safely recover the damaged vehicle and, obviously, there is no

panic button in the sense that the choice of turning off the power or activating some kind of brake is not available.

Most fault-detection schemes are model based [43.58, 59] and consider the dynamic relationship between the actuators and vehicle behavior or the specific input–output thruster dynamics. In general, fault-detection/tolerance theory has been applied to the specific case of the underwater environment even if only a few papers report experimental results; see [43.60] for a survey on this topic.

Most fault-tolerant schemes consider a thruster-redundant vehicle that, after a fault has occurred in one of its thrusters, is still actuated in six DOFs. Based on this assumption a reallocation of the desired forces on the vehicle over the working thrusters is performed [43.61]. Of interest is also the study of reconfiguration strategies if the vehicle becomes underactuated.

Possible Failures

Underwater vehicles are currently equipped with several sensors in order to provide information about their localization and velocity. The problem is not easy. No single, reliable sensor is available that gives the required position/velocity measurement, or information about the environment such as the presence of obstacles. For this reason the use of sensor fusion by, e.g., a Kalman filtering approach, is a common technique to provide the controller with the required variables. This structural redundancy can be used to provide fault-detection capabilities to the system.

For each of the sensors listed in Sect. 43.2.2 failure can consist of an output of zero if, e.g., there is an electrical trouble, or a loss of meaning. It can be considered as sensor failure also an external disturbance such as a multipath reading of the sonar that can be interpreted as a sensor fault and correspondingly detected.

Thruster blocking occurs when a solid body is present between the propeller blades. It can be checked by monitoring the current required by the thruster. This was observed, e.g., during the Antarctic mission of Romeo [43.62], in that case caused by a block of ice. During the same mission a thruster also flooded with water. The consequence was an electrical dispersion, causing an increasing blade rotation velocity and thus a thruster force higher than desired.

43.3 Applications

Underwater robots currently play prominent roles in a number of scientific, commercial, and military tasks.

A possible consequence of different failures of the thrusters is the zeroing of the blade rotation. The thruster in question thus simply stops working. This has been intentionally experienced during experiments with, e.g., ODIN [43.59, 61], Roby 2 [43.58], and Romeo [43.62].

Other failures include a hardware/software crash or the occurrence of fin sticking or loss. A very common type of failure involves the loss of electrical isolation due to seawater intrusion into underwater electrical cables or connectors. Such a condition can be detected through a technique called ground-fault monitoring. Should this occur, electrical power must be removed from the affected device.

43.2.9 Multiple Underwater Vehicles

A growing research effort has recently been devoted to developing strategies to design coordinated control for underwater vehicles. The use of multiple AUVs, in fact, might improve overall mission performance as well as provide greater tolerance to failures (Chap. 40). Specific applications of this method in the underwater environment might include the naval mine countermeasure problem, harbor monitoring, and inspection, exploration, and mapping of large areas. AUVs might be coordinated with one or more surface vessels or connected to ground or aerial vehicles to form a coordinated network of heterogeneous autonomous robots.

Beside several institutions that have developed simulation packages for multiple-AUV operations, the use of real multiple AUVs is being considered for the adaptive sampling and forecasting plan of the Autonomous Ocean Sampling Network, formed by several research institutions such as (for the robotic components) Caltech, MBARI, Princeton, and WHOI [43.63]. Adaptive sampling is also being investigated at the Autonomous Systems and Controls Laboratory of Virginia Tech, which has developed five AUVs [43.64]. The Australian National University is currently working on a shoal of small, autonomous robots, named Serafina [43.65]. At Instituto Superior Técnico (IST), work is ongoing on the coordination between an AUV and a catamaran [43.66], i.e., a multirobot system constituted by heterogeneous autonomous vehicles.

Remotely teleoperated vehicles are very well established in all these areas, and are becoming increasingly auto-

mated to relieve the burden on human operators and to improve performance. Increasingly, autonomous underwater vehicles are finding application in these areas as well. Presently, **AUVs** are used almost exclusively for survey work, but sampling and other intervention tasks are becoming more feasible. Additionally, the line between **ROVs** and **AUVs** continues to blur, as systems that have the best properties of both evolve.

The offshore oil and gas industry relies heavily on **ROVs** for installation, inspection, and servicing of platforms, pipelines, and subsea production facilities. As the search for oil and gas goes deeper, this trend can only continue. The Marine Technology Society estimates that there are over 435 *work-class ROVs* operating in the commercial offshore industry today. **AUVs** are now beginning to appear in the commercial offshore industry for survey tasks, and concepts for hybrid systems that can perform intervention tasks are now appearing. The goal is not only for these robotic vehicles to replace human divers or human-occupied vehicles, but to enable an entire new generation of subsea equipment that is serviced without intervention by drill ships or other heavy-lifting vessels. This holds the prospect of greatly reduced cost.

Scientific demand for **ROVs** and **AUVs** is also increasing dramatically. Scientific applications for **ROVs** include survey, inspection, and sampling tasks previously performed by human-occupied submersibles or towed vehicles. While **ROVs** operating for science are not nearly as numerous as those in the offshore oil and gas industry, they are becoming commonplace. Most nations involved in global seafloor studies have several vehicles. Like the vehicles for the commercial offshore sector, these vehicles are becoming increasingly automated. High-quality electronic imaging, including high-definition television, is becoming increasingly common. Scientific **ROVs** are now equipped with sophisticated sampling devices for sampling animals, microbes, caustic hydrothermal vent fluids, and a variety of rock samples. Moreover, **ROVs** are also used to deploy and operate seafloor experiments, which can involve difficult tasks such as drilling and delicate placement of instruments.

ROVs have also emerged as powerful tools for investigating underwater shipwrecks and other cultural sites. Applications include forensic investigations of modern shipwrecks to determine the cause of sinking, archaeology, and salvage. For archaeology, the goals are the same as for excavation on land: detailed mapping fol-

lowed by careful excavation. Beyond diver depths, **ROVs** are the preferred method for these investigations. Great progress has been made in the detailed mapping phase, and capabilities for excavation are evolving. Unfortunately, the same technology also opens the possibility for shipwrecks to be looted for financial gain, which usually results in the loss of the most valuable historical information.

After a long period of skepticism, **AUVs** are now accepted for scientific tasks. Presently, **AUVs** most often perform mapping tasks while tended by a vessel. Specific mapping tasks include seafloor bathymetry, sidescan sonar imaging, magnetic field mapping, hydrothermal vent localization, and photo surveys. **AUVs** have been shown to improve productivity and data quality compared to towed and tethered systems. They have also operated in environments where no other means of gathering data is possible, such as under ice shelves. Likewise, the increasing availability of sophisticated in situ chemical sensors, biological sensors, and mass spectrometers now allows **AUVs** to build spatial and temporal maps of environmental features that could previously only be studied by bringing samples back to the laboratory. Plans are now underway for **AUVs** that can dock to subsea moorings or observatory nodes to recharge batteries and receive new instructions.

The military has always been a leader in the development of underwater robotic capabilities. They pioneered **ROVs** for tasks such as recovering test weapons and deep-sea salvage, and present-day commercial and scientific **ROVs** have descended directly from these early systems. Likewise, military interests are presently pushing **AUV** technology very hard. Many different countries operate **AUVs** for military surveys, gathering environmental data as well as searching for hazards such as mines. An operational success was achieved in surveying for mines in the Persian Gulf harbor of Umm Qasr using REMUS vehicles. **AUVs** in development will not only be able to detect mines, but to disable them. Bolder, more innovative concepts are also in development. These include networks of **AUVs** that can act as extensions of conventional surface vessels and submarines, enabling surveillance over wide areas for extended periods of time at costs far less than could be achieved with conventional surface vessels, submarines, and aircraft. These developments will rely on improvements in acoustic communications, energy systems, sensors, and onboard intelligence that will likely find their way into commercial and scientific practice.

43.4 Conclusions and Further Reading

The underwater environment is extremely hostile for human engineering activities. In addition to high pressures and hydrodynamic forces that are both nonlinear and unpredictable, water is not an appropriate media for electromagnetic communication except at short ranges. This pushes underwater technology to rely on acoustic communication and positioning systems that are characterized by low bandwidth. On the other hand, the ocean is extremely important for numerous human activities from the commercial, cultural, and environmental points of view.

Research on underwater robotic applications is active both from the technological and methodological aspects. The power endurance of commercially **AUVs** is currently up to 50 h; this will increase as energy-storage devices improve. Improved energy and power capability will enable longer missions, higher speeds, or better/additional sensors such as, e.g., more powerful lighting for underwater video/photography. The current trend for the price of **AUVs** prices is downward, with more and smaller research institutions building or buying **AUVs** to enrich their research results; moreover the setup of multiple-**AUV** systems is becoming cost effective. The goal is to develop fully autonomous, reliable, robust, decision-making **AUVs**.

There are a number of technology issues that are needed in order to improve **AUV** capabilities: to increase the underwater bandwidth of current acoustic modems, to increase onboard power to handle larger tools and interact more strongly with the environment, to create **AUVs** with significant hovering capability to allow better interaction, and to enable easier launch and recovery.

In the near future, the **ROV/AUV** dichotomy will likely become less prominent, with a variety of systems appearing that have attributes of both systems:

- For offshore oil and gas intervention tasks, a vehicle could transit to the work site as a self-powered, fully autonomous vehicle, then dock to the work site. Utilizing energy and communications infrastructure at the work site, the vehicle could then be operated much like a conventional **ROV**.

- Battery-operated **ROVs** can communicate with the surface by very lightweight fiber-optic links, enabling the mobility of an **AUV** but with a high-bandwidth connection to skilled human operators for complex intervention or scientific sampling tasks.
- Acoustic and optical data links can provide moderate to high communication bandwidths over short ranges, enabling human supervision without any tether restrictions. At longer ranges, more modest acoustic bandwidths are available.

These developments make marine robotics a challenging engineering problem with strong connections to several engineering domains. Sending an autonomous vehicle into an unknown and unstructured environment with limited online communication requires some onboard intelligence and the ability for the vehicle to react in a reliable way to unexpected situations [43.67, 68].

A major challenge concerning underwater robotics is the interaction with the environment by means of one or more manipulators. Autonomous **UVMSs** are still the object of research; the current trend is in developing the first semiautonomous robotic devices, which might be acoustically operated; moreover, if physically possible, the capability to dock to the structure where the intervention is needed might significantly simplify the control. The final aim might be to develop a completely autonomous **UVMS**, able to localize the intervention site, recognize the task to be performed, and act on it without docking to the station and without human intervention. This might make it possible to perform missions that are currently impossible such as autonomous archaeological intervention at deep sites. This would also enable the oil and gas industry to significantly decrease costs and risks to humans.

For further reading on the topic of underwater systems, the reader is referred to several survey articles, including [43.5, 26, 32, 33, 60]. Additionally, several journals cover oceanic engineering topics, including robotics aspects. A variety of symposia and workshops have been held on a regular basis. Some books/monographs treating marine robotics are [43.3, 7, 8, 16, 50].

44. Aerial Robotics

Aerial Roboti

Eric Feron, Eric N. Johnson

A wide array of potential applications exist for robots that have the level of mobility offered by flight. The military applications of aerial robotics have been recognized ever since the beginnings of powered flight, and they have already been realized to sometimes spectacular effect in surveillance, targeting, and even strike missions. The range of civilian applications is even greater and includes remote sensing, disaster response, image acquisition, surveillance, transportation, and delivery of goods.

This chapter first presents a brief history of aerial robotics. It then continues by describing the range of possible and actual applications of aerial robotics. The list of current challenges to aerial robotics is then described. Building from basic notions of flight, propulsion, and available sensor technology, the chapter then moves on to describe some of the current research efforts aimed at addressing the various challenges faced by aerial robots.

The challenges faced by aerial robots span several and distinct fields, including state regulations, man-machine interface design issues, navigation, safety/reliability, collision prevention, and take-off/landing techniques. The size of aerial robots can considerably influence their flight dynamics, and small aerial robots can end up looking considerably different from their larger counterparts. Similar to their manned counterparts, aerial robots may enjoy diverse propulsion systems and operate over large speed ranges.

Aerial robots must be equipped with reliable position and actuation equipment so as to be capable of controlled flight, and this constitutes a nontrivial requirement prior to doing research

or development in this field. However, many universities, research centers, and industries have now met this requirement and are actively working on the challenges presented above. The largest obstacle to the commercial development of aerial robots is, however, the necessity to comply with and support a regulatory environment which is only beginning to address these rapidly developing systems.

44.1 Background

The term *aerial robotics* is often attributed to *Robert Michelson* [44.1], as a way to capture a new class of highly intelligent, small flying machines. However, it is clear that the range of systems and activities covered under the label *aerial robotics* could extend much further, and that its roots can be found far back in the beginning of the 20th century, together with the birth of aviation. Behind the word *aerial robotics* we can find several meanings: it could mean *robotic flying machines*, that is, a mission-independent, platform-oriented concept; however, it could also mean *robotics that use flying machines*, that is, a platform-independent, mission-oriented con-

cept. Finally, it could mean a combination of the above, that is a description of the robotic platform, together with its robotic mission. In aerospace jargon, robotic flying machines are commonly referred to as *unmanned aerial vehicles (UAVs)*, while the entire infrastructures, systems and, human components required to operate such machines for a given operational goal are often called *unmanned aerial systems (UASs)*. Finally, it is worth noting that many current manned aerial systems definitely carry relevant features of some robotic systems, and so much of this discussion is relevant to manned aircraft.

44.2 History of Aerial Robotics

The history of aerial robotics is very closely tied to the history of flight itself. Indeed, the rate of fatalities associated with early manned flight tests probably convinced engineers that there was a need to operate flying machines without the presence of humans on board even before potential applications of unmanned aircraft surfaced. In 1903, heavier-than-air flight was unambiguously shown to be feasible, following the achievements of the Wright brothers. The first successful powered flight was unmanned, presumably to reduce the risk to the pilot and to allow a smaller and less expensive vehicle (reasoning that is still put forth today) by Samuel P. Langley's *Number 5* in 1896 [44.2].

Finding a truly defining moment for aerial robotics is a challenge, with encyclopedias dating the concept back to Leonardo da Vinci, while *Newcome* [44.3], in his history of unmanned aviation, gives early credit to Nikola Tesla for devising a robotic vehicle remotely controlled

by electromagnetic waves, and with enough onboard logic to recognize and execute remotely transmitted orders. However, the concept imagined and engineered by Tesla did not apply specifically to airborne vehicles.

Using the definition

An aerial robot is a system capable of sustained flight with no direct human control and able to perform a specific task,

leads us almost immediately to the Hewitt-Sperry automatic airplane, developed before and during World War I [44.3]. The airplane's purpose was to act as a flying torpedo, carrying onboard *intelligence* to sustain flight over long periods of time without human intervention. Such intelligence was provided by a complex system involving Sperry's own gyroscopes, mechanically coupled to the airplane's control surfaces so as to stabilize the vehicle. This made the airplane suitable for

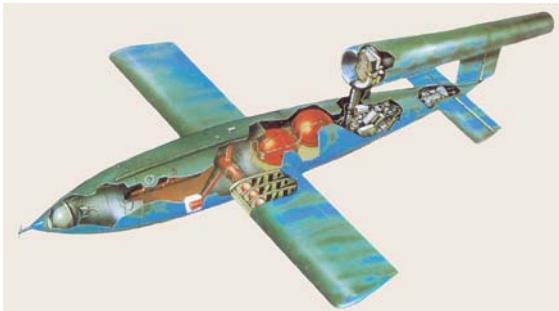

Fig. 44.1 V-1 German cruise missile (1940s)

Fig. 44.2 QH-50 DASH unmanned helicopter on final approach (US Navy)

human remote control and, eventually, prosecution of distant targets. As discussed later, one of the key characteristics of aerial robotics is this particular necessity for the robot to sustain itself in the air with no human intervention, which requires the early adoption and understanding of the critical role played by *onboard intelligence*, much more so than other robotic applications. While a string of inventors in many countries came to develop ever more sophisticated machines, credit goes to the German V-1 cruise missile for making a lasting, and unfortunately deadly, impact on large segments of the population in England. This form of robotic aircraft owed its relative inefficiency (three out of four vehicles reportedly missed their target – predominantly London) to mechanical failures and lack of good navigation capabilities beyond dead-reckoning assisted by gyroscopic

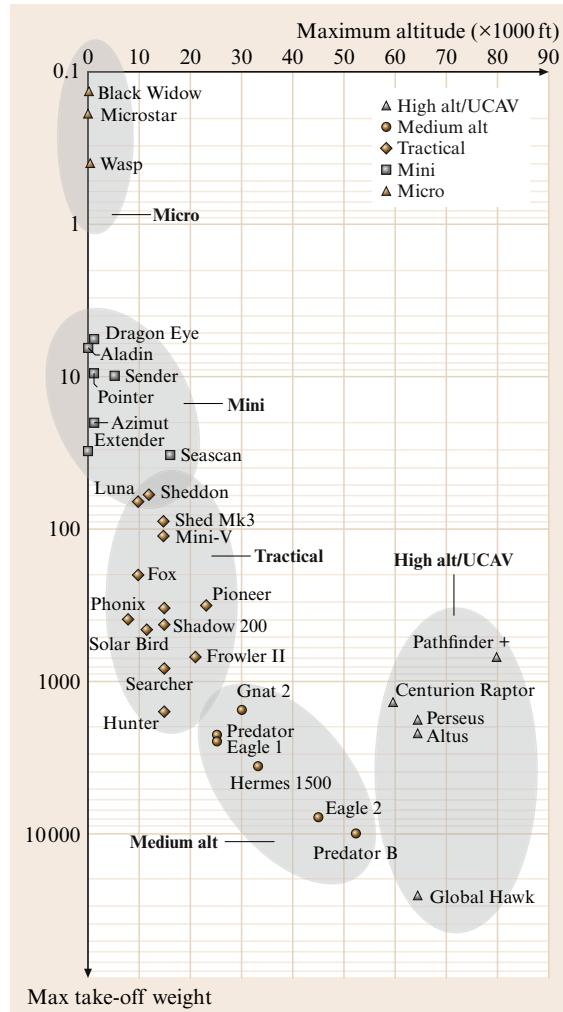

Fig. 44.3 Taxonomy of unmanned aerial vehicles (after R. Weibel [44.4,5])

devices. Many of the ensuing aerial robotics developments followed the initial idea of defense applications for unmanned systems, that is, ever more accurate flying machines for the purpose of either reconnaissance or weapon delivery. One notable machine was the US Navy's Gyrodyne QH-50 DASH, an unmanned helicopter developed in the 1950s and operated from US destroyers, which was able to perform reconnaissance missions and deliver torpedoes (Fig. 44.2). However, these machines remained relatively *unintelligent*, and their level of autonomy remained limited to the ability to sustain flight using complex inertial and other measurement systems.

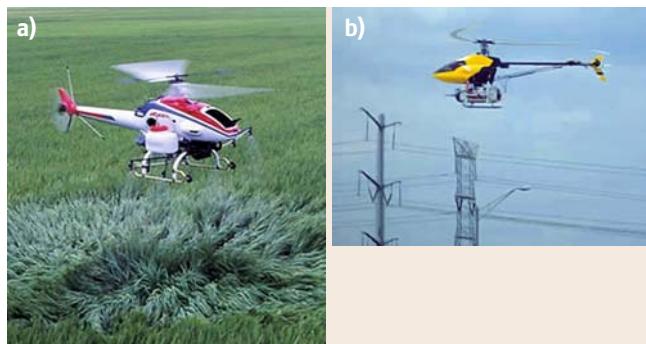

Fig. 44.4a,b Autonomous helicopters: (a) Yamaha's R-MAX (b) Nascent Technologies Corp's XS

From a robotics perspective, probably the next significant technological enabler is the advent of lightweight processors and sensor systems, together with global navigation satellite systems, which allowed aerial robots to perform increasingly complex tasks. Japan, motivated by a policy of food self-sufficiency combined with a massive shortage of agricultural workforce, took a lead in aerial robotics by developing highly reliable helicopters in the 1980s, such as the Yamaha R-50 and subsequent Yamaha R-Max (Fig. 44.4), with similar systems developed by other companies such as Yanmar. These robotic helicopters are used primarily for crop dusting applications, especially over wet rice fields. These vehicles also turned out to be very popular among universities and other institutions for their unmatched

ability to fly reliably and take off and land from limited areas, allowing researchers to focus their attention on developing higher levels of autonomy beyond basic vehicle navigation and control. Military applications of unmanned robotics followed the track of the German V1, with the advent of modern cruise missile technology.

From the mid 1980s on, the development of aerial robots has followed an exponential pace, with one notable trend for operational aerial robots to systematically find military applications as their most significant market.

A snapshot of available aerial vehicle platforms and systems appeared recently in [44.6], and regular updates on available platforms can be found in the aerospace literature. The chart in Fig. 44.3 illustrates the number of machines currently under development or in operation, which exceeds 200 vehicle types. From this chart, one concludes, however, that the vast majority of current, operational aerial robots are fixed-wing aircraft, and that they tend to be present at all altitudes.

We must also remark that onboard robotic intelligence has made its way not only into unmanned aircraft but also manned aircraft. Many commercial airliners now have the ability to fly automatically from right after take-off (a decision left to the pilot) to right *after* landing, by engaging the autopilot and letting the aircraft fly a predetermined profile. In addition, these vehicles are now able to make systems-management decisions based on sensor inputs, sometimes escaping the human pilot's ability to understand them.

44.3 Applications of Aerial Robotics

Listing all possible applications of aerial robotics is very challenging. However, there are fewer actual implementations, because of the necessity for the corresponding operations to comply with stringent air safety regulations. In the following, a brief description of possible and current applications is provided.

44.3.1 Possible Applications of Aerial Robots

The list of possible applications of aerial robots is long. According to [44.6, 7], such applications fall within nine categories:

- *Remote sensing* such as pipeline spotting, powerline monitoring, volcanic sampling, mapping, meteorol-

ogy, geology, and agriculture [44.8, 9], as well as unexploded mine detection [44.10].

- *Disaster response* such as chemical sensing, flood monitoring, and wildfire management.
- *Surveillance* such as law enforcement, traffic monitoring, coastal and maritime patrol, and border patrols [44.11].
- *Search and rescue* in low-density or hard-to-reach areas.
- *Transportation* including small and large cargo transport, and possibly passenger transport.
- *Communications* as permanent or ad hoc communication relays for voice and data transmission, as well as broadcast units for television or radio.
- *Payload delivery* e.g., firefighting or crop dusting.
- *Image acquisition* for cinematography and real-time entertainment.

Military applications of aerial robots follow the same descriptive lines, with a particular emphasis on remote sensing of humans and critical infrastructure, surveillance of human activity, and payload delivery (bombs, missiles, and ad hoc ground infrastructures devoted to communication and surveillance).

44.3.2 Current Applications

Current applications of aerial robots are somewhat fewer and they are at present driven by the military context.

Aerial Observations

The most important application of aerial robots is aerial observations, which can then be used for terrain mapping, environmental surveys, crop monitoring, target identification etc. There is a divide, however, between the state of the art for military applications and civilian applications, detailed below.

Military Operations. Military and government use of aerial robots has sharply increased in recent years in war zones. As a result, dozens of vehicles are now delivered every month, and end up flying in “hot” areas around the globe, most notably in Southwest Asia. The machines being flown range from man-portable machines flying at low altitudes, such as the Pointer or Raven aircraft, to mid-sized machines such as the Aerosonde, Seascal, or Shadow unmanned vehicles, to larger-sized vehicles such as the Predator or Global Hawk. Their wings span from a meter or so for the smaller vehicles to 35 m for Global Hawk (the same as a Boeing 737). Besides their use in military areas or war zones, these machines now find applications in border surveillance, with a particular interest in oceanic borders, where vehicles operate in desert or quasi-desert areas.

Civilian and Private Applications. Current civilian applications of aerial robots for surveillance and observation remain sporadic and ad hoc: unlike many other robotic devices, civilian aerial robots do not operate in *closed* environments but in civilian airspace, which is subject to strong safety regulations that do not yet systematically accommodate aerial robots. Consequently, the current trends in civilian aerial robotics are as follows.

Small-scale, intermittent civilian aerial robotic applications tend to happen in relatively isolated environments (e.g., for film making or environmental surveys), and often follow the safety and operations rules most familiar to their operators, derived

from model aircraft operations. Most often, the operated machines do in fact bear much resemblance to radio-controlled model airplanes. Other intermittent applications involve the use of unmanned vehicles for specific reconnaissance tasks, such as the detection of fish banks from trawlers [44.12]. Such a task constituted one of the original purposes for the development of machines such as the Seascal unmanned aerial vehicle.

Long-term scientific applications such as atmospheric sampling experiments [44.13] appear to benefit considerably from aerial robots. One report [44.13] reads

From March 6 to March 31 2006, we probed the polluted atmosphere over the North Indian Ocean with lightweight unmanned aerial vehicles (or UAVs) fully equipped with instruments. This UAV campaign launched from the Maldives laid a solid foundation for the use of UAVs to study how human beings are polluting the atmosphere and their impact on climate, including global warming.

Because such activities naturally require much planning ahead, special permits can be obtained from aviation authorities within time limits that do not significantly affect the overall experimental project. Other scientific missions led with success include [44.14], where the authors were able to survey Mount St. Helens (then active) by taking advantage of the temporary interdiction to fly in the vicinity of the volcano.

With the progressive introduction of aerial robots in the regulatory framework of many countries, we believe that intermittent applications of aerial robotics in populated areas will eventually become commonplace. However, this requires that flight authorizations be delivered within a fraction of the time duration of the event: for example, firefighting operations are often triggered within a few seconds of the fire alert. Permits for aerial robotic support should therefore be delivered about as quickly if they are ever to be embraced by firefighters.

Payload Delivery

Under the heading *payload delivery*, we find the numerous applications of aerial robots aimed at delivering solid, liquid or gaseous products in areas that are hard to reach for humans. So far, the most successful civilian application has been chemical crop spraying using small unmanned helicopters. Leveraging the high costs and prices associated with crop culture in Japan, several thousand helicopters have been purchased by farmers, resulting in a profitable

operation both for themselves and for the helicopter manufacturers, among them Yamaha and Yanmar. However, this application remains unique and involved the involvement of Japan's government for it to be successful.

Besides this particular application, military applications form the bulk of unmanned aerial robotics for the purpose of payload delivery, beginning in its crudest form with missiles, and evolving towards cruise missiles, able to navigate for thousands of miles and reach their targets with high precision. One of the most talked-about recent military application of aerial robots for payload delivery involves the Predator aircraft equipped with Hellfire missiles.

General Characteristics of Current Applications: Level of Autonomy

Most, although not all, aerial robots currently under operation are automatically controlled as far as their dynamics are concerned. However, higher levels of autonomy, such as path planning, object detection, and recognition and mission management involve human operators, who always remain in contact with the flying machine. Thus not much distinguishes current aerial robots from traditional manned aircraft, except that the pilot sits on the ground rather than in the air.

As such, most of today's operational aerial robots may be justifiably called remotely piloted vehicles (**RPVs**).

44.4 Current Challenges

In the following, we introduce six major challenges for aerial robotics. This list is not meant to be exhaustive, but it reflects the current focus of researchers. How these challenges are addressed will be discussed later.

44.4.1 Regulations and Certification

A big challenge to the success of aerial robots is doubtlessly their acceptance by certification authorities. Indeed, the operation of aerial robots is currently significantly limited by regulatory constraints. This is due to the complex set of regulations put in place by national agencies (e.g., the Federal Aviation Administration in the **US**, the National Air Traffic Services in the UK, or the Direction Générale de l'Aviation Civile in France), whose aim is to maintain very high levels of safety for air traffic. The downside of the excellent safety record reached by regulatory agencies is their (justified) risk adversity, and therefore a slow acceptance of disruptive technologies such as aerial robots. This is compounded by the current rapid pace of change and related lack of standards among aerial robotic systems and how they are used. However, with the help of other organizations, such as the Radio Technical Commission for Aeronautics (**RTCA**), regulatory agencies have moved forward towards establishing rules for the routine operation of aerial robots. Such rules include the ability for aerial robots to *see and avoid* or *sense and avoid* other traffic at least as well as a human pilot.

In the recent past, many aerial robotics research activities and corresponding flight tests have occurred at very low altitude. In the absence of clearly defined

rules by regulatory bodies until recently (2000), many researchers have operated under the rules of local radio-controlled aircraft associations (e.g., the Academy of Model Aeronautics). However, there is a rapidly growing trend for radio-controlled vehicles to incorporate more onboard electronics, including radio transmitters and sometimes guidance systems. In this environment, one can expect regulatory bodies such as the FAA to continue to evolve their policies.

The ensuing challenge is for the research community is to develop the requirements and subsequent technology that meets the constraints set by the regulatory agencies, or to propose and justify alternate constraints. In particular, the maturation of aerial robots leading to their everyday use in populated areas will require the development of more reliable components, defined maintenance procedures, formal training programs, and the automation of emergency procedures (such as the forced landing process). The core technology for **UAS** already exists to demonstrate safety concepts. However, developing highly dependable systems – and making such dependability guarantees acceptable to the regulatory authorities – is a current and urgent challenge.

44.4.2 Human–Machine Interfaces

The pilot interfaces used for manned aircraft have evolved continuously since the first manned aircraft. The standards that exist today directly benefit safety and operator costs by minimizing operational errors and training time when transitioning between aircraft types. Despite ongoing development efforts [44.15], this can-

not be said of aerial robotic systems, which run cover a much wider range of autonomy, mission capability, and operator skill. Add to this the desire to have single operators control multiple aircraft, and it clear this area presents an ongoing challenge for researchers.

44.4.3 Navigation

Figuring out absolute and relative position is a central issue for aerial robots, as it is for other robotics activities. The existence of a significant manmade infrastructure (the global navigation satellite system – **GNSS**) makes basic navigation easy but remains the subject of an intense debate; indeed, systems that overly depend on such infrastructure lack resilience and tolerance to positioning services shortage, whether such a shortage originates from the system itself or from the particular robot configuration (in cluttered environments such as cities). This situation will improve with the development of highly reliable multimode navigation systems with built-in integrity monitors, and with three independent satellite navigation constellations (Glonass, Galileo, and **GPS**) currently deployed or under deployment.

The challenge for researchers is to develop navigation technologies that allow aerial robots to live without manmade external navigation infrastructure, to handle the situations when it is not available.

44.4.4 Agile Flight and Fault Tolerance

Nearly every aircraft in operational use today has been challenged to fly far beyond its flight envelope during flight tests, including famous maneuvers such as that of the Boeing 707 that, during early flight demonstrations to customers, performed a full barrel roll. The purpose of these demonstrations is not only to show the full capabilities of the vehicle, but also to bring a sense of safety to the pilots, that the aircraft is still able to perform well after it goes into some upset condition. What applies to large, manned aircraft also applies to aerial robots,

which must be able to keep operating well at unusual attitudes and under partial system failures such as loss of actuation [44.16]. Researchers must develop automation systems that meet this need.

44.4.5 Obstacle Avoidance

The ability for a vehicle to manage its position away from obstacles represents a significant issue and a necessity for low-altitude operations in crowded environments. One of the key features of aerial robots is their possibly high speeds, which challenges many existing sensor management and data processing algorithms, especially their ability to detect hard-to-see obstacles such as suspended cables quickly.

44.4.6 Aerial Robot Landing and Interaction with Other Vehicles

Owing to the finite endurance of aerial robots, landing and docking are particularly important to them. While landing constitutes an important element, docking with other vehicles, such as during aerial refueling, is also very important. All operations involving close coordination and physical interaction between vehicles or between a vehicle and the ground require further research.

44.4.7 Multivehicle Coordination

Several tasks require aerial robots to operate as a group, rather than as individual systems. This happens, for example, in order to create phased array antennas, or to perform object geolocation, or to improve the quality of a surveillance service (e.g., fire monitoring). Other tasks requiring multivehicle coordination include the requirement for collision avoidance. More recently, multivehicle coordination has been seen as a valuable way to design aerial robotic systems that remain functional despite individual vehicle failures.

44.5 Basic Aerial Robot Flight Concepts

44.5.1 Aerial Robot Flight and the Importance of Scales

Like all flying machines, the performance of aerial robots depends extensively on: (1) their size and (2) the characteristics of their lifting mechanisms (wings, ro-

tors). A detailed description of vehicle flight mechanics is outside of the scope of this chapter; we can, nevertheless, recall a few fundamental and useful notions critical to successful flight. The reference [44.17] is an excellent and entertaining introduction to the subject, while [44.18, 19] offer a more academic perspective on

Fig. 44.5 Flying wing (Northrop's YB47) and its shrunk version flying together

the matter. One important quantity is the *mass* of a flying machine. Roughly speaking, the mass of a flying machine is proportional to its volume, and therefore grows like the cubic power of its size. Another quantity is the lifting forces that keep a vehicle up in the air; these are proportional to the pressure exercised on the lifting surface (rotor or wing), times the *area* of the lifting surface, that is, roughly the second power of the vehicle size. The pressure itself is proportional to the density of the surrounding atmosphere (it need not be air only, think of Mars), multiplied by the square of the average velocity of the gas molecules relative to the lifting surface.

For illustrative purposes, consider the flying wing shown in Fig. 44.5 and a notional scaled-down version of it flying together. To make matters simpler, we assume that the scaled-down wing is about half the size of the full-sized wing. We now examine the impact of scales on the way these wings must fly.

Consider for example the lift created by the full-scale flying wing depicted in Fig. 44.5: it is proportional to $S\rho V^2\alpha$, where S is its total surface, ρ is the air density, V is the wing speed relative to the surrounding air, and α is the angle of attack (roughly speaking the angle between the wing chord and the flow of air).

To get an idea of the importance of scales, and following arguments developed in much greater detail in [44.17], we now examine the requirements for the scaled-down wing to fly at the same speed as the large wing, assuming all its components are shrunk by a factor two in size as shown in the picture, and examine the consequences of having to meet such requirements.

First, the mass of the wing roughly gets divided by a factor 8 (2^3). However, its lifting surface has shrunk by

a factor of 4 only (2^2). So, if we were to fly this smaller wing at the same speed, same altitude, and same angle of attack as its big sister, the total generated lift must be $S/2\rho V^2$, that is, twice as much as necessary to balance out the effect of gravity.

Several solutions to this issue are possible: to reduce the actual wing dimensions at constant mass, slow it down, or reduce its angle of attack.

Shrink the Wing

To obtain the proper lift (while keeping the speed and angle of attack constant), we must shrink the wing area by another factor of two, or the wing dimensions by a factor $\sqrt{2}$. Thus we already see one important conclusion, which is that, at equal speed and angle of attack, *the relative size of the wings with respect to the overall vehicle must shrink as the overall vehicle size goes down*. Borrowing again from [44.17], this explains much of why a Boeing 747 looks, with its large deployed wings and relatively narrow fuselage, like a condor while a B737 feels more like a puffin, and the smaller Embraer 145 is like a dart, as shown in Fig. 44.6. All

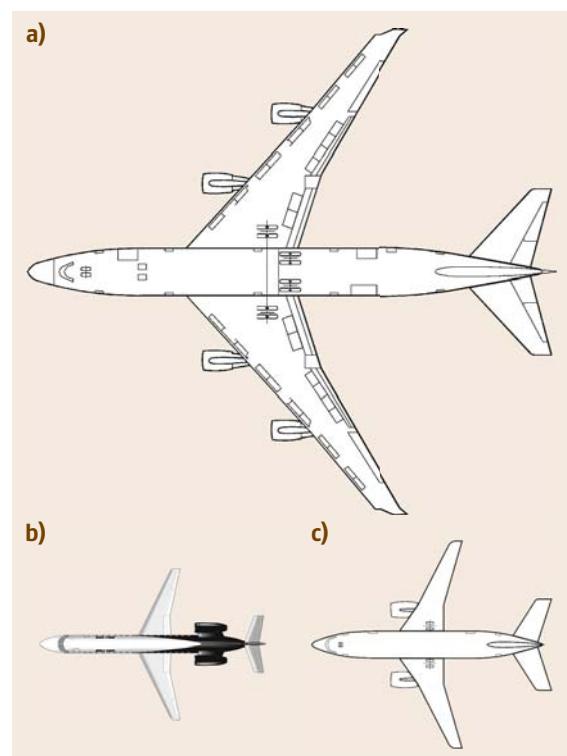

Fig. 44.6a–c Relative fuselage and wing sizes for various aircraft: (a) Boeing 747; (b) Embraer 145; (c) Boeing 737

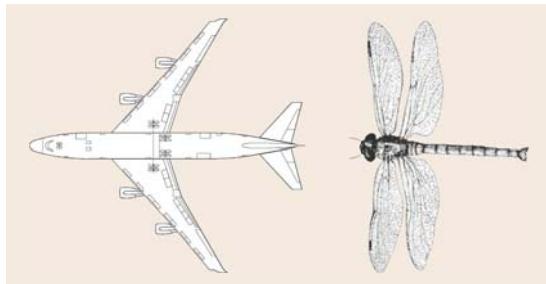

Fig. 44.7 Boeing 747 and dragonfly

these aircraft can fly about the same speeds and altitude ranges.

Reduce the Speed

If this option is chosen, then speed must be divided by a factor $\sqrt{2}$ for our scaled model to balance lift and weight. The consequences of reducing speed are many: the time required for mission completion of course increases. On the other hand, the drag generated by the flying machine (and which must be paid for by the propulsion system) goes down.

Pushed to their limits, the consequences of slowing down the vehicle as it shrinks can be quite dramatic: consider a dragonfly (one of the role models for micro-aerial robots) trying to land next to a Boeing 747 at the same airport. The figure below shows that the two share (very roughly) the same proportions.

For the sake of simplicity, assume that the dragonfly is the 1/1000 scaled-down version of the Boeing 747. In order for both to fly level, and according to our rule, the dragonfly must fly a factor $\sqrt{1000} = 32$ slower than the B747. Assume the B747 flies at 500 km/h; that makes the dragonfly fly at about 17 km/h. Imagine now that the weather is gusty, with winds topping 30 km/h. The 747 (and its passengers) will see little variation in airspeed (from 470 to 530 km/h), and the variation in produced lift will be 33%, enough to shake the aircraft a bit, but not unusually bad. As for the dragonfly, the same gusts will create airspeed variations of *well over 100%*, and the produced lift will vary from zero to five or six times the nominal lift. A rough ride naturally follows, and indeed, the flight of smaller vehicles often looks much less smooth than that of large ones.

Reduce the Angle of Attack

The latter option, reducing the angle of attack, rests upon the fact that, roughly, the lift created by a wing (or a rotor), is a linear function of the angle of at-

tack. This makes it possible to fly about the same speed with a scaled-down model of a flying machine. However, this option comes with significant drawbacks, especially for fixed-wing aircraft. In particular, the *sensitivity* of the lift created by the wing to external perturbations (e.g., air turbulence and wind gusts) would again be higher, creating another recipe for *bumpy rides*.

The previous considerations about the forces acting on aerial vehicles also apply to moments: consider the flying wings shown in Fig. 44.5, and assume that their density (mass per unit volume) is constant throughout. Their angular inertia about any axis are proportional to the *fifth* power of their size. On the other hand, the forces that apply to the wings are proportional to their area; thus when *moments* are computed, forces are multiplied by distances, and the resulting moments become proportional to *volume*, that is, the third power of vehicle size. Consider then the angular momentum equation

$$J\ddot{\theta} = M, \quad (44.1)$$

where J is the moment of inertia of the vehicle and M is the applied torque. The term to the left of (44.1) decreases *much faster* with vehicle size than that to the right of the equation. As a consequence, we might immediately conclude that the scaled-down flying wing is inherently *much more maneuverable* than the larger one, in the sense that it can change orientation much faster.

This opens up a wealth of possibilities for robotics: venturing into the world of small flying robots, enabled by improvements of battery power and computation densities opens new possibilities in terms of defining the way these vehicles fly and interact with their environment.

44.5.2 Propulsion Systems

Several propulsion systems exist for aerial robots, including: jet, internal combustion, rocket, and electric. Older but recurrent options also include pulse engines such as those used on the German V1.

Owing to established aircraft and helicopter propulsion technologies, internal combustion engines and jet engines form the bulk of the propulsion means for medium to large-sized operational vehicles (50 kg or more), allowing many of them to fly reliably over periods of several hours to several tens of hours. When considering operational robots, the kind of fuel used matters: preference is given to fuels al-

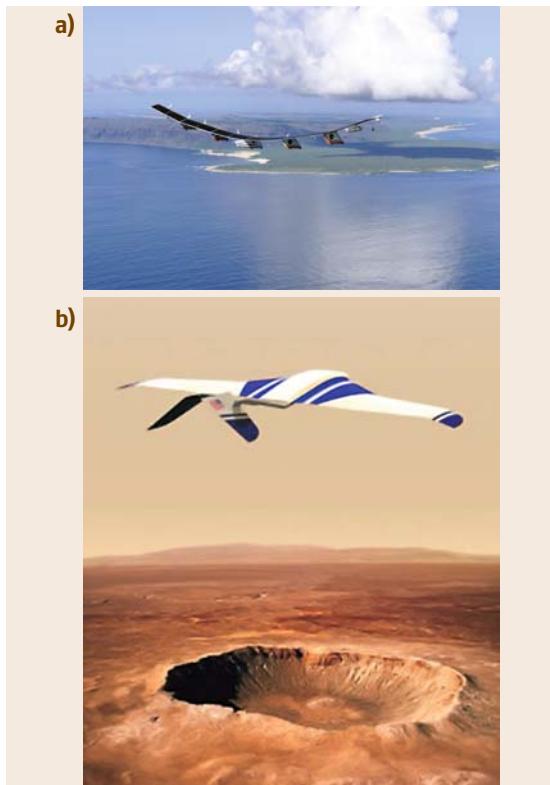

Fig. 44.8 (a) Helios high-altitude long-endurance aircraft, (b) Mars aircraft [44.20] (Source: NASA)

ready used in other devices, and preference goes to heavy fuels, which are less prone to sudden and dangerous combustion or explosion, for example after a crash.

Electric propulsion systems, once unthinkable, have become a reality for several small-sized aerial robots, thanks to the development of affordable brushless electric engines and lightweight batteries. Initially developed for computer and communication applications, these batteries have been very quickly adopted by small-sized (a few kg) aerial robots such as Aeroenvironment's Pointer and Raven aircraft, which are able to fly over periods exceeding one hour. The National Aeronautics and Space Administration's (NASA) Pathfinder unmanned aircraft combines lightweight electric engines with wing-mounted solar panels to yield the aircraft shown in Fig. 44.8.

A notable departure from these propulsion systems is the Mars airplane's propulsion system [44.20]: with an inert, low-density atmosphere on Mars, such a vehicle relies on a rocket engine for propulsion.

44.5.3 Flight Vehicle Types and Flight Regimes

Several vehicle types form the bulk of aerial robots, including fixed-wing machines, helicopters, flapping wing systems, and combinations thereof. The boundaries between these vehicle types are, however, mostly inherited from historical developments and intellectual stove-piping, rather than any fundamental guidelines dictated by the laws of mechanics and thermodynamics. For that reason, it is easier and more logical to introduce different *flight regimes* than flight vehicles, although to every regime there naturally corresponds one particular vehicle.

There are essentially two flight regimes. In the first regime, called *hover*, the speed of the vehicle relative to the surrounding air is small, such that few or no forces act on the vehicle except those resulting from the propulsion system itself. In the second regime, which we may call *cruising flight*, there is a significant relative speed between the vehicle and its surrounding environment, and significant aerodynamic forces act on the vehicle; these aerodynamic forces then largely dominate those generated by the power system.

Hover

Hover is the condition when the vehicle body does not move significantly with respect to the air mass surrounding it. Under these conditions, only propulsion systems are available to keep the vehicle up in the air (for heavier-than-air systems). Helicopters epitomize these situations, and they are especially designed to sustain such hover conditions over long periods of time. Helicopters come in all sizes and shapes. Robotic helicopters are best represented by Yamaha's R-50, and now RMAX models (see, for example, Fig. 44.4), and both have been a staple of airborne robotics research for years at several academic institutions because of their reliability and available payload, which allows them to carry many instruments of interest to robotics research (including navigation sensors such as video cameras, laser range finders, and radars). With the evolution of the economic and political context, one is bound to see other such machines abound in the future. Indeed, the ability to hover is extremely useful for delivery/pickup of materials, rescue missions, and, in general, any operations that require close proximity to rugged terrain.

Helicopters are not the only vehicles capable of hover, see for example the hover-capable fixed-wing aircraft in Fig. 44.9. Hovering aircraft, such as tailsitters,

have been tested successfully since the 1950s at the very least, and it is a classic trick for experienced remote control pilots to hover airplanes. Transitions from hover to forward flight and back have been automated [44.21]. As radio-control (R/C) equipment shrinks in size and mass, new generations of hovering vehicles will become available. Some of these vehicles include micro air and flapping wing vehicles.

Hovering flight typically not very fuel inefficient: the fuel consumption of a hovering vehicle can exceed that of a fixed-wing vehicle by an order of magnitude or more. This kind of consideration has led manufacturers to seek some of the mixed configurations shown in Fig. 44.9.

Cruising Flight

During cruising flight the aerial robot mostly uses its available surfaces and its speed relative to the surrounding atmosphere to generate lift and maintain altitude. Unlike hovering flight, cruising flight usually results in the aerial robot constantly meeting *fresh air*, which makes the range of adverse events to flight quite narrower. This, of course, is not true in the case when aerial robots fly in formation, in which case turbulence created by one robot may affect its neighbor(s), sometime adversely, and sometimes positively [44.22].

Robotic airplanes such as those shown in Fig. 44.8 epitomize fuel-efficient cruising flight, with large and highly optimized wings. Both aircraft are part of current **NASA** programs. While optimized for flight, the wings of the Mars aircraft must also be optimized for tight packaging and deployment constraints at the end of its long trip from Earth to Mars.

While many fixed-wing systems are optimized for cruising flight, any system in forward flight operates according to the same principles; for example, a helicopter in forward flight operates like an airplane whose wing is a flat disc spanning the area covered by its rotor. Constant-velocity cruising flight that generates lift from the available aerodynamic surfaces is more fuel efficient than hovering.

Stalled and High-Angle-of-Attack Flight

This flight condition can be seen as a *transitional* flight condition, where the characteristics of both forward flight and hover are present. Typically, an aircraft stalls when its tries to maintain altitude at low speeds: flying level at lower speeds forces the aircraft's angle-of-attack to increase for the wings to produce more lift. However, past a critical angle of attack, the trend reverses

Fig. 44.9a–c Non-helicopter, hover-capable vehicles: (a) Joint Strike Fighter, (b) 1950s tailsitter aircraft and (c) Aurora Flight Sciences' Golden Eye 100

and the lift produced by the wing *decreases* as the angle of attack keeps increasing. This reduced aerodynamic lift must then be compensated by increased throttle, resulting in a situation where the aircraft propeller not only acts as a means to move the aircraft forward, but also directly participates in maintaining aircraft altitude.

This flight condition, whether experienced on a helicopter or airplane, often results in important changes of the effect of control mechanisms, for example, a stalled Piper Tomahawk trainer aircraft at low throttle setting will experience ineffective ailerons, while its rudder efficiency will shift from yaw axis to roll axis control [44.23].

44.5.4 Lighter-Than-Air Systems

One way to deflect some of the concerns associated with high fuel consumption of heavier-than-air aircraft is to rely on lighter-than-air vehicles. While these vehicles are often associated with spectacular accidents and slow motion, they also offer an unmatched capability to fly for long periods of time (more than 48 h) and to do so silently [44.24, 25]. Establishing control over lighter-than-air vehicles can be, however, somewhat challenging. In particular these vehicles are quite sensitive to winds and often tend to *go where the wind takes them*. Smaller platforms used for research must therefore evolve in closed environments [44.26]. The use of such vehicles for outdoor research can be quite daunting, because their large size requires considerable infrastructure to store them.

44.6 The Entry Level for Aerial Robotics: Inner-Loop Control

Aerial robots exhibit the complex flight dynamics associated with flight vehicles. As a consequence, precise motion control rapidly becomes a necessity for *any* aerial robotics activity to occur successfully. This means that effort must go into reliable basic flight control before more advanced, intelligent mission management can be attempted. Inner-loop control is achieved by the right sensing equipment, and by adequate control algorithms. Efficient hovering vehicles tend to be unstable, which makes their stabilization more difficult than that of purely cruising vehicles, for which many commercial control packages are now commonly available.

44.6.1 Sensing and Estimation

Airborne robots come with a variety of sensing options, which include

- inertial navigation systems (gyroscopes, accelerometers)
- global navigation satellite systems (GLONASS, [GPS](#), Galileo)
- terrestrial radio navigation systems (VHF omnidirectional range ([VOR](#)), distance measuring equipment (DME), instrument landing system ([ILS](#)))
- air data probes and altimeters
- radar and passive vision sensors
- magnetic compasses
- distance measuring (altitude radars, ultrasonic sensors, and laser range finders)

The choice of sensors is critical to obtaining a properly flying robot. Usually, the same suite of sensors may not apply to all phases of flight. We will concentrate our discussion on the first four sensor types.

Inertial Navigation Systems

Inertial measurement systems consist of a combination of usually three orthogonally mounted accelerometers

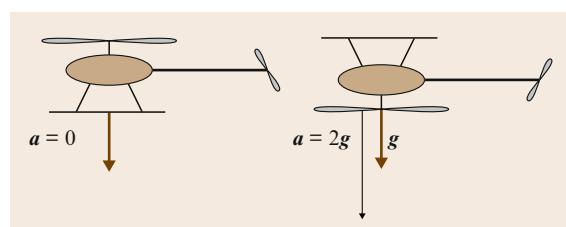

Fig. 44.10 Two inertially equivalent helicopter configurations

and three orthogonally mounted gyroscopes (more may be used for the purpose of achieving redundancy). The accelerometer suite measures, up to sensor error, the accelerations experienced by the vehicle at the location of the inertial sensor minus gravity. Gyroscopes measure vehicle angular velocities. Modern inertial sensors are usually rigidly linked to the vehicle to form strap-down inertial measurements systems. Such systems have become very cheap and very popular. Unlike many nonflying applications, unaided inertial measurement packages are not sufficient for estimating the attitude of an airborne vehicle. Indeed, consider Fig. 44.10, showing two helicopters equipped with inertial measurement systems. One, straight up, is hovering. The second, upside down, races towards the ground with an acceleration of $2g$. The accelerations and rotation rates recorded by the onboard inertial measurement unit will be strictly the same in both cases. While attitude can be estimated by integrating angular rates over time, the approach will eventually fail without correcting for accumulated error from another source. It remains that inertial measurement units are extremely useful to measure variations in acceleration and angular velocities, and constitute a staple of inner-loop control systems. Small radio-controlled helicopters now come with built-in gyroscopic yaw dampers that make their manual operation much more manageable. A key progress was made when Analog Devices introduced a low-cost micromechanical gyroscope [44.27]. Since then, this technology appears to have made its way into most commercially available inertial measurement units (IMUs), thereby greatly reducing their cost and weight. Practical inertial navigation systems on aircraft typically receive at least position updates from other sensors (discussed below), called inertial aiding.

Global Navigation Satellite Systems

The Global Positioning System ([GPS](#)) and its Russian equivalent GLONASS and future European Galileo space-based systems offer real-time absolute position information, using a constellation of satellites circumnavigating the earth. Ever since the beginning of their operation, global navigation systems ([GNS](#)) have been the object of a debate concerning their use in aerial robotics, with many researchers recommending against using such a large manmade navigation infrastructure to achieve *true autonomy*. Their arguments tend to become justified by the occurrence of recent needs in such applications as Mars exploration and low-altitude flight

in obstacle-laden environments (such as cities) where satellite-based navigation is often unavailable. Wherever they are available, however, satellite navigation systems are a convenient and cheap means for a vehicle to locate itself. This modest investment has often been the enabler of automatic flight for many researchers and is currently used by virtually all existing industrial systems. Pushed to their limits, satellite navigation systems have been shown to achieve the entire range of desired navigation and sensing functions, which include vehicle position and attitude: GPS-only flight for a small helicopter robot was achieved in 1995 at Stanford University [44.28].

Altimeter and Air Data Probes

Pressure-measuring devices are immensely useful sensors in aerial robotics. With ingenious arrangements of pressure sensors (such as pitot tubes) it is possible to measure (1) the atmospheric pressure at the location of the robot and (2) the so-called *dynamic pressure*, $\rho v^2/2$, along all vehicle axes. These data can themselves be transformed into precious information about the aerial robot's altitude and direction of motion relative to the air it is flying in. Depending on the vehicle used, air data probes may be challenging to build and constitute an interesting field of investigation. Indeed, pressure probes are very sensitive to flow perturbations generated by fuselage, wings, and most importantly rotors and propellers. Air data probes are therefore positioned as far away from the main elements of the vehicle as possible (for example, along a boom extending forward of the vehicle fuselage). Figure 44.11 shows one such air data probe configuration. Mounted together with inertial measurement systems, air data probes allow aircraft to maintain stable flight at a prescribed altitude. With the current state of technology, they remain somewhat insufficient to achieve, alone, stable hovering flight for helicopters.

Passive Vision

Passive vision has become a very popular sensor for inner-loop control. Even unsophisticated light sensors able to differentiate between the intensity of infrared activity from the ground versus that emitted by the sky has made its way into small commercial products, mostly aimed at assisting remote-controlled vehicle flight. As will be discussed later, passive vision devices have also found applications for vehicle–obstacle and vehicle–vehicle proximity management, and for landing applications. Recent research aimed at using vision for inner-loop control applications includes work aim-

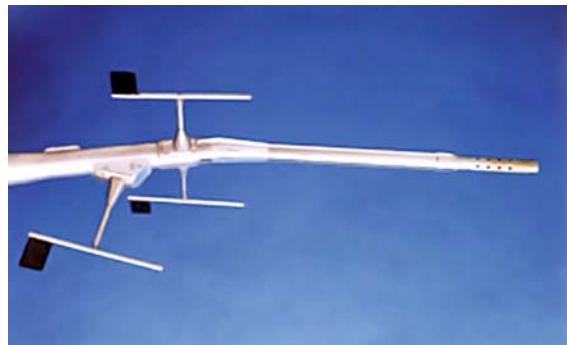

Fig. 44.11 Air data probe (Source: NASA Dryden Flight Research Center). The vanes are used to measure angle of attack and sideslip angle

ing at tracking relatively invariant features such as the horizon [44.29].

44.6.2 Estimator Design

The individual inputs collected from each sensor are usually not sufficient to estimate the state of the vehicle. Different sensors may be efficient over different flight regimes. The proper way to leverage individual information provided by each sensor is through an appropriate *filtering* process that can yield rather comprehensive information about the entire system's state. Unlike ground robots, the necessity for good robot state estimates arises early in the robot development process since closed-loop flight would be impossible otherwise. However, the structure of the filters is usually a great deal simpler than their ground-based equivalent, since the difficulty of flight is compensated by a rather simple and uniform environment structure. As a consequence, simple filters such as (extended) Kalman filters are usually enough for a large number of applications and quickly enable flight [44.30].

44.6.3 Inner-Loop Control

Inner-loop control of aerial vehicles naturally builds upon the previously discussed state estimator, and is relatively easy for routine flight operations. By this we mean that the process by which a good vehicle controller is obtained only requires following standard textbook techniques such as proportional, integral, and derivative control or linear quadratic control [44.31–33], appropriately scheduled against essential parameters such as vehicle speed and altitude. As a result, several research groups, and now several companies, have built basic

guidance and control packages suitable for aerial robots, both fixed-wing and helicopter.

Among the notable recent advances for the inner-loop control of aerial robots, we find the successful

experimental application of adaptive and learning control techniques [44.21, 34, 35], which offer stable controlled helicopter flight from very coarse initial vehicle dynamics knowledge.

44.7 Active Research Areas

This section presents some of the active research in aerial robotics. Such research efforts aim at answering the challenges outlined in Sect. 44.4.

44.7.1 Interfacing with the Human Infrastructure: Meeting the Regulations

While manned flight operations indeed have an excellent safety record, the price paid for this safety is a strong specialization of those regulations to human-operated systems, and a slow evolution of these regulations towards accepting aerial robots of all sizes. Currently none of the existing aerial robots is able to meet these regulations in the absence of a human pilot. This includes the ability to see (or sense) and avoid other aircraft, comply with air-traffic rules, and operate harmoniously with the current ground-based, manned air-traffic control system [44.4, 5, 36]. In the case of the US however, the FAA has acknowledged the economic potential of aerial robots by opening an office specifically devoted to such systems (the Unmanned Aircraft System Group), and by delivering permits to fly over certain areas (especially disaster areas) within a couple of hours of a request. However, the FAA currently emphasizes access for remotely piloted machines (as opposed to fully autonomous machines), where a ground-based pilot must have the means to communicate by voice with the FAA control center in charge of the geographical area where the vehicle is operated.

Efforts to help aerial robots improve their interface with other vehicles include the adaptation of existing systems to prevent mid-air collisions between aerial robots and other traffic, the development of *see-and-avoid procedures*, and means to interact with an aerial robot as one would interact with a human pilot (natural language interfaces). We now detail these efforts.

Collision Avoidance for Remotely Piloted Vehicles

The most immediate efforts aimed at inserting aerial robots in the civilian airspace consists of adapting existing airborne collision avoidance systems (ACAS),

originally designed for manned systems, to aerial robots. Such systems are based on cooperative position information sharing between aircraft extracted from radar-based navigation and surveillance systems. The reason for emphasizing such systems over other, newer technologies is that they have already undergone extensive, and expensive, development, validation and testing. As such, several unmanned vehicles, such as the Global Hawk unmanned aircraft, are now fitted with ACAS systems [44.37]. However, such systems are not automated, meaning that the remote human pilot ultimately decides whether to execute the maneuvers recommended by the system. The possibility of completely automating such collision avoidance systems is the object of recent studies [44.38], with the clear intent of fitting them on aerial robots. However, the weight of ACAS system hardware, as well as the power required to operate them, makes such systems suitable only for large vehicles. In the context of rapidly evolving technology (such as the generalization of positioning information using global navigation satellite systems), current ACAS technology may also become rapidly obsolete.

Sense and Avoid

The idea, encouraged by institutional service providers, is to ensure that aerial robots are able to detect the presence of other traffic and avoid it as necessary and at least as well as a human pilot. Several candidate sensing technologies are currently in development, including passive vision systems [44.39–42], in an effort aimed at making aerial robots as able as humans to avoid other traffic when the sky is clear (visual flight rules). While much can be done in the visible spectrum, concerns over vehicle flight in clouds raises the necessity to consider other frequency bands, such as the near infrared, if aerial robots will need to be able to detect other traffic better than a human pilot [44.43].

Human Interfacing

Another active research venue is to facilitate the interfacing of robots with humans (e.g., an aerial robot interacting with a human air-traffic controller). Recent research in human–aerial robot interaction has

shown that aerial robots can interact productively with humans, by combining natural language processing interfaces with advanced vehicle path and task planning capabilities [44.44–46]. A natural interface might capture standard, unambiguous phraseology such as North Atlantic Treaty Organization (NATO) phraseology or air-traffic control phraseology. The impact of such technology on aerial robots would be profound since they would then be able to enter airspace with little or no visibility and be able to interact with the predominantly ground-based, human-intensive air-traffic control structure.

44.7.2 High-Agility Flight

One of the important characteristics of aerial robots is the ability to operate at the limit of its structural strength, unimpeded by the presence and physiological limitations of a human pilot. This allows aerial robots, especially small ones, to operate very aggressively. As a result, several research groups have explored the possibility of achieving aggressive flight with either fixed-wing or rotary-wing vehicles. The key factors that have enabled the onset of highly aggressive flight has been the emergence of lightweight computing environments and sensors, notably GPS and inertial systems. Indeed, aggressive flight (where aggressive flight refers to any abrupt change in vehicle attitude) is closely related to available vehicle mass and size, as discussed earlier.

Figure 44.12 shows the evolution of three helicopter configurations over time. While the vehicle platform has evolved little or not at all, the onboard avionics has progressively shrunk. In the mid-1990s, the onboard avionics typically would weigh the same or more than the helicopter mass. By the early 2000s, the onboard avionics would be about half of the vehicle mass, while by the mid-2000s the onboard avionics represent only a small fraction of the helicopter mass.

The corresponding levels of achievable agility have evolved correspondingly. By the early 2000s, basic aerobatic maneuvers became feasible [44.47], and by 2007 fully fledged aerobatics had been reported [44.48]. Other efforts involving unusual flight attitudes and fault recovery include those of Chiba University (Japan), who demonstrated autorotation landings for autonomous helicopters [44.49].

Parallel to rotorcraft agile flight, several efforts have also successfully enabled aerial agility for fixed-wing robots [44.21].

44.7.3 Take-Off, Landing, and Interaction with Other Vehicles

One of the richest current areas of investigation for aerial robots involves vehicle operation next to other vehicles or infrastructures. These operations include take-off, landing, docking, and separation.

Take-Off and Landing

Take-off and landing experimentation and research is proving particularly interesting for small-sized aerial robots. Indeed, the dynamics of smaller vehicles enable strong departures from conventional, manned-vehicle take-off and landing operations, for example, most fixed-wing unmanned aerial vehicles under 5 kg are better off simply flying into the ground than attempting to land in a smooth fashion. One of the best illustrations of how vehicle landing procedures may dramatically change for smaller-sized aerial robots is Insitu's and Hood Technology's Skyhook concept: small, fixed-wing aerial robots are recovered by allowing them to catch a vertical cable with the tip of one of their wings [44.12]. The cable itself is held by means of a crane, itself mounted on a surface vehicle (e.g., truck or ship). At take-off, similar scaling considerations apply, with many fixed-wing vehicles being launched by hand or by means of a catapult. One of the consequences of the increased tolerance of small ve-

Fig. 44.12a–c Avionics versus vehicle. (a) Stanford Helicopter (c. 1995). (b) MIT helicopter (c. 2001). (c) Stanford Helicopter (c. 2006)

Fig. 44.13 Skyhook system in action (courtesy Insitu, Inc.)

hicles to *crash landings* is also their reduced need for high-resolution navigation information, for example, it has been shown possible to land small-sized vehicles on a designated target with monocular vision only [44.50].

Helicopter robots have, so far, not benefitted from the same kind of developments, and much of their take-off and landing procedures are similar to their larger counterparts. The main reason may be attributed to the presence of a fragile rotor that spins at high speed, and that must avoid contact with other vehicles or the ground. Many of the current robotic helicopter landing procedures simply consist of hovering above the landing area, then commanding a limited descent rate until the vehicle records it has touched the ground. More

challenging situations (e.g., sloped terrain or moving platforms), traditionally handled by humans in large platforms, remain difficult for aerial robots. For this reason, the *helicopter landing problem* has attracted the attention of many research teams. On the one hand, there have been many efforts combining advanced sensing environments [44.51–55] with advanced control algorithms to enable affordable landing in structured environments which are not simply horizontal landing pads. On the other hand, identifying suitable landing places in unprepared environments by means of remote sensing and signal processing is also an area of active research [44.56–58].

Operations in the Vicinity of Other Vehicles: Docking and Undocking

Docking operations for unmanned aerial vehicles are necessary to improve their range and autonomy. Indeed, it is conceivable that some optimal aerial robot configuration consist of a parent–child system, whereby a larger machine provides a primary deployment and retrieval mechanism for several smaller vehicles. Such a concept has existed for a long time, with airships acting as carriers for smaller aircraft [44.59]. More recently however, it is in-flight aerial refueling that has motivated recent research on docking aerial robots. Indeed, the possibility for such vehicles to refuel considerably increases their operational range [44.60–62]. The NASA Dryden Flight Research Center has recently reported the completion of the first vision-aided fully automated aerial refueling operation, using computer vision for the purpose of recognizing and tracking the fuel hose

Fig. 44.15 Georgia Tech's unmanned helicopter in a parent–child configuration. The child is a hover-capable ducted fan

Fig. 44.14a,b Automatic airborne refueling. **(a)** Typical refueling configuration. **(b)** Camera view of refueling basket (Source: NASA Dryden Flight Research Center)

that must be captured by the aerial robot, as shown in Fig. 44.14.

Undocking operations are comparatively easier to perform. They remain, however, spectacular since the dynamics of the aerial robot dramatically change as it is dropped from its mother ship. An extreme example of such a situation is illustrated by Georgia Tech's successful dropping of a small ducted fan aerial robot from a larger autonomous helicopter. The small ducted fan then successfully stabilized itself. Pictures of this experiment are shown in Fig. 44.15.

44.7.4 Reactive Flight in Cluttered Environments and Obstacle Avoidance

Flight in cluttered environments includes any phase of the flight where vehicles are in close proximity to obstacles. This flight mode is particularly important for low-altitude applications. Several achievements have been reported in this area in the recent past, using a variety of sensing techniques.

Among the first significant works relying on passive vision techniques, *Beard* and *McLain*'s certainly stands out as one of the most entertaining and spectacular [44.63], using fixed-wing vehicles performing autonomous flight within a canyon using low-cost, optical flow computation techniques.

Other institutions involved with active as well as passive sensing techniques for vehicle navigation in cluttered environments and obstacle avoidance include Carnegie-Mellon University [44.64], where the authors report fast vehicle flight in highly cluttered environments, including obstacles as difficult to deal with as suspended cables. The [NASA Ames](#) research center also recently reported successes along similar lines as part of their work on adaptive landing in unprepared environments [44.56–58].

44.7.5 Path Planning and Higher-Level Planning Capabilities

Single-Robot Path Planning

Path planning for aerial robots resembles path planning for any robot, with the following distinctive characteristics: aerial robots are able to fly very fast (or may *have to* fly fast). Thus there is the distinct possibility of significant discrepancies between intended and actual trajectories. The vehicle dynamics must be fully accounted for when designing trajectories. Several path planning concepts have been proposed to handle this

problem, including [44.65–67] and many others. Another key issue in aerial robot trajectory planning arises when there is a discrepancy between the complexity of the environment and the maneuvering space needed for the vehicle. When planned for finite time or geographical horizons, it becomes important that a planner constantly keep a feasible loitering solution within the known environment [44.46].

Multirobot Path Planning and Coordination

There has recently been a surge in research activities for multivehicle path planning and coordination. Such research activities have been motivated by problems as diverse as the generation of noncolliding paths, the generation of *swarming* behaviors for applications such as phased-array, robot-borne antenna systems, collaborative target detection and prosecution, and collaborative search for thermal currents.

This rich literature, of which only a few references have been cited, stems from the conjunction of several constraints in the problem under study, including

- highly constrained dynamical systems (with restricted radius of curvatures and minimum speed requirements, for example)
- a variety of information management possibilities (including centralized, decentralized, distributed information)
- catastrophic consequences in case of failures

Initial work aimed at studying aerial-robot coordination from the perspective of mission execution include [44.68–71]. Swarming behaviors, or the ability for a vehicle group to generate a coherent, consensual behavior using only local information, has become the focus of much attention in the research community since the recent paper [44.72].

Collision avoidance has also formed the motivation for much research in multirobot coordination, see for example [44.73–75].

44.7.6 Integrated Aerial Robotic Operations: Aerial Robotics Contests

Research on the ability of aerial robots to perform completely autonomous missions, especially at low altitudes, is clearly well represented in contests such as the International Aerial Robotics Competition, initiated in 1991 by *Michelson* [44.1]. In this contest, universities, possibly supported by industry and government, compete against each other by demonstrating how their vehicles,

or vehicle systems, meet the requirements of the competition. A basic tenet of the competition is that the small aerial robotic systems entrants must be capable of complete autonomy (no human interaction) during the mission.

The rules of the competition have evolved from the inception of this effort to reflect advances in the capabilities of the proposed systems. One of the key characteristics of the competition is that it has always emphasized the simultaneous demonstration of several robotic functionalities, including basic mission execution, object reconnaissance and detection, and object manipulation. During the early days of the competition, the task asked for an aerial robot to recognize and pick up an object in a designated area, and carry it to another designated area. As universities were able to meet the initial challenges posed by the competition rules, the rules have evolved to a higher level of sophistication. As of today, the competition rules require complete autonomous operation of the vehicles over longer distances. The vehicles must now find and reach a village from a distance of three kilometers. They must also evolve towards higher reasoning capabilities about the objects and events being encountered. Moreover, emphasis has been placed on multimodal robotics, since the robotic system must be able to enter a building and explore it, a task currently best performed by ground robots.

Recognizing the growing gap between experienced participants and new entrants, several different competition levels have been established. While US participation in the competition is predominant, several non-US participants are also present, including Germany, England, Switzerland, Canada, and India. In 2000, the Technische Universitaet Berlin won the contest. Other contest win-

ners include Carnegie-Mellon University, the Georgia Institute of Technology, MIT/Draper Laboratory, and Stanford University.

Other aerial robotic competitions have since been established. For example, the French governmental organization Delegation Generale pour L'Armement ([DGA](#)), together with the Supaero and Ecole Nationale Supérieure Des Constructions Aeronautiques ([ENSICA](#)) engineering schools have proposed a contest involving very small-sized aerial robots in 2004, with a focus on their flight mechanics at various flight regimes. The government of Queensland, Australia together with the local research organizations Commonwealth Scientific and Industrial Research Organization ([CSIRO](#)) and Queensland University of Technology launched a new contest focusing on search-and-rescue missions in 2007.

The distribution of vehicle types involved in these contests is very different from the distribution of operational aerial robots. While operational aerial robotic systems are overwhelmingly of fixed-wing type, the machines used by universities during these contests offer a much more balanced distribution of aircraft and rotorcraft. Several reasons contribute to these differences and they have been outlined earlier. The operation of fixed-wing aircraft at relatively high altitude, for reconnaissance and surveillance missions offers a large and technologically easy market to reach, although it faces significant regulatory constraints. In comparison, the operation of small vehicles in cluttered environments definitely favors hovering-like vehicles. However, these vehicles, like other robots, face significantly more constraints in terms of environment sensing, obstacle avoidance, and task planning and execution complexity. As such, they are closer to the realm of basic research typical of universities.

44.8 Conclusions and Further Reading

Aerial robots represent a very interesting and exciting area of robotics, involving very dynamic platforms whose size ranges from a few centimeters to several tens of meters. It seems highly probable they will continue to see new applications, beginning with those that happen in relatively unpopulated areas and relatively high altitudes. The current applications of aerial robots are focused primarily on military operations. However, an ambitious civilian market led by Japan is currently burgeoning.

Aerial robots currently pose a challenge to all regulatory agencies, which must find modalities and rules

to insert them into airspace occupied by other traffic such as manned systems. The resulting technical research challenges include the development of a proper and affordable *sense-and-avoid* technology, and the ability for aerial robots to be conversant with other traffic and the ground control infrastructure.

Lower-altitude aerial robotics, often operating in cluttered environments, offers the opportunity to explore many generic robotics topics, including vision, path planning, mapping, and other algorithms in a progressive manner, while offering potential benefit of still more important applications.

A very dynamic research and development field, aerial robotics can be seen from a historical perspective by reading [44.3]. A snapshot of current UAV technology can be obtained, for example, from [44.76]. The lack of a known comprehensive, book-like presentation

of aerial robotics and its applications clearly indicates that the field is still very young, that operational experience is slowly building up, and that many challenges, most notably regulatory and safety challenges, must still be overcome.

Space Robots

Kazuya Yoshida, Brian Wilcox

In the space community, any unmanned spacecraft can be called a robotic spacecraft. However, *space robots* are considered to be more capable devices that can facilitate manipulation, assembling, or servicing functions in orbit as assistants to astronauts, or to extend the areas and abilities of exploration on remote planets as surrogates for human explorers.

In this chapter, a concise digest of the historical overview and technical advances of two distinct types of space robotic systems, orbital robots and surface robots, is provided. In particular, Sect. 45.1 describes orbital robots, and Sect. 45.2 describes surface robots. In Sect. 45.3, the mathematical modeling of the dynamics and control using reference equations are discussed. Finally, advanced topics for future space exploration missions are addressed in Sect. 45.4.

Key issues in space robots and systems are characterized as follows. *Manipulation* – Although manipulation is a basic technology in robotics, microgravity in the orbital environment requires special attention to the motion dynamics of manipulator arms and objects being handled. Reaction dynamics that affect the base body, impact dynamics when the robotic hand contacts an object to be handled, and vibration dynamics due to structural flexibility are included in this issue. *Mobility* – The ability to locomote is particularly important in exploration robots (rovers) that travel on the surface of a remote planet. These surfaces are natural and rough, and thus challenging to traverse. Sensing and perception, traction mechanics, and vehicle dynamics, control, and navigation are all mobile robotics technologies that must be demonstrated in a natural untouched environment. *Teleoperation and autonomy* – There is a significant time delay between a robotic system at a work site and a human operator in an operation room on the Earth. In earlier orbital robotics demonstrations, the latency was typically 5 s, but

can be several tens of minutes, or even hours for planetary missions. Telerobotics technology is therefore an indispensable ingredient in space robotics, and the introduction of autonomy is a reasonable consequence. *Extreme environments* – In addition to the microgravity environment that affects the manipulator dynamics or the natural and rough terrain that affects surface mobility, there are a number of issues related to extreme space environments that are challenging and must be solved in order to enable practical engineering applications. Such issues include extremely high or low temperatures, high vacuum or high pressure, corrosive atmospheres, ionizing radiation, and very fine dust.

45.1 Historical Developments and Advances of Orbital Robotic Systems

The first robotic manipulator arm used in the orbital environment was the Space Shuttle remote manipulator system. It was successfully demonstrated in the STS-2 mission in 1981 and is still operational today. This success opened a new era of orbital robotics and inspired a number of mission concepts to the research community. One ultimate goal that has been discussed intensively after the early 1980s is the application to the rescue and servicing of malfunctioning spacecraft by a robotic free-flyer or free-flying space robot (see, for example, the Space Application of Automation, Robotics and Machine Intelligence ([ARAMIS](#)) report [45.1], Fig. 45.1). In later years, manned service missions were conducted for the capture–repair–deploy procedure of malfunctioning satellites (Anik-B, Intelsat 6, for example) and for the maintenance of the Hubble space telescope (STS-61, 82, 103, and 109).

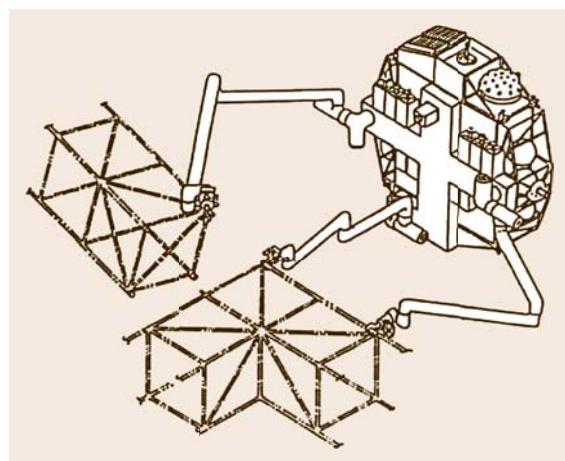

Fig. 45.1 A conceptual design of a telerobotic servicer [45.1]

For all of the above examples, the Space Shuttle, a manned spacecraft with dedicated maneuverability was used. However, unmanned servicing missions have not yet become operational. Although there were several demonstration flights, such as engineering test satellite ([ETS](#))-VII and Orbital Express (to be elaborated later), the practical technologies for unmanned satellite servicing missions await solutions to future challenges.

45.1.1 Space Shuttle Remote Manipulator System

Onboard the Space Shuttle, the *shuttle remote manipulator system (SRMS)*, or Canadarm, is a mechanical arm that maneuvers a payload from the payload bay of the Space Shuttle orbiter to its deployment position and then releases it [45.2]. It can also grapple a free-flying payload and berth it to the payload bay of the orbiter. The SRMS was first used on the second Space Shuttle mission STS-2, launched in 1981. Since then, it has been used more than 100 times during Space Shuttle flight missions, performing such payload deployment or berthing as well as assisting human *extravehicular activities (EVAs)*. Servicing and maintenance missions to the Hubble space telescope and construction tasks of the International Space Station have also been successfully carried out by the cooperative use of the SRMS with human EVAs.

As depicted in Fig. 45.2, the SRMS arm is 15 m long and has six degrees of freedom, comprising shoulder yaw and pitch joints, an elbow pitch joint and wrist pitch, yaw, and roll joints. Attached to the end of the arm is a special gripper system called the *standard end-effector (SEE)*, which is designed to grasp a pole-like fixture (GF) attached to the payload.

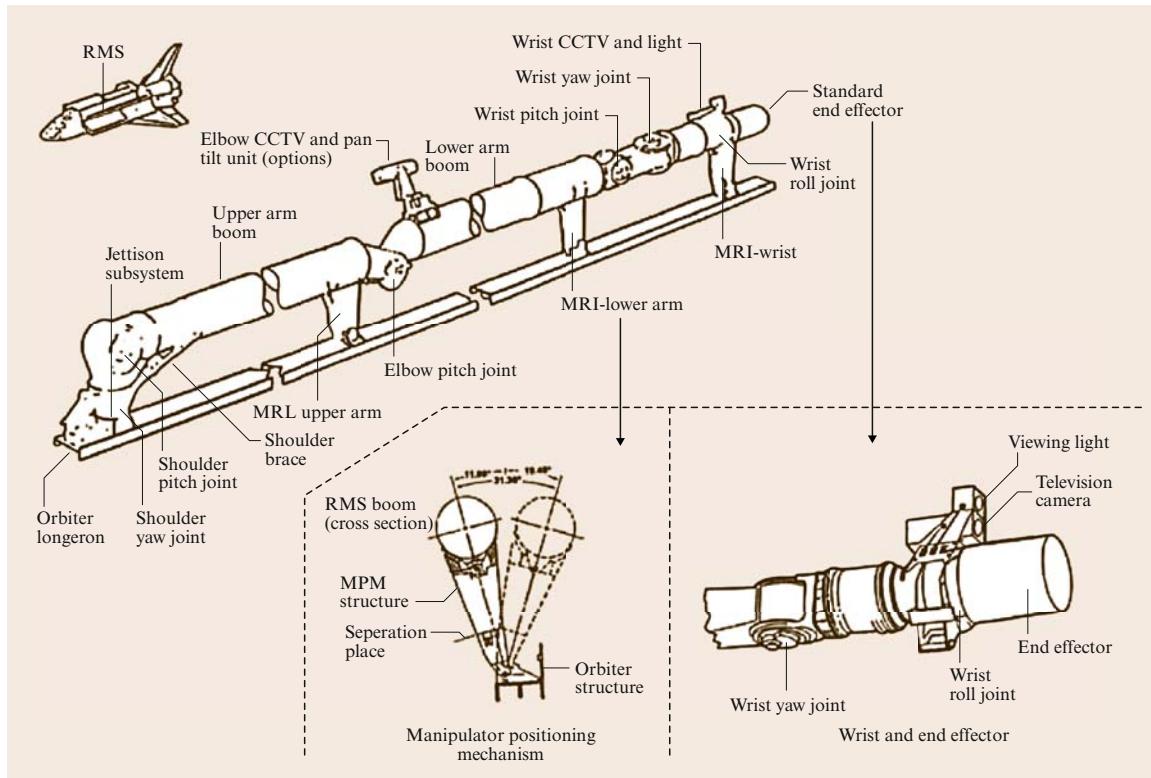

Fig. 45.2 The space shuttle remote manipulator system (SRMS) [45.2]; manipulator retention latch (MRL), manipulator positioning mechanism (MPM), remote manipulator system (RMS)

By attaching a foothold at the end point, the arm can serve as a mobile platform for an astronaut's extravehicular activities (Fig. 45.3).

After the Space Shuttle COLUMBIA accident during STS-107, the National Aeronautics and Space Administration (NASA) outfitted the SRMS with the orbiter boom sensor system (OBSS) – a boom containing instruments to inspect the exterior of the shuttle for damage to the thermal protection system [45.3]. The SRMS is expected to play a role in all future shuttle missions.

45.1.2 ISS-Mounted Manipulator Systems

The International Space Station (ISS) is the largest international technology project, with 15 countries making significant cooperative contributions. The ISS is an *outpost* of the human presence in space, as well as a *flying laboratory* with substantial facilities for science and engineering research. In order to facilitate various activities on the station, there are several robotic systems, some

of which are already operational, while others are ready for launch.

The *space station remote manipulator system* (SS-RMS) or Canadarm 2, (Fig. 45.4), is the next generation of the SRMS, for use on the ISS [45.4]. Launched in 2001 during STS-100 (ISS assembly flight 6A), the SSRMS has played a key role in the construction and maintenance of the ISS both by assisting astronauts during EVAs and using the SRMS on the Space Shuttle to hand over a payload from the Space Shuttle to the SS-RMS. The arm is 17.6 m long when fully extended and has seven degrees of freedom. Latching end-effectors, through which power, data, and video can be transmitted to and from the arm, are attached to both ends. The SSRMS is self-relocatable using an inch-worm-like movement with alternate grappling of *power data grapple fixtures* (PDGFs), which are installed over the station's exterior surfaces to provide the power, data, and video, as well as a foothold.

As another mobility aid for the SSRMS to cover wider areas of the ISS, a *mobile base system* (MBS) was

Fig. 45.3 Space shuttle remote manipulator system (SRMS) used as a platform for an astronaut's extravehicular activity in the shuttle cargo bay

added in 2002 by STS-111 (ISS assembly flight UF-2). The MBS provides lateral mobility as it traverses the rails on the main trusses [45.5].

The *special-purpose dexterous manipulator* (SPDM), or Dextre, which will be attached at the end of the SSRM, is a capable mini-arm system to facilitate the delicate assembly tasks currently handled by astronauts

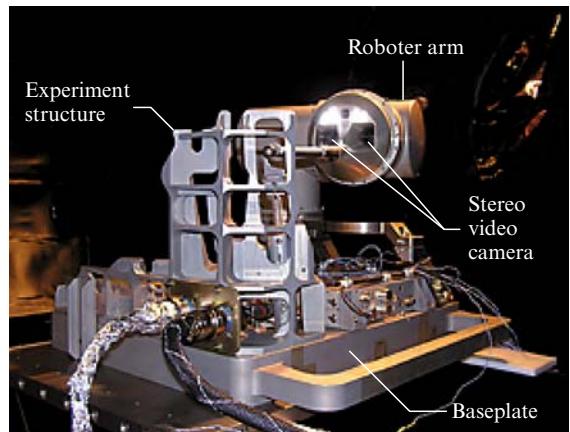

Fig. 45.5 Laboratory test bed for the ROKVISS manipulator system

during EVAs. The SPDM is a dual-arm manipulator system, where each manipulator has seven degrees of freedom and is mounted on a one-degree-of-freedom body joint. Each arm has a special tool mechanism dedicated to the handling of standardized *orbital replacement units* (ORUs). The arms will be teleoperated from a *robotic work station* (RWS) inside the space station [45.6].

The European Space Agency (ESA) will also provide a robotic manipulator system for the ISS, the *European robotic arm* (ERA), which will be used mainly to work on the Russian segments of the station [45.7]. The arm is 11.3 m long and has seven degrees of freedom. Its basic configuration and functionality are similar to SSRMS [45.8].

As a precursor demonstration of the ERA, the German Aerospace Agency (DLR) has developed a 0.5 m-long, two-degree-of-freedom manipulator arm with a dedicated test bench, called *robotic components verification on the ISS* (ROKVISS), see Fig. 45.5. ROKVISS was launched by an unmanned Russian Progress transport vehicle in 2004 and installed on the outer platform of the Russian segment of the station in early 2005 [45.9]. Although the number of joints is small, challenging experiments of telepresence have been conducted in which human operators on the ground operate the arm based on stereovision images and bilateral, high-fidelity force feedback using a force-reflecting joystick on the ground, and a joint torque control system on board. The secondary goal of the experiment was the space qualification of the joint drives, which are the key components of DLR's torque-controlled lightweight robots [45.10].

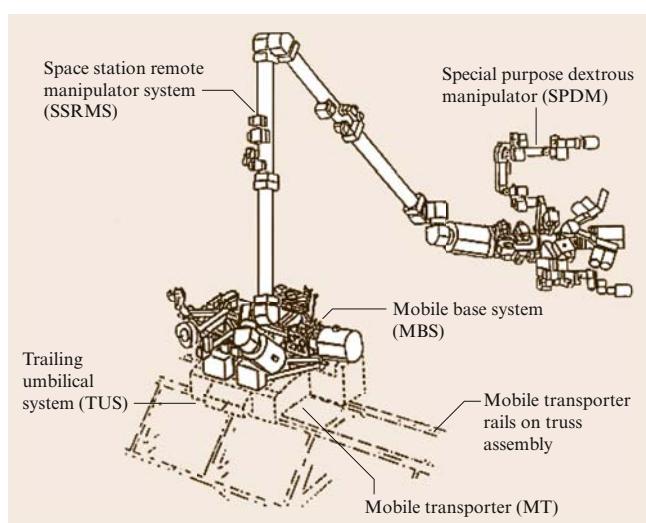

Fig. 45.4 Space station remote manipulator system (SSRMS) [45.4]

In Japan, the *Japanese experiment module remote manipulator system (JEMRMS)*, shown in Fig. 45.6, has been developed by the *Japan space exploration agency (JAXA)* [45.11]. The arm will be attached to the Japanese module of the ISS. JEMRMS consists of two components: the main arm, a 9.9 m-long, six-degree-of-freedom arm and the small fine arm, a 1.9 m-long, six-degree-of-freedom arm. Unlike the SSRMS or the ERA, the main arm does not have self-relocation capability, but is fitted with a small fine arm, with which JEMRMS can form a serial 12-degree-of-freedom macro–micro manipulator system. After installation, the arm will be used to handle and relocate the components for the experiments and observations on the exposed facility [45.12, 13].

45.1.3 ROTEX

The *robot technology experiment (ROTEX)*, developed by the German Aerospace Agency (DLR), is one of the important milestones of robotics technology in space [45.14]. A multisensory robotic arm was flown on the Space Shuttle COLUMBIA (STS-55) in 1993. Although the robot worked inside a work cell on the shuttle, several key technologies, such as a multisensory gripper, teleoperation from the ground and by the astronauts, shared autonomy, and time-delay compensation by the use of a predictive graphic display were successfully tested (Fig. 45.7).

45.1.4 ETS-VII

Engineering test satellite (ETS)-VII, shown in Fig. 45.8, was another milestone in the development of robotics technology in space, particularly in the area of satellite servicing. ETS-VII was an unmanned spacecraft developed and launched by the *National Space Development Agency of Japan (NASDA*, currently *JAXA*) in November 1997. A number of experiments were successfully conducted using a 2 m-long, six-degree-of-freedom manipulator arm mounted on its carrier (main) satellite.

The mission objective of ETS-VII was to test free-flying robotics technology and to demonstrate its utility in unmanned orbital operation and servicing tasks. The mission consisted of two subtasks: autonomous rendezvous/docking (RVD) and a number of robot experiments (RBT). The robot experiments included:

1. teleoperation from the ground with a large time delay
2. robotic servicing task demonstrations such as ORU exchange and deployment of a space structure

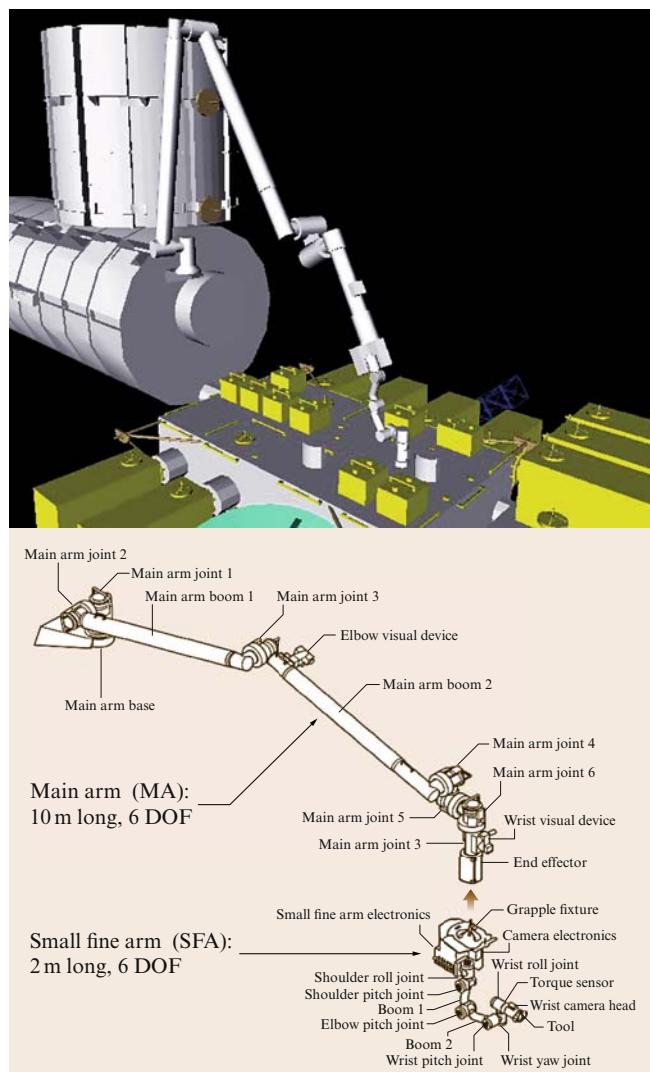

Fig. 45.6 Japan experiment module (JEM) on the ISS and the JEMRMS manipulator system

3. dynamically coordinated control between the manipulator reaction and the satellite attitude response
4. capture and berthing of a target satellite [45.15]

The communication time delay due to radio propagation (speed of light) is relatively small, for example, 0.25 s for a round trip to *geostationary Earth orbit (GEO)*. However, to have a global coverage of communication in low-Earth-orbit operations, the signals are transmitted via multiple nodes including data relay satel-

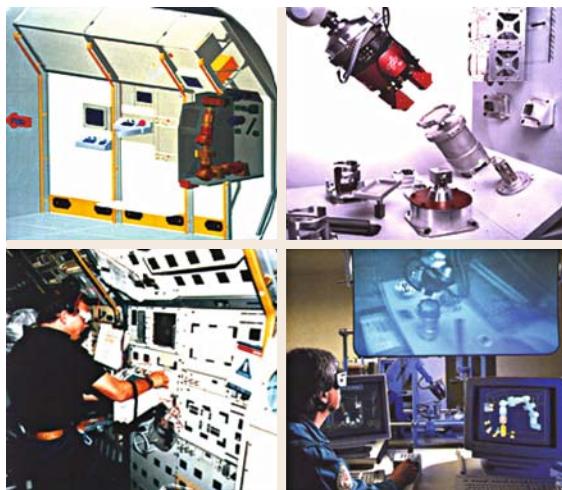

Fig. 45.7 ROTEX manipulator arm onboard the Spacelab D2 mission, the first remotely controlled space robot

lites located at **GEO** and ground stations. This makes the transmission distance longer, and even more additional delays are added at each node. As a result the cumulative delay becomes some seconds, actually 5–7 s in the case of the **ETS-VII** mission.

Opportunities for academic experiments were also opened to Japanese universities and European institutions (e.g., **DLR** and **ESA**) and important flight data were obtained that validate the concepts and theories for free-flying space robots [45.16, 17].

45.1.5 Ranger

Ranger is a teleoperated space robot being developed at the University of Maryland's Space Systems Lab-

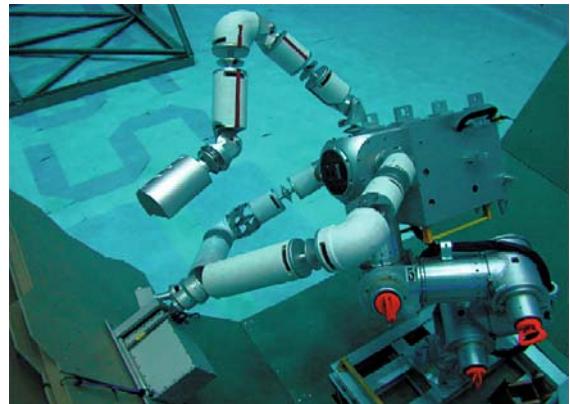

Fig. 45.9 Neutral buoyancy test of the Ranger telerobotic shuttle experiment

oratory [45.18]. Ranger consists of two seven-degree-of-freedom manipulators with interchangeable end-effectors to perform such tasks as changeout of *orbital replacement units* (**ORUs**) in orbit. Also discussed was the changeout of the *electronics controller unit* (**ECU**) of the Hubble space telescope, which previously required human **EVA**. A number of tests and demonstrations for servicing missions have been conducted at the University of Maryland neutral buoyancy facility (Fig. 45.9). Originally designed for a free-flying flight experiment, Ranger has been redesigned for a Space Shuttle experiment, but has not yet been manifested on a flight.

45.1.6 Orbital Express

The Orbital Express space operations architecture program is a **DARPA** program developed to validate the

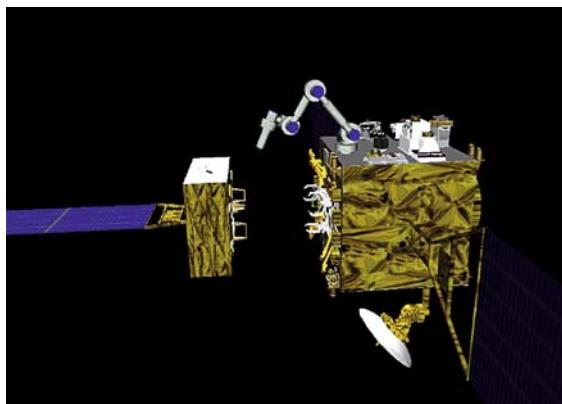

Fig. 45.8 Japanese engineering test satellite **ETS-VII**

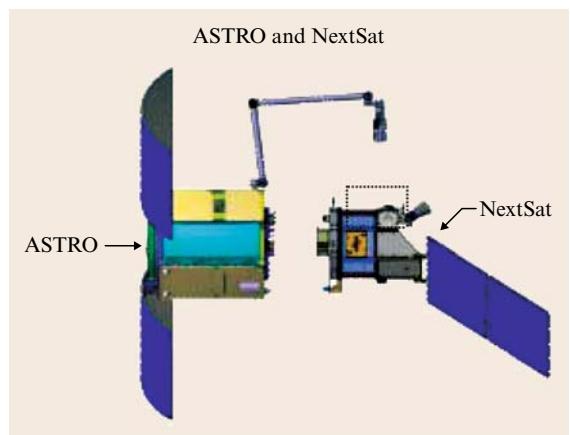

Fig. 45.10 Orbital Express flight mission configuration

technical feasibility of robotic on-orbit refueling and reconfiguration of satellites, as well as autonomous rendezvous, docking, and manipulator berthing [45.19]. The system consists of the *autonomous space transport robotic operations (ASTRO)* vehicle, developed by Boeing Integrated Defense Systems and a prototype modular next-generation serviceable satellite, NextSat, developed by Ball Aerospace. The *ASTRO* vehicle is equipped with a robotic arm to perform satellite capture and ORU exchange operations (Fig. 45.10).

After its launch in March 2007, various mission scenarios have been conducted. These scenarios include

1. visual inspection, fuel transfer, and ORU exchange on NextSat using *ASTRO*'s manipulator arm when both spacecrafts are connected
2. separation of NextSat from *ASTRO*, orbital maneuvers by *ASTRO* and fly-around, rendezvous, and docking with NextSat
3. capture of NextSat using *ASTRO*'s manipulator arm

These scenarios were successfully completed by July 2007, with *ASTRO*'s onboard autonomy using onboard cameras and advanced video guidance system.

45.2 Historical Developments and Advances of Surface Robotic Systems

The research on surface exploration rovers began in the mid-1960s, with an initiative (that never flew) for an unmanned rover for the Surveyor lunar landers and a manned rover (Moon buggy) for the human landers in the United States. In the same period, research and development began for a teleoperated rover named Lunokhod in the Soviet Union. Both the Apollo manned rover and the Lunokhod unmanned rover were successfully demonstrated in the early 1970s on the Moon [45.20]. In the 1990s the exploration target had expanded to Mars and in 1997, the Mars Pathfinder mission successfully deployed a microrover named Sojourner that safely traversed the rocky field adjacent to the landing site by autonomously avoiding obstacles [45.21, 22]. Following on from this success, today autonomous robotic vehicles are considered indispensable technology for planetary exploration. The twin Mars exploration rovers, Spirit and Opportunity, were launched in 2003 and have had remarkable success in terms of remaining operational in the harsh environment of Mars for over four years. Each has traveled more than 5000 m and has made significant scientific discoveries using onboard instruments [45.23, 24].

45.2.1 Teleoperated Rovers

The first remotely operated robotic space surface vehicle was Lunokhod (Fig. 45.11) [45.20]. Lunokhod 1 landed on the Moon on 17 November 1970 as a payload on the lander Luna-17 and Lunokhod 2 landed on the Moon on 16 January 1973. Both were eight-wheeled skid-steered vehicles having a mass of about 840 kg, where almost all components were in a pressurized *bathhtub* thermal enclosure with a lid that closed over the tub to allow it to survive the deep cold ($\approx 100\text{ K}$) of the long lunar

nights using only the heat emitted by small pellets of radioisotope. On the inside of the lid were solar arrays which recharged batteries during the day as required to maintain the operation of the vehicle. Lunokhod 1 operated for 322 Earth days, traversing over 10.5 km during that period and returned over 20 000 TV images, 200 high-resolution panoramas, and the results of more than

Fig. 45.11 Lunokhod

500 soil penetrometer tests and 25 soil analyses using its X-ray fluorescence spectrometer. Lunokhod 2 operated for about 4 months, having traversed more than 37 km, with the mission officially terminating on 4 June 1973. It has been reported that Lunokhod 2 was lost prematurely when it began sliding down a crater slope and hasty commands were sent in response which ultimately caused the end of the mission.

Each of the eight wheels on the Lunokhod vehicles were 0.51 m in diameter and 0.2 m wide, giving an effective ground pressure of less than 5 kPa based on an assumed sinkage of 3 cm. Each wheel had a brush-type direct-current (DC) motor, a planetary gear reduction, a brake and a disengagement mechanism allowing it to free-wheel in the event of some problem with the motor or gears. The mobility commands to the vehicle included two speeds forward or backward, braking, and turning to the right or the left either while moving or in place.

The vehicles had both gyroscope- and accelerometer-based tilt sensors which could automatically stop the vehicle in the event of excessive tilt of the chassis. Typical mobility commands specified a time duration over which the motors would run and then stop. Precision turning commands specified the angle through which the vehicle should turn. These commands were terminated when the specified turn angle had been reached according to the heading gyroscope. Odometry was determined by a ninth *small wheel* which was unpowered and lightly loaded and used only to determine over-the-ground distance. There was an onboard current-overload system and motor currents, pitch and roll measurements, and distance traversed and many component temperatures were telemetered to the ground operators.

The Lunakod crew consisted of a driver, a navigator, a lead engineer, an operator for steering the *pencil-beam* communication antenna, and a crew commander. The driver viewed a monoscopic television image from the vehicle and gave the appropriate commands (*turn, proceed, stop or back up*) along with their associated parametric value in terms of duration or angle. The navigator viewed displays of telemetry from the vehicle's *course gyroscope*, *gyrovertical sensor*, and odometer and was responsible for calculating the trajectory of the vehicle and laying out the route to be followed. Thus the driver was responsible for vehicle stability about its center of mass and the navigator was responsible for the trajectory of that center of mass. The lead engineer (assisted by many specialists as required), was responsible for assessing the health of the onboard systems. The lead engineer provided both routine updates on energy supply, thermal conditions, etc. as well as possible

emergency alerts such as extreme motor currents or chassis tilt. The pencil-beam antenna operator oversaw the functioning of an independent ground-based closed-loop control system that servoed the antenna to always point at Earth, independent of the vehicle motion. The crew commander supervised the implementation and execution of the overall plan, gave any detailed commands for making actual contact with the surface (e.g., by the penetrometer) and also could override any command to the vehicle as he viewed the same information as the driver.

The entire driving system was tested extensively prior to the Lunokhod 1 mission at a *lunodrome* with simulated lunar terrain which proved to be more challenging than that actually encountered during the Lunokhod 1 mission. Despite this, the operators of Lunokhod 1 said they *encountered a dangerous situation* (unforeseen entrance into a crater, rolling onto a rock, etc.) slightly more often than once per kilometer. This was attributed to inadequate driving experience, the modest quality of the television images and the poor illumination conditions on the Moon. The driving direction was often selected primarily to give the best images; even so, the operators reported *fictitious dangers* caused by varying illumination conditions. In the first three months (lunar days) of operation, the vehicle traversed 5224 m in 49 h of driving using 1695 driving commands, including about 500 turns. Sixteen signals were sent for protection against excessive tilt during that time; approximately 140 craters were traversed at maximum slope angles of 30°.

With the approximately 2.6 s speed-of-light delay, the operators stated that "control experience confirmed the desirability of movement in a starting-stopping regime with mandatory stopping each few meters." The soil properties were found to "differ substantially even in terrain sectors not very distant from one another." The soil penetrometer determined that the upper layer of regolith varied from a stiffest where the penetrometer required about 16 kg (Earth weight) of force to penetrate about 26 mm, to a weakest measurement where only 3 kg of Earth weight caused a penetration of about 39 mm. The cone penetrometer had a base diameter of 50 mm and a cone height of 44 mm. Thus the upper layer of regolith had a rate of increase of load-bearing strength ranging from about 400 kPa/m for the weakest soil to about 3 MPa/m for the stiffest soil. Crater walls and the immediate ejecta blanket around craters generally exhibited the weakest soil. Below 5–10 cm of penetration depth, the regolith generally became rapidly stiffer. The mean value of wheel slippage for the first three lunar days was about 10%. On horizontal terrain,

the slippage was 0–15%, depending on surface irregularities and ground inhomogeneity. On crater slopes the slip increased to 20–30%. The specific resistance of the Lunokhod wheels was generally in the range 0.05–0.25, while the specific free traction (the ratio of traction to weight) was in the range 0.2–0.41. The crater distribution in the area explored by Lunokhod 1 was found to be closely approximated by the formula $N(D) = AD^{-\delta}$, where $N(D)$ is the number of craters larger than diameter D meters per hectare of lunar surface, A is a scale factor found to be about 250 and δ is the distribution exponent, found to be about 1.4 [45.20].

45.2.2 Autonomous Rovers

In the mid-1960s, research began on a lunar rover at the US Jet Propulsion Laboratory (JPL) in Pasadena, California, when it was proposed to put a small rover on the Surveyor lunar landers. These landers were led by JPL (based on a system-level contract to Hughes) and were designed to land softly on the Moon to establish the safety of such a landing prior to the Apollo landers with humans aboard. At the time it was speculated (notably by T. Gold) that the Moon might be covered in a thick layer of soft dust that would *swallow* any lander. In 1963 JPL issued a contract to build a small rover concept prototype in support of the Surveyor program to the General Motors Defense Research Laboratories in Goleta, California. That GM facility had recently hired M.G. (Greg) Bekker, who was considered *the father of off-road locomotion*, having written several seminal textbooks on the subject and having introduced many of the key concepts relating soil properties to off-road vehicle performance that are still used today [45.25, 26] (Sect. 45.3.12).

Bekker and his team proposed an articulated six-wheeled vehicle based on a novel three-cab configuration with an axial spring-steel suspension. This vehicle exhibited remarkable mobility, being able to climb vertical steps up to three wheel radii high and crossing crevasses three wheel radii wide. Notable people working with Bekker were Farenc Pavlics, who went on to lead the development of the mobility system for the Apollo lunar rover (under contract from Boeing), and Fred Jindra, who developed the underlying equations describing the mobility of the six-wheeled articulated vehicle that were later used by Don Bickler in conceiving the *rocker bogie* chassis used on the Sojourner and the Mars exploration rovers. Bekker and his team proposed the six-wheeled articulated vehicle after experimenting with many types of vehicles, including multitracked ve-

hicles, screw-type vehicles (for fine-powdered terrain) and others. In scale-model testing the six-wheeled vehicle demonstrated superior performance over both soft and rocky terrain.

They built and delivered two vehicles that were about 2 m long with approximately 0.5 m wheel diameters. Those vehicles were used in testing throughout the 1960s and early 1970s to conduct simulated operations to determine how such vehicles could actually be used on the Moon. One key issue was that the speed-of-light round trip from the Moon (about 3 s) precluded direct *driving* of the vehicle. Perhaps most annoying was the fact that, during vehicle motion, the highly directional radio antenna used to communicate with Earth would lose its pointing and so communications would briefly be lost. This meant that operators driving the rover would be confronted with a series of still images, instead of a stream of moving images. It was quickly realized that much of an operator's *situation awareness* and depth perception needed to drive a vehicle with a monocular camera comes from motion. It was very difficult to drive from frozen monocular images. A crude form of stereo was incorporated where the camera mast was raised and lowered slightly and the operator could switch back and forth between the two views.

Following the successful landing of several of the Surveyor spacecraft and the discovery that all landing sites seemed to have relatively firm soil, it was concluded that the Surveyor lunar rover was not needed. As a result, the prototype was used for research into the early 1970s and subsequently restored for use again in research in the 1980s, becoming the first vehicle to be outfitted with *waypoint navigation* of the sort later used on the Sojourner and MER missions.

About the time that the stationary 1976 Viking landers were conceived and developed, JPL began the 1984 Mars Rover effort. (1984 was an energetically favorable launch opportunity from Earth to Mars and the next likely major mission opportunity after Viking.) Two test bed vehicles were developed, a *software* prototype and a *hardware* prototype. The software prototype had a *Stanford* arm, designed by Vic Scheinman (who went on to design the Unimation PUMA arm and many other famous early robotic devices). This was the only *1.5-scale* Stanford arm ever built. Antal (Tony) *Bejczy* became well known in robotics for solving the kinematics of this arm, one of if not the first full kinematics ever done in robotics up to that time [45.27]. A stereo pan-tilt head was implemented, equipped with the first solid-state cameras to become available. A number of very important works were published in

the 1977 International Joint Conference on Artificial Intelligence [45.28]. The first *hand-eye locomotion* co-ordination was done with this vehicle, where a rock was designated in a stereo image and the vehicle maneuvered autonomously to a point where the arm could reach out and pick it up. One of the first demonstrations of *pin in hole* insertion and other *dexterous* manipulations were also done with this system in the 1970s.

The *hardware* prototype was built using elastic *loop wheels* made by *Lockheed* [45.29]. The vehicle was battery powered and controlled via a handheld remote-control (*RC*) unit of the type used by hobbyists.

In late 1982 the *JPL* had a contract with the *US Army* to study the use of robotic support vehicles. During this study, Brian Wilcox at *JPL* proposed a technique to reduce the need for a real-time video link or high-bandwidth communication channel between the vehicle and the operator. This technique (which became known as *computer-aided remote driving* or *CARD*) [45.30], re-

quired the transmission of a single stereo image from the vehicle to the operator, so the operator could designate waypoints in that image using a three-dimensional (3-D) cursor. By the use of a single stereo image instead of a continuous stream of monocular images, the amount of information that needed to be transmitted by the vehicle was reduced by orders of magnitude. *JPL* first demonstrated *CARD* on the resurrected *surveyor lunar rover vehicle* (*SLRV*), which had been painted baby-blue and so became known as the *Blue Rover*, see Fig. 45.12a), and later on a modified Humvee. During field tests in the Mojave desert Dn 1988, *CARD* was demonstrated on the Humvee with path designations of 100 m per stereo image and with time to designate each path of only a few seconds.

As the *CARD* work was ongoing, an internally funded effort at *JPL* demonstrated a concept called *semi-autonomous navigation* (*SAN*). This concept involved humans on Earth designating *global* paths using maps of the sort that could be developed from orbiter imagery and then having the vehicle autonomously refine and execute a *local* path that avoids hazards. The moderate success of that effort led to a *NASA*-funded effort, leading to the development of a new vehicle, called *Robby* (Fig. 45.12b). *Robby* was a larger vehicle that could support the onboard computing and power needed for untethered operation. (The *SLRV* had been tethered to a VAX 11/750 minicomputer over a 500 m tether during arroyo field testing of *CARD*.) For the first time (in 1990), an autonomous vehicle had made a traverse through an obstacle field that was faster than a rover could have done on Mars using human path designation done on Earth.

However, *Robby* had a severe *public relations* problem – it was perceived as too large. Of course none of the computers or power systems had been miniaturized or lightweighted – it was composed entirely of the lowest-cost components that could do the job. However, because it was the size of a large automobile, observers and *NASA* management got the impression that future rovers would be car-sized or even truck-sized vehicles. This was compounded by the *Mars rover sample return* (*MRSR*) study done by *JPL* in the late-1980s, which suggested a mass for the rover of 882 kg. An independent study of the *MRSR* study by *Science Applications International, Inc.* (*SAIC*) estimated the overall cost at \$13B. When word of this *outrageous* price tag filtered around *NASA* Headquarters and into the Congressional Staff, *MRSR* was summarily killed. *Robby* died along with it. At about the same time, *NASA* funded Carnegie Mellon University to develop *Ambler*

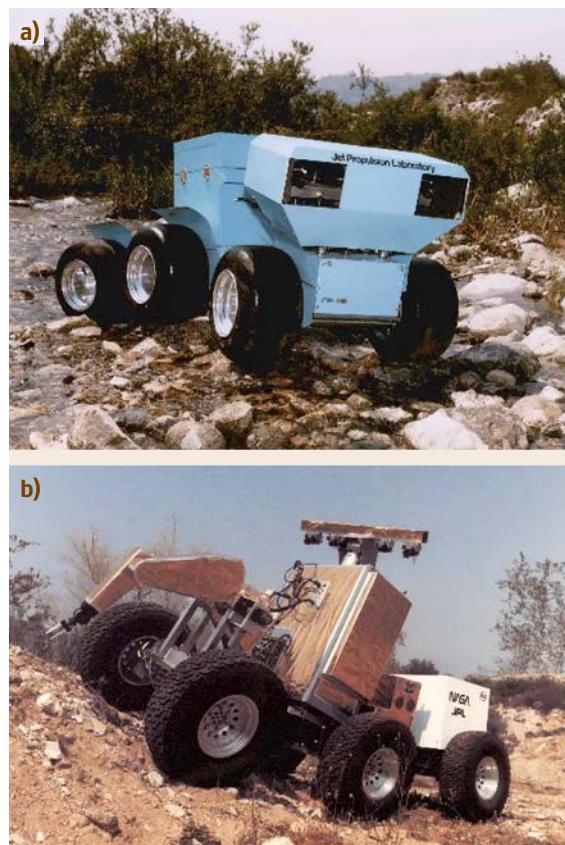

Fig. 45.12a, b Six-wheel articulated body rovers developed by *JPL* (a) *SLRV* and (b) *Robby*

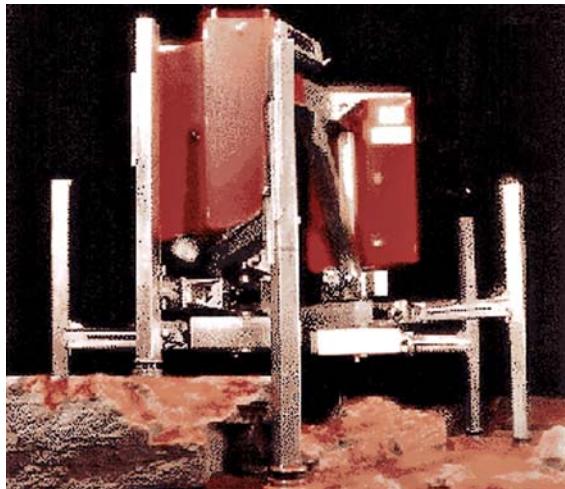

Fig. 45.13 Ambler

(Fig. 45.13), a large walking robot that was able to autonomously choose safe footfall locations, also as a test bed Mars Rover [45.31,32]. Ambler had a similar public-relations problem, being about the same mass as Robby, that the NASA management community was very skeptical that such large systems could affordably be flown to Mars. Both Robby and Ambler had all-onboard power and computing systems, which at that time were not sufficiently miniaturized to make autonomous rovers credible for actual flight missions. *Moore's law* was not only causing the computing technology to become miniaturized at a high rate, but also the energy required per computing instruction was dropping rapidly. This meant that early systems devoted most of their power to computing rather than to motive power. Later systems,

such as the Mars exploration rovers, have a more nearly equal balance between power for mobility and power for computation. Future systems will presumably devote the majority of their power to mobility as opposed to computation.

Soon thereafter, the *Mars environmental survey* (MESUR) mission set was proposed as a lower-cost alternative to a sample return mission. The MESUR Pathfinder mission was proposed as a first test of what was envisioned as a network of 16–20 surface stations to provide global coverage of Mars. A small rover was proposed to the Mars science working group [45.33,34]. A very short-term development effort culminated in a demonstration in July 1992 of a ≈ 4 kg rover that could move to directed points on the surface nearby a lander using stereo designation of waypoints in a 3-D display of frozen images taken from a lander mast camera pair (Fig. 45.14). This demonstration was sufficiently successful that a similar rover was manifested for the Mars Pathfinder mission. The Pathfinder rover (Fig. 45.15) was later named Sojourner, and became the first autonomous vehicle to traverse the surface of another planet, using a hazard detection and avoidance system to move safely between waypoints through a rock field [45.21,22]. The hazard detection system avoided obstacles and was also used to position the vehicle accurately in front of rocks. Sojourner operated successfully for 83 Martian days (until the failure of the lander, which was acting as a communications relay between the rover and Earth). Sojourner examined approximately a dozen rock and soil samples with its alpha–proton–X-ray spectrometer, which gives the elemental composition of the rocks and soil. The success of Sojourner led directly to the decision to build the twin Mars exploration rovers

Fig. 45.14 Rocky 4

Fig. 45.15 The Pathfinder rover, Sojourner

launched in 2003. Both Sojourner and the [MER](#) rovers use waypoint designation in stereo images by the human operator together with autonomous hazard detection and avoidance to keep the rovers safe if they should wander off the designated path.

During the 1992–1993 summer season in Antarctica, the Dante I robot, built by Carnegie-Mellon University and funded by [NASA](#), attempted to rappel into the caldera of the active volcano Mt. Erebus. Dante was a walking robot and was the first serious attempt to make a robot rappel down a grade that was too steep to traverse using purely frictional contact. Unfortunately, the extreme cold (even in the summer) compounded by human error caused a kink in the fiber-optic umbilical to snag going through an eyelet, breaking the high-bandwidth fiber communications on which the system depended. The fiber could not be repaired in the field and so the mission was aborted. Undaunted, in the summer of 1994, Dante II (Fig. 45.16) made a successful rappel into the caldera of Mt. Spur in Alaska, exploring the active vents on the crater floor in a way that would be unsafe in the extreme if done by human explorers. The Dante robot series demonstrated that rappelling, especially when combined with legged locomotion, allows

robots to conduct exploration to extremely hazardous sites in ways that humans cannot.

In 1984 [NASA](#) started the Telerobotics Research program [45.35,36]. This program demonstrated various aspects of on-orbit assembly, maintenance, and servicing. Some highlights of this activity were the automated tracking and grappling of a free-spinning satellite (suspended with a counterweight and gimbal for realistic reactions under external forces), connection of a flight-like fluid coupler and many *busy box* functions such as door opening, threaded fastener mating and demating, use of power tools, dual-arm manipulation of a simulated hatch cover and flexible thermal blanket, etc. by various control approaches ranging from force-reflecting teleoperation to fully autonomous sequences. This activity ended in about 1990.

45.2.3 Research Systems

There have been many mobile robots built by government, university, and industrial groups whose objective was to develop new technologies for planetary surface exploration or to excite students or young engineers about the possibilities in that area. Carnegie Mellon University developed the Ambler, Dante, Nomad, Hyperion, Zoe, and Icebreaker robot series. The *Jet Propulsion Laboratory (JPL)*, Draper Labs, MIT, Sandia National Lab, and Martin-Marietta (later Lockheed-Martin) each built more than one planetary surface robot test bed. The Marsokhod chassis built by VNII Transmash of St. Petersburg, Russia was used by research groups there and also in Toulouse ([LAAS](#) and CNRS) [45.37,38] as well as the [NASA](#) Ames Research Center and McDonnell Douglas Corporation (later part of the Boeing Company) in the [US](#).

These research platforms have been used for two basic avenues of research. One is to perfect safe driving techniques on planetary surfaces, despite the speed-of-light latencies inherent in robotic exploration of the planets. This includes the waypoint navigation technology developed at [JPL](#) in the 1980s, where frozen stereo images are used to plan a possibly lengthy series of waypoints or activity sites and then executed with various sorts of reflexive hazard avoidance or safing techniques, such as used on the Sojourner rover on Mars in 1997. The other is to develop higher-level autonomy for improved science data return or mission robustness. Technologies in this latter category include mission planners that attempt to optimize routes and activity sequences based on time, limits to peak power, total energy, expected temperature, illumination angles, availability of

Fig. 45.16 Dante II at Mt. Spur in Alaska

communications and others. Automated classification of possible science targets based on clustering of spectral data, figure-ground segmentation of rocks and other approaches have been attempted with some success. At the time of this writing some of these technologies have been uploaded to the twin Mars exploration rovers *Spirit* and *Opportunity* (Fig. 45.18) [45.23], including automated detection of temporary events of scientific interest such as dust-devils and clouds [45.39].

45.2.4 Sensing and Perception

In the 1980s, most planetary rover sensing research was based on laser ranging or stereo vision. Stereo vision was too computationally intensive for early low-power, radiation-hard processors, so the Sojourner Mars rover used a simple form of laser ranging to determine which areas were safe to traverse. Between the launch of Sojourner (1996) and the Mars exploration rovers (2003) sufficient progress had been made in radiation-hardened flight processors that stereo vision was used for hazard detection on Mars exploration rovers (**MER**) [45.40], mostly in experiments conducted with the Rocky-7 rover (Fig. 45.17). This allowed much larger numbers of range points to be incorporated into the hazard-detection algorithm (thousands of points, instead of the 20 discrete range points used by Sojourner). Perception of hazards on Sojourner was based on simple computations of average slope and roughness over the 4×5 array of range measurements, as well as the maximum height differences.

Each **MER** rover used a more sophisticated evaluation of the safety of the rovers along a large number of candidate arcs from its current location. Many other algorithms for the perception of terrain hazards have been used with reasonable success by various organizations. Today it is probably fair to say that the *unsolved problems* lie not in the area of geometric hazards (e.g., hazards that can be evaluated completely based on accurate knowledge of the shape of the terrain) but rather in the area of nongeometric hazards (e.g., hazards where uncertainties in the load-bearing or frictional properties of the terrain determine the safety of a proposed traverse). Accurate estimation of the load-bearing or friction properties of terrain by remote sensing is a very challenging task that will not be completely *solved* anytime soon, if ever.

45.2.5 Estimation

Most estimation for planetary surface exploration relates to the internal state of the robot or its position, pose, and

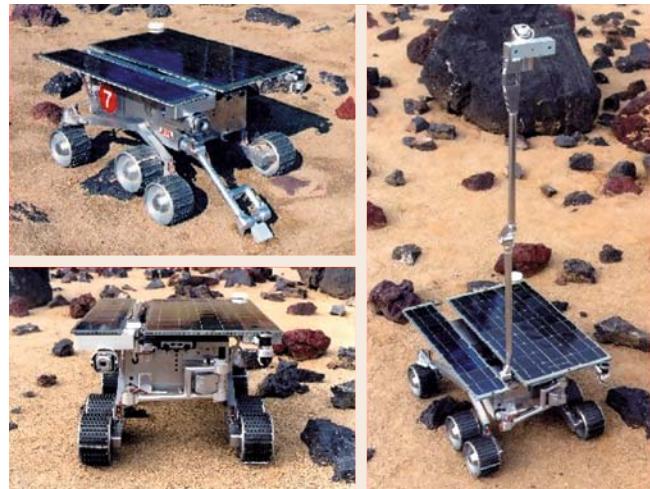

Fig. 45.17 Rocky 7

kinematic configuration with respect to the environment. Internal state sensors such as encoders on any active or passive articulations in the vehicle are used, along with a kinematic model and inertial sensors such as accelerometers and gyroscopes, to estimate the pose of the vehicle in inertial space. Perceptual algorithms such as surface reconstruction from clouds of range points as developed by stereo vision put terrain geometry estimates into this same representation. Heading in inertial space is generally the most difficult to estimate reliably, due to the lack of navigation aids such as the global positioning system or any easily measured heading reference such as a global magnetic field. Integration of rate-gyro data is used to maintain local attitude during motion while accu-

Fig. 45.18 The Mars exploration rovers, spirit and opportunity, with a manipulator arm in front

rate estimation of the rotation axis for Mars is possible by long integrations of three-axis rate-gyro data while the vehicle is stopped. Similar approaches are probably not feasible for the Moon, because of its slow rotation rate. Imaging of the solar disk or constellations of stars at precisely known times can be combined with stored models of the rotation of the planet to allow accurate estimation of the complete pose of the vehicle in inertial space. Kalman filtering or related techniques are generally employed to reduce the effects of measurement noise.

45.2.6 Manipulators for In Situ Science

The Mars exploration rovers were the first planetary exploration vehicles to have general-purpose manipulators. (Lunokhod had a single-purpose soil penetrometer and Sojourner had a single-degree-of-freedom device to place an alpha–proton–X-ray spectrometer in direct contact with the terrain.) The MER arms each have five degrees-of-freedom and a reach of over 1 m. Accurate gravity-sag models of the lightweight arm allow the precise position to be predicted in advance of any command to deploy an instrument and contact sensors allow the

arm to stop before any excessive forces build up in the relatively flexible arm. Future arms for planetary surface operations, especially any proposed assembly, maintenance or servicing tasks as part of the proposed lunar outpost, will require force sensing to protect the stronger but much more rigid arms from damage, as well as to allow controlled forces to be applied to workpieces. Of course there is a huge body of knowledge associated with industrial robot arms and undersea robotics (e.g., for the offshore oil industry), but such arms are generally very heavy, fast, and stiff compared with credible systems for planetary surface use. Delicate force control has rarely been applied to industrial settings. Space hardware is necessarily very lightweight and so both the arms and the workpieces will need to have well-resolved force sensing and control to prevent damage to one or both. Because of severe limits on both mass and power, space manipulation tends to be slow. Historically, this means the gear ratio between each motor and the corresponding output shaft is very large, making the use of motor current as an estimator for output torque very problematic. Other low-mass and robust means for accurate sensing of applied forces in the space environment are needed.

45.3 Mathematical Modeling

45.3.1 Space Robot as an Articulated-Body System

Broadly speaking, both on-orbit manipulators and surface mobile robots are considered to be common articulated body systems with a moving base. One point that clearly distinguishes them from other ground-based robots, such as industrial manipulators, is the existence of a moving base. The robotic systems discussed in this chapter consist of one or multiple articulated limbs mounted on a base body that has a dynamic coupling with these limbs. Typical styles of such moving base systems are categorized into the following groups [45.41].

Free-Floating Manipulator Systems

A space free-flyer that has one or more manipulator arms, as illustrated schematically in Fig. 45.19a, is a typical example of this group. When operating the manipulator arm(s), the position and orientation of the base spacecraft fluctuates due to the manipulator reaction. The kinetic momentum of the system is conserved if no external forces or moments are applied and the conservation law for this system governs the reaction

dynamics. Coordination or isolation between the base and manipulator dynamics is key to advanced motion control.

Macro–Micro Manipulator Systems

A robotic system that comprises a relatively small arm (micro arm) for fine manipulation mounted on a relatively large arm (macro arm) for coarse positioning, is called a macro–micro manipulator system. The SSRMS (Canadarm2) and the SPDM (Dextre) system, as well as the JEMRMS on the Japanese module of the ISS, are good examples. Here, the connecting interface at the end point of the macro arm or the root of the micro arm is modeled as the base body (Fig. 45.19b) A free-flying space robot may be treated in this group when its base body is actively controlled by actuators that produce external forces and moments, such as gas-jet thrusters. In this case, these actuators can be modeled as a virtual macro arm [45.42].

Flexible-Based Manipulator Systems

If the macro arm behaves as a passive flexible (elastic) structure in a macro–micro manipulator system, the

system is considered to be a flexible-based manipulator (Fig. 45.19c). Such a situation can be observed in the operation of the ISS, when the SSRMS is servo or brake locked after its coarse operation. Here, the issue is that the base body (the root of the micro arm or the end of the macro arm, according to the definition above) is subject to vibrations that will be excited by the reaction of the micro arm.

Mobile Robots with Articulated Limbs

Mobile robots for surface locomotion have the same structure in terms of the dynamics equation as the above groups. This group includes wheeled vehicles, walking (articulated limb) robots, and their hybrids. In a wheeled vehicle, suspension mechanisms, if any, are also modeled as articulated limb systems. The forces and moments yielded by contact with ground or planetary surface govern the motion of the system (Fig. 45.19d)

45.3.2 Equations for Free-Floating Manipulator Systems

Let us consider first a free-floating system with a single or multiple manipulator arm(s) mounted on a base spacecraft. The base body, termed link 0, is floating in inertial space without any external forces or moments. At the end point of the arm(s), external forces/moment may apply. For such a system, the equation of motion is expressed as follows

$$\begin{pmatrix} \mathbf{H}_b & \mathbf{H}_{bm} \\ \mathbf{H}_{bm}^\top & \mathbf{H}_m \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{x}}_b \\ \ddot{\boldsymbol{\phi}} \end{pmatrix} + \begin{pmatrix} \mathbf{c}_b \\ \mathbf{c}_m \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \boldsymbol{\tau} \end{pmatrix} + \begin{pmatrix} \mathbf{J}_b^\top \\ \mathbf{J}_m^\top \end{pmatrix} \mathbf{F}_h . \quad (45.1)$$

The kinematic relationship among \mathbf{x}_h , \mathbf{x}_b , and $\boldsymbol{\phi}$ is expressed using Jacobian matrices as

$$\dot{\mathbf{x}}_h = \mathbf{J}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \dot{\mathbf{x}}_b , \quad (45.2)$$

$$\ddot{\mathbf{x}}_h = \mathbf{J}_m \ddot{\boldsymbol{\phi}} + \dot{\mathbf{J}}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \ddot{\mathbf{x}}_b + \dot{\mathbf{J}}_b \dot{\mathbf{x}}_b , \quad (45.3)$$

where the symbols are:

$\mathbf{x}_b \in \mathbb{R}^6$: position/orientation of the base

$\boldsymbol{\phi} \in \mathbb{R}^n$: joint angle of the arm

$\mathbf{x}_h \in \mathbb{R}^{6k}$: position/orientation of the end point(s)

$\boldsymbol{\tau} \in \mathbb{R}^n$: joint torque of the arm

$\mathbf{F}_h \in \mathbb{R}^{6k}$: external forces/moment on the end point(s)

n : number of total joints

k : number of manipulator arms

and \mathbf{H}_b , \mathbf{H}_m , and \mathbf{H}_{bm} are inertia matrices for the base body, manipulator arm, and the coupling between

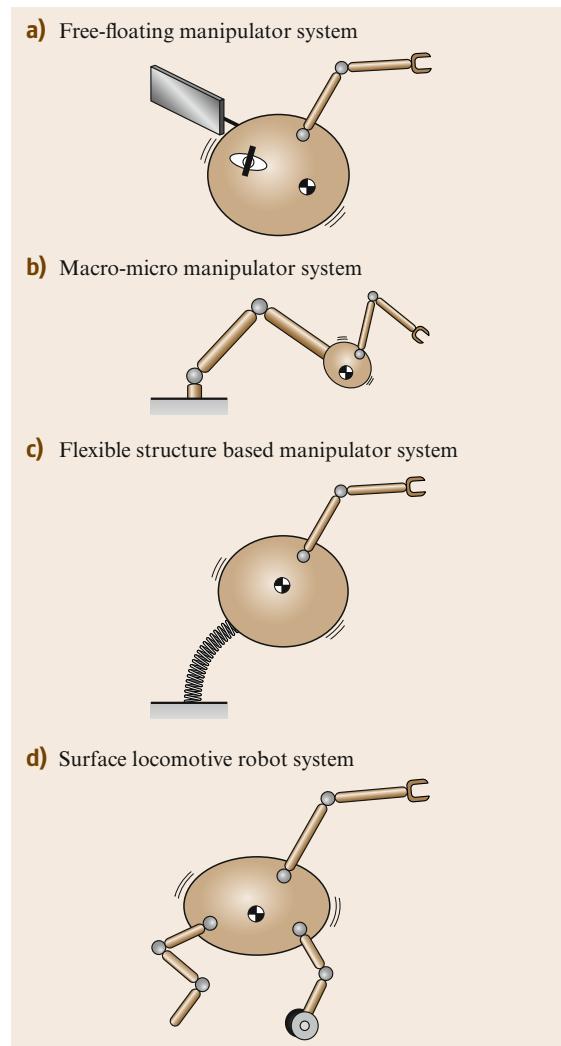

Fig. 45.19a–d Four basic types for moving base robots:
(a) Free-floating manipulator system, **(b)** macro–micro manipulator system, **(c)** flexible-structure-based manipulator system, **(d)** surface locomotive robot system

the base and the arm, respectively, and \mathbf{c}_p and \mathbf{c}_q are nonlinear Coriolis and centrifugal forces, respectively.

For a free-floating manipulator in orbit, the gravity forces exerted on the system can be neglected and so the nonlinear term becomes $\mathbf{c}_b = \dot{\mathbf{H}}_b \dot{\mathbf{x}}_b + \mathbf{H}_{bm} \dot{\boldsymbol{\phi}}_b$. Integrating the upper set of equation in (45.1) with respect to time, we obtain the total momentum of the system as

$$\mathcal{L} = \int \mathbf{J}_b^\top \mathbf{F}_h dt = \mathbf{H}_b \dot{\mathbf{x}}_b + \mathbf{H}_{bm} \dot{\boldsymbol{\phi}} . \quad (45.4)$$

For the case in which reaction wheels are mounted on the base body, they are included as additional manipulator arms.

45.3.3 Generalized Jacobian and Inertia Matrices

From (45.2) and (45.4), the coordinates of the manipulator base \dot{x}_b , which are passive and unactuated coordinates, can be eliminated, as follows

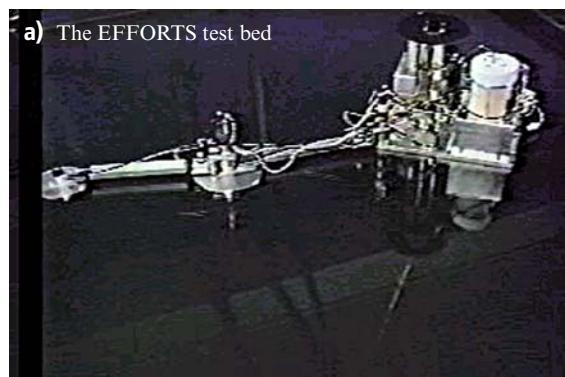

$$\dot{x}_h = \hat{J}\dot{\phi} + \dot{x}_{h0}, \quad (45.5)$$

where

$$\hat{J} = J_m - J_b H_b^{-1} H_{bm} \quad (45.6)$$

and

$$\dot{x}_{h0} = J_b H_b^{-1} \mathcal{L}. \quad (45.7)$$

b) A target capture result

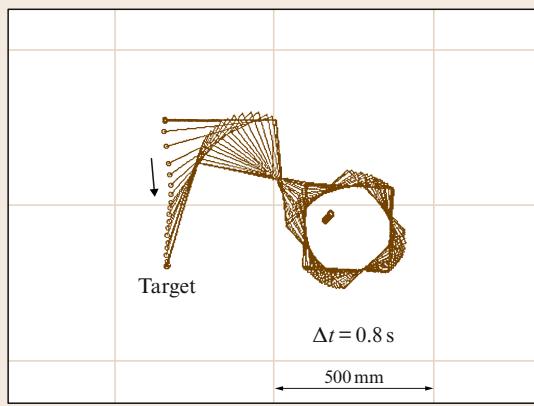

Fig. 45.20a,b Laboratory test bed for a free-floating space robot: (a) the EFFORTS test bed, (b) a target capture result

Since H_b is the inertia tensor of a single rigid body (the manipulator base), it is always positive definite and so its inverse exists.

The matrix \hat{J} was first introduced in [45.43, 44] and is referred to as the *generalized Jacobian matrix*. In its original definition, it was assumed that no external forces/momenta acted on the system. If $F_h = \mathbf{0}$, then the term \dot{x}_{h0} becomes constant and, in particular, if the system has zero initial momentum $\dot{x}_{h0} = \mathbf{0}$, then (45.5) becomes simple. However, note that in the derivation of (45.6), zero or constant momentum is not a necessary condition.

Using this matrix, the manipulator hand can be operated under a resolved motion-rate control or resolved acceleration control in inertial space. Thanks to the generalized Jacobian, although the reactive base motion occurs during the operation, the hand is not disturbed by the reactive motion.

From the upper and lower sets of equations in (45.1), \dot{x}_b can be eliminated to obtain the following expression

$$\hat{H}\ddot{\phi} + \hat{c} = \tau + \hat{J}F_h, \quad (45.8)$$

where

$$\hat{H} = H_m - H_{bm}^\top H_b^{-1} H_{bm}. \quad (45.9)$$

The matrix \hat{H} is known as the *generalized inertia matrix* for space manipulators [45.45]. This matrix represents the inertia property of the system in the joint space and can be mapped onto the Cartesian space using the generalized Jacobian matrix:

$$\hat{G} = \hat{J}\hat{H}^{-1}\hat{J}^\top. \quad (45.10)$$

The matrix \hat{G} is referred to as the *inversed inertia tensor* for space manipulators and is useful for the discussion of impact dynamics when a space manipulator collides with or captures a floating target in orbit [45.46].

The *generalized Jacobian matrix (GJM)* is a useful concept, with which the manipulator end point can perform positioning or trajectory tracking control by a simple control algorithm regardless of the attitude deviation during the operation.

A simplified laboratory demonstration was carried out using a two-dimensional free-floating test bed called *EFFORTS* [45.47]. To simulate the motion in a microgravity environment, a robot model was floated on a thin film of pressurized air on a horizontal plate, so that frictionless motion with momentum conservation was achieved.

Figure 45.20 depicts the test bed and a typical experimental result. For Fig. 45.20b, the control command was given to the floating robot by

$$\dot{\phi} = \tilde{J}^{-1} \dot{x}_d, \quad (45.11)$$

where \dot{x}_d is the desired velocity of the manipulator end point, the value of which was given and updated by online measurement of the end point position x_h and the target position x_t , as follows

$$\dot{x}_d = \frac{x_t - x_h}{\Delta t}, \quad (45.12)$$

where Δt is the time interval of the online control loop. The desired end point velocity was simply resolved into the joint velocity by (45.11).

The result clearly shows that the manipulator end point properly reached the target in an optimum manner, although the robot base rotated considerably due to the manipulator reaction. Note that, since the target was stationary in this example, the resulting motion trace was a straight line. However, thanks to the online control, the manipulator was also able to track and reach a moving target with the same control law.

The validity and effectiveness of the GJM-based manipulator control were also demonstrated in orbit by Japanese ETS-VII mission [45.16].

45.3.4 Linear and Angular Momenta

The integral of the upper set of equation in (45.1) gives a momentum equation, as shown in (45.4), which is composed of the linear and angular momenta. The linear part is expressed as

$$\check{H}_b v_b + \check{H}_{bm} \dot{\phi} = P, \quad (45.13)$$

where v_b is the linear velocity of the base, P is the initial linear momentum, and the inertia matrices with the over-tilde are the corresponding components for the linear momentum [45.45]. When the linear momentum is further integrated, the result verifies the principle that the mass centroid of the entire system either remains stationary or translates with a constant velocity.

The angular momentum equation, however, does not have a second integral and therefore provides a first-order nonholonomic constraint [45.48]. The equation can be expressed as

$$\tilde{H}_b \omega_b + \tilde{H}_{bm} \dot{\phi} = L, \quad (45.14)$$

where ω_b is the angular velocity of the base, L is the initial angular momentum and the inertia matrices with the

over-tilde are the corresponding components for the angular momentum [45.45]. $\tilde{H}_{bm} \dot{\phi}$ represents the angular momentum generated by the manipulator motion.

Equation (45.14) can be solved for ω_b with zero initial angular momentum

$$\omega_b = -\tilde{H}_b^{-1} \tilde{H}_{bm} \dot{\phi}. \quad (45.15)$$

This expression describes the resulting disturbance motion of the base when there is joint motion $\dot{\phi}$ in the manipulator arm.

There are a number of points worth discussion when analyzing this equation. The magnitudes and directions of the maximum and minimum disturbances can be obtained from the singular value decomposition of the matrix $(-\tilde{H}_b^{-1} \tilde{H}_{bm})$ and displayed on the map. Such a map is called a *disturbance map* [45.49, 50]. Equation (45.15) is also used for the feedforward compensation in the coordinated manipulator–base control model [45.51, 52].

45.3.5 Virtual Manipulator

The concept of the *virtual manipulator (VM)* is an augmented kinematic representation that considers the base motion due to reaction forces or moments. The model is based on the fact that the mass centroid of the entire system does not move in the free-floating system without any external forces [45.53]. The mobility of the end point of the arm is decreased by the base motion. In the VM representation, such mobility degradation is expressed by virtually shrinking the length of the real arm according to the mass property. Note that the VM considers only conservation of linear momentum. If the differential expression of VM is obtained using a Jacobian matrix, the Jacobian is not a conventional kinematic Jacobian, but rather a version of the generalized Jacobian defined by the combination of the kinematic equation (45.2) and the linear momentum equation (45.13).

45.3.6 Dynamic Singularity

Dynamic singularities are singular configurations in which the manipulator end point loses mobility in some inertial direction [45.54]. Dynamic singularities are not found in Earth-based manipulators, but rather occur in free-floating space manipulator systems due to the coupling dynamics between the arm and the base. Dynamic singularities coincide with the singularities of the generalized Jacobian matrix determined by (45.6). The *singular value decomposition (SVD)*

of a manipulator Jacobian matrix provides *manipulability* analysis. Likewise, the *SVD* of the generalized Jacobian matrix yields the manipulability analysis of a free-floating space manipulator [45.55]. Figure 45.21 shows the comparison of the manipulability distribution between a two-degree-of-freedom (2-DOF) ground-based manipulator and a 2-DOF floating manipulator, from which the degradation of the manipulability is observed in the space arm due to the dynamic coupling.

45.3.7 Reaction Null Space (RNS)

From a practical point of view, any change in the base attitude is undesirable. As such, manipulator motion planning methods that minimize the base attitude disturbance have been investigated extensively. Analysis of the angular momentum equation reveals that the ultimate goal of achieving zero disturbance is possible.

The following is the angular momentum equation with zero initial angular momentum $\mathbf{L} = \mathbf{0}$ and the zero attitude disturbance $\boldsymbol{\omega}_b = \mathbf{0}$ given in (45.14)

$$\tilde{\mathbf{H}}_{bm}\dot{\boldsymbol{\phi}} = \mathbf{0}. \quad (45.16)$$

This equation yields the following null-space solution

$$\dot{\boldsymbol{\phi}} = (\mathbf{E} - \tilde{\mathbf{H}}_{bm}^+ \tilde{\mathbf{H}}_{bm})\dot{\boldsymbol{\xi}}, \quad (45.17)$$

where \mathbf{E} is an identity matrix. The joint motion given by this equation is guaranteed not to disturb the base attitude. Here, the vector $\dot{\boldsymbol{\xi}} \in \mathbb{R}^n$ is arbitrary and the null space of the inertia matrix $\tilde{\mathbf{H}}_{bm} \in \mathbb{R}^{3 \times n}$ is called the *reaction null space (RNS)* [45.56].

The number of *degrees of freedom (DOF)* of $\dot{\boldsymbol{\xi}}$ is $n - 3$. For example, if a manipulator arm mounted on

a free-floating space robot has six *DOFs*, i.e., $n = 6$, then three *DOFs* remain in the reaction null space. These *DOFs* can be specified by introducing additional motion criteria, such as end point positioning of the arm. Such manipulator operation that produces no reaction in the base is called *reactionless manipulation* [45.57].

The validity and effectiveness of the *RNS*-based reactionless manipulation were demonstrated in orbit by Japanese *ETS-VII* mission [45.16].

45.3.8 Equations for Flexible-Based Manipulator Systems

Next, let us consider a flexible-based manipulator system in which a single or multiple manipulator arm(s) are supported by a flexible-beam or a spring and damper (viscoelastic) system. For such a system, the equation of motion is obtained using the following variables

$\mathbf{x}_b \in \mathbb{R}^6$: position/orientation of the base

$\boldsymbol{\phi} \in \mathbb{R}^n$: joint angle of the arm

$\mathbf{x}_h \in \mathbb{R}^{6k}$: position/orientation of the end point(s)

$\mathbf{F}_b \in \mathbb{R}^6$: forces/moment to deflect the flexible base

$\boldsymbol{\tau} \in \mathbb{R}^n$: joint torque of the arm

$\mathbf{F}_h \in \mathbb{R}^{6k}$: external force/torque on the end point(s)

$$\begin{pmatrix} \mathbf{H}_b & \mathbf{H}_{bm} \\ \mathbf{H}_{bm}^\top & \mathbf{H}_m \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{x}}_b \\ \dot{\boldsymbol{\phi}} \end{pmatrix} + \begin{pmatrix} \mathbf{c}_b \\ \mathbf{c}_m \end{pmatrix} = \begin{pmatrix} \mathbf{F}_b \\ \boldsymbol{\tau} \end{pmatrix} + \begin{pmatrix} \mathbf{J}_b^\top \\ \mathbf{J}_m^\top \end{pmatrix} \mathbf{F}_h \quad (45.18)$$

$$\dot{\mathbf{x}}_h = \mathbf{J}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \dot{\mathbf{x}}_b \quad (45.19)$$

$$\ddot{\mathbf{x}}_h = \mathbf{J}_m \ddot{\boldsymbol{\phi}} + \dot{\mathbf{J}}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \ddot{\mathbf{x}}_b + \dot{\mathbf{J}}_b \dot{\mathbf{x}}_b. \quad (45.20)$$

Here, with the gravitational force \mathbf{g} in Cartesian space, the term \mathbf{c}_b is generally expressed as

$$\mathbf{c}_b = \mathbf{f}(\mathbf{x}_b, \boldsymbol{\phi}, \dot{\mathbf{x}}_b, \dot{\boldsymbol{\phi}}) + \mathbf{g}(\mathbf{x}_b, \boldsymbol{\phi}). \quad (45.21)$$

The difference from the equation of a free-floating manipulator system (45.1) is the existence of the base constraint force \mathbf{F}_b . Let \mathbf{D}_b and \mathbf{K}_b be the damping and spring factors, respectively, of the flexible base. The constraint forces and moments \mathbf{F}_b are then expressed as

$$\mathbf{F}_b = -\mathbf{D}_b \dot{\mathbf{x}}_b - \mathbf{K}_b \Delta \mathbf{x}_b, \quad (45.22)$$

where $\Delta \mathbf{x}_b$ denotes the elastic base displacement from its neutral position.

Since the base is constrained, the total momentum is not conserved and it might be meaningless to check the system momentum. However, it is important to consider the partial momentum \mathcal{L}_m for the part of the manipulator arm:

$$\mathcal{L}_m = \mathbf{H}_{bm} \dot{\boldsymbol{\phi}}, \quad (45.23)$$

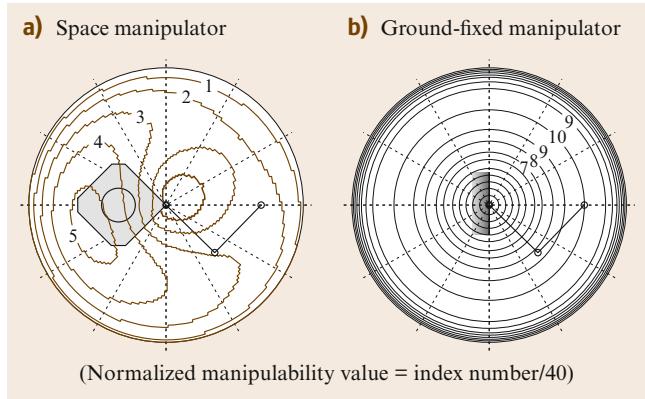

Fig. 45.21 Manipulability distribution in the work space

which is termed the *coupling momentum* [45.58]. Its time derivative describes the forces and moments \mathbf{F}_m , which are yielded by the dynamic reaction from the manipulator arm to the base

$$\mathbf{F}_m = \mathbf{H}_{bm} \ddot{\phi} + \dot{\mathbf{H}}_{bm} \dot{\phi}. \quad (45.24)$$

Using \mathbf{F}_b and \mathbf{F}_m , the upper set of equation in (45.18) is rearranged as

$$\mathbf{H}_b \ddot{\mathbf{x}}_b + \mathbf{D}_b \dot{\mathbf{x}}_b + \mathbf{K}_b \Delta \mathbf{x}_b = -\mathbf{g} - \mathbf{F}_m + \mathbf{J}_b^\top \mathbf{F}_h. \quad (45.25)$$

Equation (45.18) or (45.25), is a familiar expression for flexible-base manipulators [45.59, 60].

45.3.9 Advanced Control for Flexible Structure Based Manipulators

In this subsection, advanced control issues for a macro-micro space manipulator are discussed. The SSRMS attached to the **SPDM** (Fig. 45.4) and the **JEMRMS** (Fig. 45.6) are examples. Operation modes for this class of space manipulators include coarse motion by the macro (long-reach) component and fine manipulation by the micro component. In normal cases, these two control modes are executed exclusively. Namely, while one component is active the other component should be servo (or brake) locked. Thus, during the operation of the micro component, the macro component behaves just like a passive base.

Due to the flexible nature of the space long-reach arm, the macro part is subject to vibrations. These vibrations can be excited during coarse positioning and may remain for a long time after each operation. In fine manipulation, the macro arm behaves as a passive flexible structure, but then vibrations can be excited by reactions from the motion of the micro arm. These motions degrade the control accuracy and operational performance of the system. In practice, the booms are usually sufficiently stiff, but flexibility comes mainly from the low stiffness at the joints and gear trains. In addition, lightweight and microgravity characteristics make the structure sensitive to yield vibrations and the surrounding vacuum or the lack of air viscosity, provides a reduced damping effect to the structure.

Conventionally, the vibration issue has been managed for **SRMS** and **SSRMS** by the operational skill of well-trained astronauts and by limiting the maximum operational velocity according to the inertia of the handling object. However, if an advanced controller is introduced on the **ISS**, the training time for astronauts will be reduced and the operational speed can be increased.

Here, the following two subtasks are considered in dealing with this issue:

- suppression of the vibrations of the flexible base
- end point control in the presence of vibrations

To suppress the vibrations of the macro arm (flexible base), the coupled dynamics is effectively used. Such control is called *coupled vibration suppression control* [45.61]. The coupled dynamics is a solution space of the micro arm motion with maximum coupling with the vibration dynamics of the macro arm. Note that this solution space is perpendicular to the reaction null space introduced in Sect. 45.3.7. Since the spaces are orthogonal, the coupled vibration suppression control and reactionless manipulation can be superimposed without any mutual interference.

The motion command of the micro arm to suppress the vibrations is determined with a feedback of the linear and angular velocity of the end point of the macro arm $\dot{\mathbf{x}}_b$:

$$\ddot{\phi} = \mathbf{H}_{bm}^+ \mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b, \quad (45.26)$$

where $(\cdot)^+$ denotes the right pseudo-inverse and \mathbf{G}_b is a positive-definite gain matrix.

If written in the form of a joint torque input, the vibration control law is expressed as

$$\tau = \mathbf{H}_m \mathbf{H}_{bm}^+ \mathbf{G}_b \dot{\mathbf{x}}_b. \quad (45.27)$$

In the presence of redundancy in the micro arm, (45.26) can be extended to control with a null-space component

$$\ddot{\phi}_m = \mathbf{H}_{bm}^+ (\mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b - \dot{\mathbf{H}}_{bm} \dot{\phi}_m) + \mathbf{P}_{RNS} \zeta, \quad (45.28)$$

where ζ is an arbitrary n -DOF vector and $\mathbf{P}_{RNS} = (\mathbf{E} - \mathbf{H}_{bm}^+ \mathbf{H}_{bm})$ is a projector onto a null space of the coupling inertia matrix \mathbf{H}_{bm} . When the micro arm is operated using (45.28), the closed-loop system is expressed as

$$\mathbf{H}_b \ddot{\mathbf{x}}_b + \mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b + \mathbf{K}_b \Delta \mathbf{x}_b = \mathbf{F}_b + \mathbf{J}_b^\top \mathbf{F}_h. \quad (45.29)$$

Equation (45.29) represents a second-order damped vibration system. With no force input, i.e., $\mathbf{F}_b = \mathbf{F}_h = 0$, the vibrations converge to zero with a proper choice of the gain matrix \mathbf{G}_b .

For the determination of the vector ζ , feedback control to reduce the positioning error of the micro arm end point is considered. The error vector is defined as

$$\tilde{\mathbf{x}}_h = \mathbf{x}_h^d - \mathbf{x}_h. \quad (45.30)$$

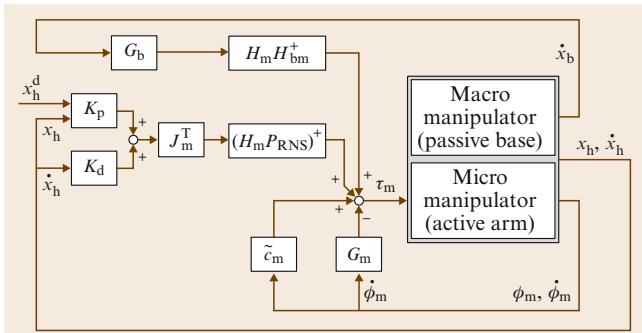

Fig. 45.22 Block diagram for simultaneous vibration suppression and manipulator end point control for a flexible-structure-mounted manipulator system

After some manipulation, the control law for the joint torque of the micro arm is obtained in the form [45.61, 62]

$$\tau = [(J_m^T)^+ H_m P_{RNS}]^+ (K_p \tilde{x}_h - K_d J_m \dot{\phi}) - G_m \dot{\phi}, \quad (45.31)$$

where K_p , K_d , and G_m are positive-definite gain matrices.

Figure 45.22 shows a block diagram for the control system described by Eqs. (45.27) and (45.31).

As a simplified demonstration, a planar system with a four-joint redundant manipulator arm atop a flexible beam is considered. Figure 45.23 shows the vibration amplitude of the flexible beam after an impulsive external force. The trace labeled ‘w/o vs’ depicts the vibrations of the beam without any manipulator control but with natural damping. The graph labeled ‘with vs’ depicts the case in which vibration suppression control given by (45.27) is applied, where the vibrations are damped quickly.

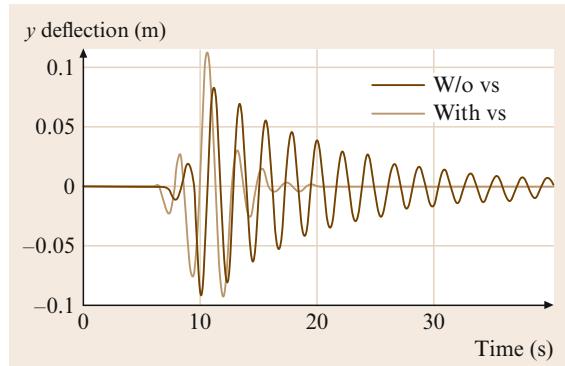

Fig. 45.23 Vibrations of the flexible base

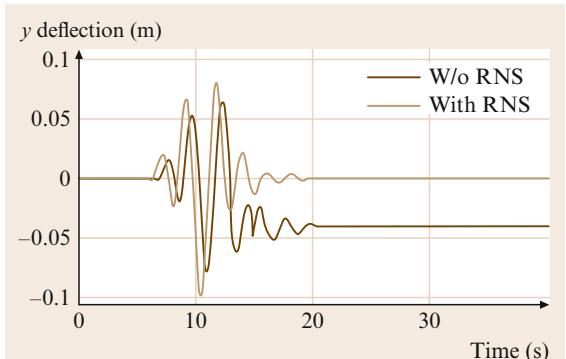

Fig. 45.24 Positioning error of the manipulator end tip

In addition, Fig. 45.24 shows the end point motion of the manipulator arm during the control. The graph labeled ‘w/o RNS’ is the case of using (45.27), where the base vibrations were successfully suppressed but the position of the manipulator end point was deflected by this suppression behavior. The graph labeled ‘with RNS’ depicts the case in which both vibration suppression control given by (45.27) and the end point control given by (45.31) are applied simultaneously. This last case shows that the vibrations were damped successfully and that the positioning error of the manipulator end point converged to zero. This is a result of the redundancy of the arm.

Here, note that the proposed control method requires precise information on dynamic characteristics, such as the inertia parameters of the arms and the handled payload, if any. To achieve more practical applications, the proposed method must be extended to schemes for parameter identification [45.63] and adaptive control [45.64], with which the convergence of the control is guaranteed even with imprecise a priori knowledge of the dynamic parameters [45.62].

45.3.10 Contact Dynamics and Impedance Control

The capture and retrieval operation of a floating and tumbling *target*, such as a malfunctioning satellite, by a manipulator arm mounted on a servicing robot (called a *chaser*) can be decomposed into the following three phases:

1. approach phase (before contact with the target)
2. contact/impact phase (at the moment of contact)
3. post-contact phase (after contact or grasping)

If the contact is impulsive, the first and the third phases are discontinued by the impulsive phenomena of the second phase. Understanding of this impulsive phenomena is indispensable when designing a comprehensive capture control scheme. In this subsection, the formulation of impact dynamics is first considered and impedance control (which is useful to minimize the impact forces and prolong the contact duration) is then discussed.

Let us consider a chain of rigid links composed of $n+1$ bodies freely floating in inertial space. As discussed in Sect. 45.3.3, the equation of motion for this type of system becomes (45.8). Here, the impulsive contact force is assumed to yield at the manipulator end tip and is expressed as $\mathbf{F}_h = (\mathbf{f}_h^\top, \mathbf{n}_h^\top)^\top \in \mathbb{R}^6$. This impulsive force also yields a change in the system momenta $(\mathbf{P}_g^\top, \mathbf{L}_g^\top)^\top \in \mathbb{R}^6$, as expressed by

$$\begin{aligned} \begin{pmatrix} \dot{\mathbf{P}}_g \\ \dot{\mathbf{L}}_g \end{pmatrix} &= \begin{pmatrix} w\mathbf{E} & 0 \\ 0 & \mathbf{I}_g \end{pmatrix} \begin{pmatrix} \dot{\mathbf{v}}_g \\ \dot{\boldsymbol{\omega}}_g \end{pmatrix} + \begin{pmatrix} 0 \\ \boldsymbol{\omega}_g \times \mathbf{I}_g \boldsymbol{\omega}_g \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{E} & 0 \\ \tilde{\mathbf{r}}_{gh} & \mathbf{E} \end{pmatrix} \begin{pmatrix} \mathbf{f}_h \\ \mathbf{n}_h \end{pmatrix}, \end{aligned} \quad (45.32)$$

where \mathbf{E} is a 3×3 identity matrix, w is a total mass, \mathbf{I} is an inertia matrix, and the symbols with the suffix ‘g’ indicate the corresponding values observed around the mass centroid of the $(n+1)$ -link system.

In the above equations, (45.8) describes an internal joint motion (termed *local motion*) of the system, whereas (45.32) describes the overall motion (termed *global motion*) about the centroid of the system. As a result of force input \mathbf{F}_h , the floating chain induces both the local motion around its articulated joints and the global translation and rotation with respect to the centroid.

From (45.8) and (45.32), the acceleration of the manipulator end tip $\boldsymbol{\alpha}_h$ can be expressed in the inertial frame as

$$\boldsymbol{\alpha}_h = \mathbf{G}^* \mathbf{F}_h + \mathbf{d}^*, \quad (45.33)$$

where

$$\mathbf{G}^* = \hat{\mathbf{J}} \hat{\mathbf{H}}^{-1} \hat{\mathbf{J}}^\top + \mathbf{R}_h \mathbf{M}^{-1} \mathbf{R}_h^\top, \quad (45.34)$$

$$\mathbf{R}_h = \begin{pmatrix} \mathbf{E} & -\tilde{\mathbf{r}}_{gh} \\ 0 & \mathbf{E} \end{pmatrix}, \quad \mathbf{M} = \begin{pmatrix} w\mathbf{E} & 0 \\ 0 & \mathbf{I}_g \end{pmatrix}, \quad (45.35)$$

and \mathbf{d}^* is a velocity-dependent term.

Equations (45.33)–(45.35) are expressions for the motion of the hand (the point at which collision occurs) induced by the impact force \mathbf{F}_h , where the matrix \mathbf{G}^* , which is the augmented version of (45.10), represents the dynamic characteristics of this system.

Further augmentation for the inverted inertia matrix has been discussed for the case in which the contact duration is not considered to be infinitesimal [45.46].

Now let us assume the case in which two free-floating chains, A and B, with dynamic characteristics \mathbf{G}_A^* and \mathbf{G}_B^* collide with each other at their respective hands (end points) and an impact force \mathbf{F}_h is induced by this collision.

The equations of motion at the instance of collision are

$$\mathbf{G}_A^* \mathbf{F}_h = \begin{pmatrix} \dot{\mathbf{v}}_{hA} \\ \dot{\boldsymbol{\omega}}_{hA} \end{pmatrix} - \mathbf{d}_A^* \quad (45.36)$$

for chain A and

$$\mathbf{G}_B^* (-\mathbf{F}_h) = \begin{pmatrix} \dot{\mathbf{v}}_{hB} \\ \dot{\boldsymbol{\omega}}_{hB} \end{pmatrix} - \mathbf{d}_B^* \quad (45.37)$$

for chain B, where the subscripts A and B indicate the label of the chain.

Assuming that \mathbf{G}_A^* and \mathbf{G}_B^* remain constant during the infinitesimal contact duration and that the velocity-dependent terms \mathbf{d}_A^* and \mathbf{d}_B^* are small and negligible, integration of (45.36) and (45.37) yields

$$\mathbf{G}_A^* \int_t^{t+\delta t} \mathbf{F}_h dt = \begin{pmatrix} \mathbf{v}'_{hA} \\ \boldsymbol{\omega}'_{hA} \end{pmatrix} - \begin{pmatrix} \mathbf{v}_{hA} \\ \boldsymbol{\omega}_{hA} \end{pmatrix}, \quad (45.38)$$

$$\mathbf{G}_B^* \int_t^{t+\delta t} \mathbf{F}_h dt = \begin{pmatrix} \mathbf{v}'_{hB} \\ \boldsymbol{\omega}'_{hB} \end{pmatrix} - \begin{pmatrix} \mathbf{v}_{hB} \\ \boldsymbol{\omega}_{hB} \end{pmatrix}, \quad (45.39)$$

where {'} indicates the velocity after the collision. Integration of \mathbf{F}_h

$$\bar{\mathbf{F}}_h = \lim_{\delta t \rightarrow 0} \int_t^{t+\delta t} \mathbf{F}_h dt \quad (45.40)$$

represents the impulse (force-time product) acting on both chains. Providing that the total momenta of the two systems are strictly conserved before and after the collision, we obtain the following expression from (45.38) and (45.39).

$$\begin{aligned} (\mathbf{G}_A^* + \mathbf{G}_B^*) \bar{\mathbf{F}}_h &= \left[\begin{pmatrix} \mathbf{v}'_{hA} \\ \boldsymbol{\omega}'_{hA} \end{pmatrix} - \begin{pmatrix} \mathbf{v}'_{hB} \\ \boldsymbol{\omega}'_{hB} \end{pmatrix} \right] \\ &\quad + \left[\begin{pmatrix} \mathbf{v}_{hB} \\ \boldsymbol{\omega}_{hB} \end{pmatrix} - \begin{pmatrix} \mathbf{v}_{hA} \\ \boldsymbol{\omega}_{hA} \end{pmatrix} \right]. \end{aligned} \quad (45.41)$$

In general collision analysis, the coefficient of restitution (elasticity factor) associated with the relative

velocities before and after the collision is often employed [45.65]. If we accept this restitution coefficient for six-DOF linear and angular velocities, the relationship between relative velocities before and after contact becomes

$$\begin{pmatrix} v'_{hA} \\ \omega_{hA} \end{pmatrix} - \begin{pmatrix} v'_{hB} \\ \omega_{hB} \end{pmatrix} = \epsilon \left[\begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} - \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix} \right], \quad (45.42)$$

where

$$\epsilon \equiv \text{diag}(e_1, \dots, e_6) \quad 0 \leq e_i \leq 1 \quad (45.43)$$

is the restitution coefficient matrix.

Substituting (45.42) into (45.41), the impulse induced by this collision can be expressed only by the relative velocity of two points before the contact

$$\bar{F}_h = (E_6 + \epsilon) G_\Sigma^{*-1} v_{hAB}, \quad (45.44)$$

where

$$G_\Sigma^* = G_A^* + G_B^* \quad (45.45)$$

$$v_{hAB} = \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} - \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix}. \quad (45.46)$$

Using the above notation, the magnitude of impulse is expressed as

$$\|\bar{F}_h\| = \sqrt{(E_6 + \epsilon)^\top \mathcal{V}_{hAB}^\top G_\Sigma^{*-T} G_\Sigma^{*-1} \mathcal{V}_{hAB} (E_6 + \epsilon)} \quad (45.47)$$

and the velocity after collision becomes

$$\begin{pmatrix} v'_{hA} \\ \omega_{hA} \end{pmatrix} = (G_A^{*-1} + G_B^{*-1})^{-1} \left[(E_6 + \epsilon) G_B^{*-1} \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} + (G_A^{*-1} - \epsilon G_B^{*-1}) \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix} \right], \quad (45.48)$$

where the suffixes A and B are interchangeable.

These expressions are considered to be an augmentation of the impact theory for a two-point-mass system into articulated body systems.

Impedance control is a concept by which to control the manipulator end tip so as to obtain the desired mechanical impedance characteristics. Such control is useful to alter the dynamic characteristics of the arm during the contact phase. In a special case, the desired impedance of the manipulator end tip (hand) may be tuned to achieve *impedance matching* with the colliding target object so that the hand can easily maintain stable contact with the target [45.66].

Let M_d , D_d , and K_d be matrices for the desired impedance properties of inertia, viscosity, and stiffness, respectively, measured at the manipulator end point. The equation of motion for the desired system is then expressed as

$$M_d \ddot{x}_h + D_d \Delta \dot{x}_h + K_d \Delta x_h = F_h. \quad (45.49)$$

From (45.8) and (45.49), the impedance control law for a free-floating manipulator system is obtained as follows [45.67]:

$$\begin{aligned} \tau_h = H^* \hat{J}^{-1} & [M_d^{-1} (D_d \Delta \dot{x}_h + K_d \Delta x_h - F_h) \\ & - \hat{J} \dot{\phi} - \ddot{x}_{gh}] - \hat{J}^\top F_h + c^*. \end{aligned} \quad (45.50)$$

The usefulness of the impedance control in free-flying space robots has been discussed in [45.67–69].

45.3.11 Dynamics of Mobile Robots

The equation of motion for a mobile robot that has multiple articulated limbs, such as that shown in Fig. 45.25, is given by the following equation

$$\begin{pmatrix} H_b & H_{bm1} & \cdots & H_{bmk} \\ H_{bm1}^\top & H_{m11} & \cdots & H_{m1k} \\ \vdots & \vdots & \ddots & \vdots \\ H_{bmk}^\top & H_{m1k}^\top & \cdots & H_{mkk} \end{pmatrix} \begin{pmatrix} \ddot{x}_b \\ \ddot{\phi}_1 \\ \vdots \\ \ddot{\phi}_k \end{pmatrix} + \begin{pmatrix} c_b \\ c_{m1} \\ \vdots \\ c_{mk} \end{pmatrix} = \begin{pmatrix} F_b \\ \tau_1 \\ \vdots \\ \tau_n \end{pmatrix} + \begin{pmatrix} J_b^\top F_{ex} \\ J_{m1}^\top F_{ex1} \\ \vdots \\ J_{mk}^\top F_{exk} \end{pmatrix}, \quad (45.51)$$

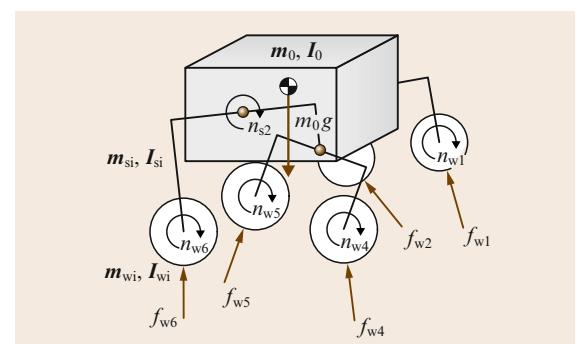

Fig. 45.25 Schematic model of a mobile robot

where the symbols have the following meanings

k :
 $\mathbf{x}_b \in \mathbb{R}^6$:

$\boldsymbol{\phi} = (\boldsymbol{\phi}_1^\top, \dots, \boldsymbol{\phi}_k^\top)^\top \in \mathbb{R}^n$:

$\mathbf{x}_{\text{ex}} = (\mathbf{x}_{\text{ex}1}^\top, \dots, \mathbf{x}_{\text{ex}k}^\top)^\top \in \mathbb{R}^{6k}$:

$\mathbf{F}_b \in \mathbb{R}^6$:

$\boldsymbol{\tau} = (\boldsymbol{\tau}_1^\top, \dots, \boldsymbol{\tau}_k^\top)^\top \in \mathbb{R}^n$:

$\mathbf{F}_{\text{ex}} = (\mathbf{F}_{\text{ex}1}^\top, \dots, \mathbf{F}_{\text{ex}k}^\top)^\top \in \mathbb{R}^{6k}$:

number of limbs
position/orientation of the base

articulated joint angles

position/orientation of the end points

forces/moment directly apply on the base

joint articulated torque
external forces/moment on the end points

Note that for Fig. 45.25, $\mathbf{F}_{\text{exi}} = (\mathbf{f}_{\text{wi}}^\top, \mathbf{n}_{\text{wi}}^\top)^\top$.

Comparing the above equations with (45.1), no difference is observed in the mathematical structure. The gravity force on the vehicle main body and the configuration-dependent gravity terms of the articulated bodies are included in \mathbf{c}_b and \mathbf{c}_{mi} , respectively. In practice, however, one substantial difference is the existence of ground contact forces/moment at the end point of each limb. Unlike floating target capture discussed in Sect. 45.3.10, the contact is not considered impulsive, but instead continues for a nonnegligible period of time. In such cases, a well-accepted approach is to evaluate the contact forces/moment \mathbf{F}_{ex} explicitly, according to the virtual penetration of the end point into the collided object or the ground surface [45.65].

In cases in which each limb has a wheel on its end terminal, rather than the point penetration model, a wheel traction model shall be adopted to evaluate \mathbf{F}_{ex} . For planetary exploration missions, rovers (mobile robots) are expected to travel over natural rough terrain. A number of studies have examined the modeling of tire traction forces on loose soil, called *regolith* (where there is no organic component) [45.70–78].

In the following subsection, models for wheel traction mechanics are summarized.

45.3.12 Wheel Traction Mechanics

Terramechanics is the study of soil properties, specifically the interaction of wheeled, legged, or tracked vehicles and various surfaces. For the modeling of the wheel traction forces and the analysis of the vehicle mobility, textbooks written by Bekker [45.25, 26] and Wong [45.79] are good references. Although these books

were written in the 1960s and 1970s, basic formulae from these books are frequently cited by researchers even today [45.80]. In this subsection, the models for a rigid wheel on loose soil are summarized.

Slip Ratio and Slip Angle

Slips are generally observed when a rover travels on loose soil. In particular, slips in the lateral direction are observed during steering or slope-traversing maneuvers.

The slip in the longitudinal direction is measured by the slip ratio s , which is defined as a function of the longitudinal traveling velocity v_x of the wheel and the circumference velocity of the wheel $r\omega$ (r is the wheel radius and ω is the angular velocity of the wheel):

$$s = \begin{cases} (r\omega - v_x)/r\omega, & \text{if } |r\omega| > |v_x| : \text{driving}, \\ (r\omega - v_x)/v_x, & \text{if } |r\omega| < |v_x| : \text{braking}. \end{cases} \quad (45.52)$$

The slip ratio takes a value of from -1 to 1 .

On the other hand, the slip in the lateral direction is measured by the slip angle β , which is defined in terms of v_x and the lateral traveling velocity v_y as

$$\beta = \tan^{-1}(v_y/v_x). \quad (45.53)$$

Note that the above definitions, Eqs. (45.52) and (45.53), have traditionally been used in the vehicle community as standards. However, planetary rovers in a challenging terrain, such as Spirit and Opportunity on Mars, experienced the cases in which the rovers slip backward while attempting to drive up hill or travel faster than the wheel's circumference velocity in downhill driving. In these cases the slip ratio can exceed the range from -1 to 1 . Also while traversing side slopes, the case may arise in which $v_y > 0$ but v_x is nearly 0, making the definition (45.53) nearly singular. Therefore,

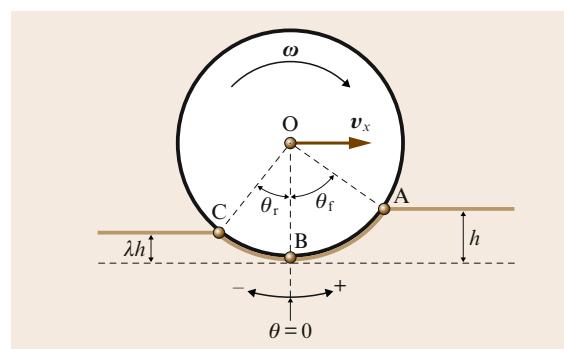

Fig. 45.26 Wheel contact angles

these definitions need to be further discussed for rovers in very loose terrain.

Wheel–Soil Contact Angle

Figure 45.26 depicts a schematic model of a rigid wheel contacting loose soil. In the figure, the angle from the surface normal to the point at which the wheel initially makes contact with the soil ($\angle AOB$) is defined as the entry angle. The angle from the surface normal to the point at which the wheel departs from the soil ($\angle BOC$ in Fig. 45.26) is the exit angle. The wheel contact region on loose soil is represented from the entry angle to the exit angle.

The entry angle θ_f is geometrically described in terms of wheel sinkage h as

$$\theta_f = \cos^{-1}(1 - h/r). \quad (45.54)$$

The exit angle θ_r is described using the wheel sinkage ratio λ , which denotes the ratio between the forward and rear sinkage of the wheel

$$\theta_r = \cos^{-1}(1 - \lambda h/r). \quad (45.55)$$

The value of λ depends on the soil characteristics, the wheel surface pattern and the slip ratio. It becomes

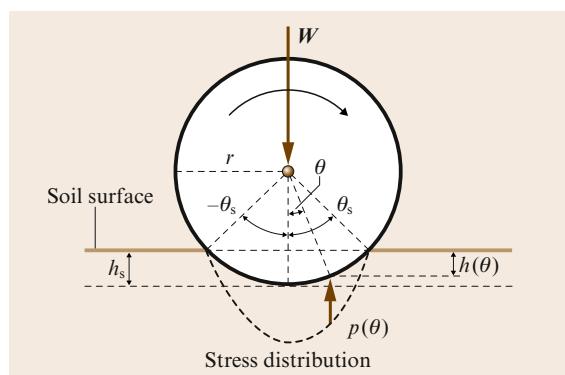

Fig. 45.27 Static sinkage

smaller than 1.0 when the soil compaction occurs, but can be greater than 1.0 when the soil is dug up by the wheel and transported to the rear region of the wheel.

Wheel Sinkage

The amount of wheel sinkage is constituted by static and dynamic components. The static sinkage depends on the vertical load on the wheel, while the dynamic sinkage is caused by the rotation of the wheel.

According to the equation formulated by *Bekker* [45.25], the static stress $p(h)$ generated under a flat plate, which has a sinkage h and a width b , is calculated as

$$p(h) = (k_c/b + k_\phi)h^n, \quad (45.56)$$

where k_c and k_ϕ are pressure-sinkage modules and n is the sinkage exponent. Applying (45.56) to the wheel, as shown in Fig. 45.27, the static sinkage is evaluated as follows.

First, the wheel sinkage $h(\theta)$ at an arbitrary wheel angle θ is geometrically given by

$$h(\theta) = r(\cos \theta - \cos \theta_s), \quad (45.57)$$

where θ_s is the static contact angle. Then, substituting (45.57) into (45.56) yields

$$p(\theta) = r^n(k_c/b + k_\phi)(\cos \theta - \cos \theta_s)^n. \quad (45.58)$$

The wheel eventually sinks into the soil until the stress from the soil balances the vertical load W on the wheel.

$$\begin{aligned} W &= \int_{-\theta_s}^{\theta_s} p(\theta)br \cos \theta d\theta \\ &= r^{n+1}(k_c + k_\phi b) \int_{-\theta_s}^{\theta_s} (\cos \theta - \cos \theta_s)^n \cos \theta d\theta. \end{aligned} \quad (45.59)$$

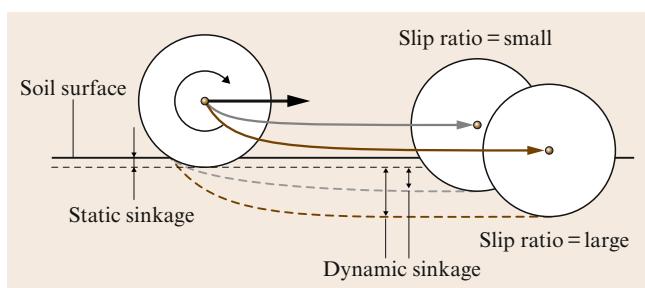

Using this equation, the static contact angle θ_s is evaluated for the given W . In practice, (45.59) does not yield a closed-form solution for θ_s , although θ_s can be evaluated numerically.

Finally, the static sinkage h_s is obtained by substituting θ_s into the following equation

$$h_s = r(1 - \cos \theta_s). \quad (45.60)$$

However, as illustrated in Fig. 45.28, the dynamic sinkage becomes a complicated function depending on the slip ratio of the wheel, the wheel surface pattern, and the soil characteristics. Although it is difficult to obtain an analytical form for the dynamic sinkage, it is again

Fig. 45.28 Dynamic sinkage

possible to evaluate the dynamic sinkage numerically, using the condition $W = F_z$, where F_z is the normal force given by (45.71), which will be presented later herein. The force F_z increases with the wheel sinkage because the area of the contact patch increases accordingly.

Stress Distribution under the Wheel

Based on terramechanics models, the stress distribution under the rotating wheel can be modeled as shown in Fig. 45.29.

The normal stress $\sigma(\theta)$ is determined by the following equation [45.80, 81]:

$$\begin{aligned}\sigma(\theta) &= r^n \left(\frac{k_c}{b} + k_\phi \right) [\cos \theta - \cos \theta_f]^n && \text{for } \theta_m \leq \theta < \theta_f \\ \sigma(\theta) &= r^n \left(\frac{k_c}{b} + k_\phi \right) \left\{ \cos \left[\theta_f - \frac{\theta - \theta_r}{\theta_m - \theta_r} (\theta_f - \theta_m) \right] \right. \\ &\quad \left. - \cos \theta_f \right\}^n && \text{for } \theta_r < \theta \leq \theta_m\end{aligned}\quad (45.61)$$

Note that the above equations are based on Bekker's formula, as given in (45.56) and they become equivalent to the Wong–Reece model for normal stress [45.82] when $n = 1$. Note also that, by linearizing this distribution, Iagnemma et al. [45.70, 80] developed a Kalman-filter-based method to estimate the soil parameters.

The term θ_m is the specific wheel angle at which the normal stress is maximized

$$\theta_m = (a_0 + a_1 s) \theta_f, \quad (45.62)$$

where a_0 and a_1 are parameters that depend on the wheel–soil interaction. Their values are generally assumed to be $a_0 \approx 0.4$ and $0 \leq a_1 \leq 0.3$ [45.82].

The maximum terrain shear force is a function of the terrain cohesion c and internal friction angle ϕ and can be computed from Coulomb's equation

$$\tau_{\max}(\theta) = c + \sigma_{\max}(\theta) \tan \phi. \quad (45.63)$$

Based on the above equation, the shear stresses under the rotating wheel, $\tau_x(\theta)$ and $\tau_y(\theta)$, are written as [45.83]

$$\tau_x(\theta) = (c + \sigma(\theta) \tan \phi) (1 - e^{-jx(\theta)/k_x}), \quad (45.64)$$

$$\tau_y(\theta) = (c + \sigma(\theta) \tan \phi) (1 - e^{-jy(\theta)/k_y}), \quad (45.65)$$

where k_x and k_y are the shear deformation moduli in each direction. In addition, jx and jy , which are the

soil deformations in each direction, can be formulated as a function of the wheel angle θ with the slip ratio and the slip angle, respectively [45.73, 82]

$$jx(\theta) = r[\theta_f - \theta - (1 - s)(\sin \theta_f - \sin \theta)], \quad (45.66)$$

$$jy(\theta) = r(1 - s)(\theta_f - \theta) \tan \beta. \quad (45.67)$$

Drawbar Pull: F_x

Using the normal stress $\sigma(\theta)$ and the shear stress in the x direction $\tau_x(\theta)$, the drawbar pull F_x , which is the net traction force exerted from the soil to the wheel, is calculated as the integral from the entry angle θ_f to the exit angle θ_r [45.82]

$$F_x = rb \int_{\theta_f}^{\theta_r} \{\tau_x(\theta) \cos \theta - \sigma(\theta) \sin \theta\} d\theta. \quad (45.68)$$

Side Force: F_y

The side force F_y appears in the lateral direction of the wheel when the vehicle makes steering maneuvers or traverses a side slope. The side force is decomposed into two components [45.63]

$$F_y = F_u + F_s,$$

where F_u is the force produced by the shear stress in the y direction $\tau_y(\theta)$ underneath the wheel and F_s is the reaction force generated by the bulldozing phenomenon on a side face of the wheel. The above equation can be

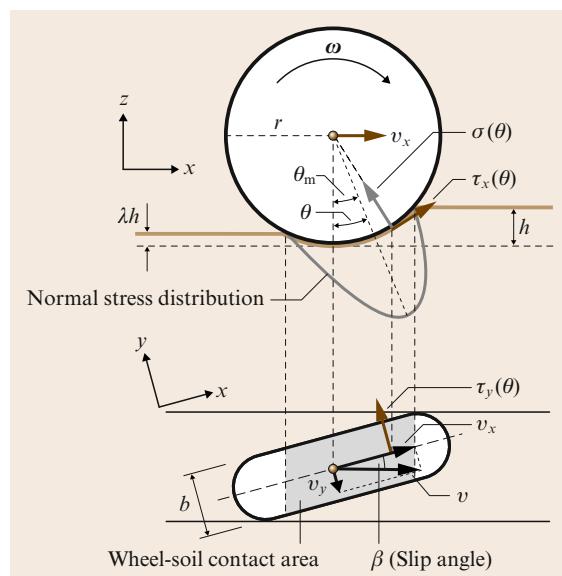

Fig. 45.29 Stress distribution model under a wheel

rewritten as

$$F_y = \int_{\theta_r}^{\theta_f} \left\{ \underbrace{rb\tau_y(\theta)}_{F_u} + \underbrace{R_b[r - h(\theta) \cos \theta]}_{F_s} \right\} d\theta . \quad (45.69)$$

Here, Hegedus's bulldozing resistance estimation [45.84] is employed to evaluate the side face force F_s . As shown in Fig. 45.30, a bulldozing resistance R_b is generated on a unit width blade when the blade moves towards the soil. According to Hegedus's theory, the bulldozed area is defined by a destructive phase that is modeled by a planar surface. In the case of a horizontally placed wheel, the angle of approach α' should be zero. R_b can then be calculated as a function of wheel sinkage $h(\theta)$:

$$R_b(h) = D_1 \left[ch(\theta) + D_2 \frac{\rho_d h^2(\theta)}{2} \right], \quad (45.70)$$

where

$$\begin{aligned} D_1(X_c, \phi) &= \cot X_c + \tan(X_c + \phi), \\ D_2(X_c, \phi) &= \cot X_c + \cot^2 X_c / \cot \phi . \end{aligned}$$

In the above equations, ρ_d denotes the soil density. Based on Bekker's theory [45.25], the destructive angle X_c can be approximated as

$$X_c = 45^\circ - \phi/2 .$$

Normal Force: F_z

The normal force F_z is obtained in the same manner as for (45.68) [45.82]:

$$F_z = rb \int_{\theta_r}^{\theta_f} [\tau_x(\theta) \sin \theta + \sigma(\theta) \cos \theta] d\theta , \quad (45.71)$$

which should balance the normal load of the wheel in a static condition.

Motion dynamics simulation for a vehicle traveling over loose soil can be performed by substituting the forces F_x , F_y , and F_z obtained from the above equations into the equation of motion of (45.51).

A better understanding of the soil-wheel contact and traction mechanics is important in order to

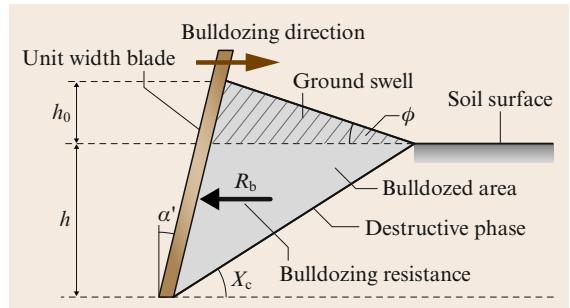

Fig. 45.30 Estimation model of the bulldozing resistance

improve the navigation and control behavior of exploration rovers, in terms of minimization of wheel slippage, for example. Reducing the wheel slippage will increase the power efficiency of surface locomotion, decrease the errors in path tracking maneuvers and decrease the risks of wheel spinning and sinking, which can cause immobilization of the vehicle.

One key to realizing such advanced control of slippage minimization is determining how to properly estimate the slip ratios and slip angles in real time using onboard sensors. The slip ratio is determined by the ratio between the wheel spinning velocity and the traveling velocity of the vehicle, but proper sensing of the velocity of the vehicle is usually difficult. One simple solution is to use a free wheel specialized for traveling velocity measurement. Another solution is to employ inertial sensors, which are however usually subject to noise and drift.

An alternative, but promising, possibility is visual odometry, which is based on optical flow or feature tracking in the sequence of optical images. Actually, this technique has been applied to the Mars exploration rovers, Spirit and Opportunity, in their long-range navigation, and there verified to be very useful. Particularly, the algorithm based on feature detection and tracking using a stereo pair of cameras provides reliable results with good accuracy for the estimation of driving distance as well as the wheel slippage [45.24].

45.4 Future Directions of Orbital and Surface Robotic Systems

45.4.1 Robotic Maintenance and Service Missions

Robotic maintenance and service missions for space infrastructure have been a long-term dream in the

space robotics community since their conceptual designs were first published in ARAMIS report in early 1980s (Fig. 45.1) [45.1].

ROTEX, ETS-VII, Ranger, and ASTRO, which were introduced in earlier sections, are technological devel-

Fig. 45.31 A conceptual drawing for robotic rescue of Hubble space telescope

opments toward this goal, but robotic maintenance and service missions have not become routinely operational yet. A good comparative study of orbital robotic missions is provided by [45.85]. The *Hubble space telescope (HST)* is a huge space telescope which has the capability to be serviced in orbit, but it has been visited by Space Shuttle and serviced (components exchanged and problems fixed) only by human **EVA**. After the COLUMBIA accident in 2003, NASA seriously considered the possibility of robotic maintenance of the **HST**, investigating available technologies and selecting a prime contractor of the mission development. Figure 45.31 depicts one possible configuration for the robotic rescue mission. Ultimately, it was decided to perform this last servicing mission with human astronauts. Maintenance of the **HST** involves tasks that are currently too complicated to be done by a robot, because the **HST** itself was designed for human-based maintenance and not specifically designed for robots.

Robonaut, which is described in the following subsection, is therefore considered as an interesting option for conducting practical maintenance and service missions due to its compatibility and similar level of dexterity as human astronauts.

45.4.2 Robonaut

Robonaut (Fig. 45.32a) is a humanoid robot designed by the Robot Systems Technology Branch at the **NASA** Johnson Space Center in a collaborative effort with **DARPA**. The Robonaut project seeks to develop and demonstrate a robotic system that can function as an **EVA** astronaut equivalent. Robonaut jumps generations ahead by eliminating the robotic scars (e.g., special

robotic grapples and targets), but it still keeps the human operator in the control loop through its telepresence control system. Robonaut is designed to be used for **EVA** tasks not specifically designed for robots [45.86].

A key challenge is to build machines that can help humans work and explore in space. Working side by side with humans or going where the risks are too great for people, machines like Robonaut will expand capabilities for construction and discovery. Over the past five decades, space flight hardware has been designed for human servicing. Space walks are planned for most of the assembly missions for the International Space Station and they are a key contingency for resolving on-orbit failures. To maintain compatibility with existing **EVA** tools and equipments, a humanoid shape and an assumed level of human performance (at least a human in a space suit) are required for this robotic surrogate.

The manipulator and dexterous hand have been developed with a substantial investment in mechatronics design. The arm structure has embedded avionics elements within each link, reducing cabling and noise interference. Robonaut has been designed based on a biologically inspired approach. For example, it uses a chordate neurological system in data management, bringing all feedback to a central nervous system, where even low-level servo control is performed. Such a biologically inspired approach is extended to left-right computational symmetry, sensor and power duality and kinematical redundancy, enabling learning and optimization in mechanical, and electrical and software forms.

Robonaut has a broad mix of sensors including thermal, position, tactile, force, and torque instrumentation, with over 150 sensors per arm. The control system for Robonaut includes an onboard, real-time central processing unit (CPU) with miniature data acquisition and power management. Off-board guidance is delivered with human supervision using a telepresence control station with human tracking.

One potential application of Robonaut is a regular monitoring and contingent maintenance work of human habitant modules of the space station. Fig. 45.32b, depicts such an application where Robonaut crawls on the surface of the station module by using hand rails which were originally designed for human **EVA**.

The application of Robonaut technology is not limited to orbital tasks. Figure 45.32c,d depicts conceptual designs at **NASA** and **DLR**, respectively, to combine the humanoid torso on a surface mobility system, which will be useful for robotic planetary explorations.

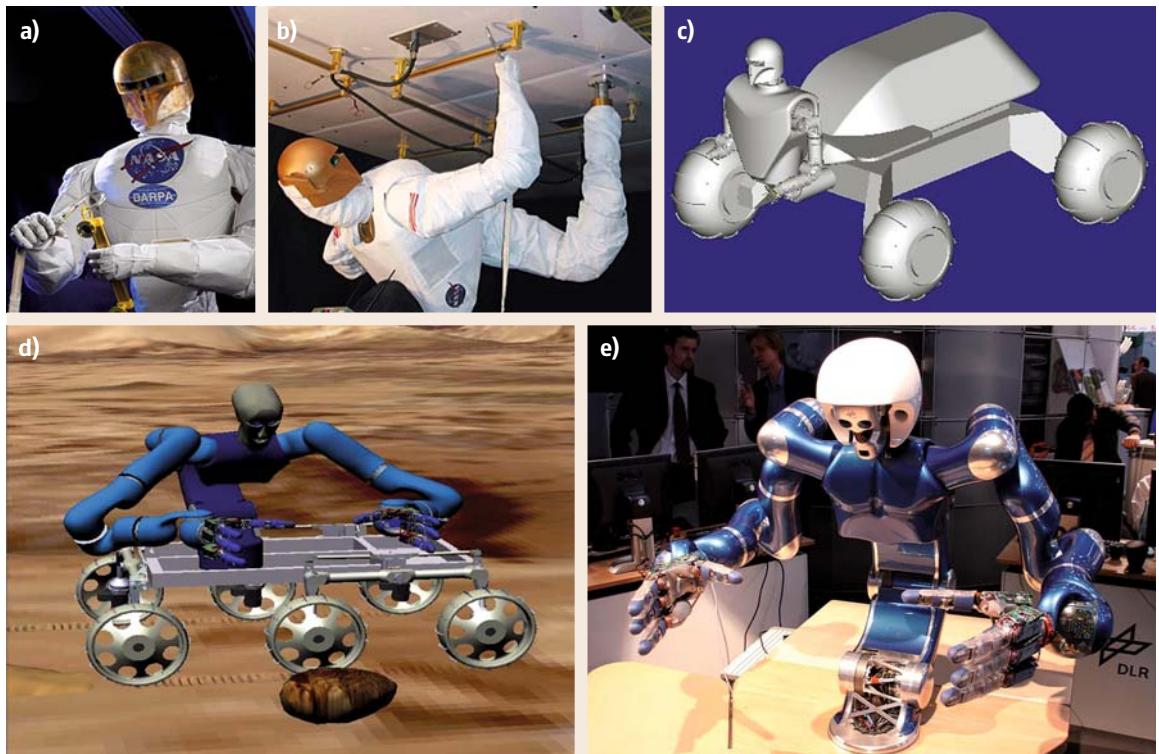

Fig. 45.32a–e Robonaut: (a,b) current model and future concepts by NASA (c), future concepts by DLR (d) which are based on the torso JUSTIN (e)

45.4.3 Aerial Platforms

There are three nonterrestrial planetary candidates for aerial robotic systems: Venus, Mars, and Titan (a moon of Saturn) [45.87, 88]. Venus has a very dense but hot atmosphere (460°C and 65 kg/m^3 at the surface) and so can easily float relatively heavy payloads. Mars has a very thin and cold atmosphere (somewhat variable but often -100°C and 0.02 kg/m^3). Titan has an atmosphere even colder than that of Mars ($\approx 100\text{ K}$) but about 50% denser than Earth's atmosphere. Thus very different vehicles have been envisioned for the three candidate mission targets. On Venus, buoyant devices are generally considered, especially those that can continuously or periodically rise high enough to reach moderate temperatures where conventional electronics can survive. One candidate is to use a phase-change fluid as part of the buoyant system, so that the fluid can condense in the cool upper atmosphere and be trapped in a pressure vessel, causing a loss of buoyancy and allowing the vehicle to descend, possibly all the way to the surface. After a brief stay and before the heat flux to the interior of

the device destroys all the sensitive equipment, a valve would be opened so that the phase-change fluid can evaporate, increasing the buoyancy and allowing the craft to ascend to the cool upper atmosphere. After a suitable period of heat rejection into this cool zone, the process can be repeated, perhaps indefinitely. The density of the Venus atmosphere is sufficiently high that powered dirigibles can be used, so that the buoyant vehicles can use propulsion and steering to reach particular locations in the atmosphere or on the surface [45.89].

In contrast, the Mars atmosphere is too thin for powered dirigibles to work (at least with the power-to-weight ratio of any current propulsion technology). Balloon aerobots could be deployed in the Mars atmosphere and could ascend and descend, but probably could not be steered precisely to specific locations, at least not by use of a propulsion system. Polar balloons could circumnavigate either pole many times or equatorial balloons could make one partial circuit around the planet, until they impact the *Tharsis Bulge*, a North-South string of high-altitude volcanoes that represents an essentially impenetrable barrier to any equatorial bal-

loon with a reasonable payload. Because of the problems with *lighter-than-air* vehicles in the thin Martian atmosphere, there has been considerable study of airplanes for use in exploring Mars. Aircraft can be designed to have reasonable lift-to-drag ratios in the Mars atmosphere, so that their performance is not too different from airplanes on Earth. Most often considered are gliders that deploy directly from an aeroshell that comes into the Mars atmosphere at hypersonic velocity and then proceed to glide hundreds or a thousand kilometers before impact. One common mission concept is to fly down the great Valles Marineris canyon, taking high-resolution imagery and spectrometry of the walls of that canyon. Powered aircraft have also been considered, including those that land and regenerate their propellant (e.g., using solar power and atmospheric CO₂) so as to be able to make multiple flights.

On Titan, like Venus, buoyant devices are generally considered most attractive (although helicopters have been proposed). Also like Venus, the atmosphere on Titan contains many obscuring particles and aerosols so that high-resolution imaging over a broad spectrum is only possible by getting close to the surface. This makes balloons or powered dirigibles very attractive. On Venus the extreme surface temperature makes it challenging to make a surface vehicle operate for an extended duration. On Titan, there is a significant risk that some sort of hydrocarbon *goo* exists on the surface that might foul any surface vehicle. Thus both Titan and Venus are considered especially attractive targets for the use of aerobots, especially in the form of powered dirigibles. Navigation of such aerobots would presumably be accomplished primarily by sensing the terrain and navigating relative to any landmarks that can be discerned. When these vehicles operate in the upper atmosphere, they can augment their position knowledge by means of sun or star tracking (as referenced to the local vertical). Deeper in the atmosphere, this may not be possible. One key issue is whether direct communications to Earth are envisioned or relay via satellite. If there is a satellite in orbit, it can provide considerable radio-navigation assistance and relatively frequent communications when the aerobot is on the side away from the Earth (both Venus and Titan spin very slowly). However, a satellite relay is expensive, so the least expensive options require that the dirigible have a large high-gain antenna (usually presumed to be inside the gas bag). Radio-based servo pointing at the Earth will provide precise navigation information (again along with precise measurements of local vertical). However, when the aerobot goes out of sight beyond the limb of the planet, it may spend days

or weeks out of communications with the Earth. This is probably the situation calling for the highest degree of autonomy of any that have been envisioned in robotic planetary exploration of the solar system.

45.4.4 Subsurface Platforms

Subsurface exploration of planetary bodies holds great promise: it is believed that a liquid-water aquifer may exist at significant depths on Mars, Europa, or Ganymede which probably represent the best possible locations within the solar system to look for extant (as opposed to extinct) extraterrestrial life. Also, in the lunar polar *dark craters* there is some evidence of the existence of water ice or other volatiles and there may exist a layered geologic record of impacts in the Earth–Moon system in these cold traps. Even access to a depth of a few meters holds the promise of reaching pristine scientific samples that have not been exposed to thermal cycling or ionizing radiation [45.90].

The prevailing wisdom has been that traditional sorts of drilling rigs are required to access these places, involving drill towers, multisegmented drill strings, large robotic systems to serve the function of a terrestrial drilling crew, and large power systems. Also, terrestrial drilling is usually done using large amounts of fluids (water, air or mud) to flush away cuttings and to cool and lubricate the cutter. The NASA Mars Technology Program has funded contractors that have demonstrated reaching 10 m of depth in a realistic setting with segmented drill strings without the use of fluids. While this is much less than needed to reach the putative liquid-water aquifers, it is much more than is reachable by previous techniques [45.91].

Other approaches have been proposed such as *moles* or *inchworms* that could be relatively self-contained and yet reach great depths without the mass and complexity of a large drill tower and segmented drill string. A key issue is that it appears that the needed energy cannot be stored onboard such self-contained drills, at least if it is stored as chemical energy. This is because drilling through terrain requires that some of the chemical bonds that hold the terrain together be broken and so if the energy of chemical bonds is used to provide that power, then a given volume of chemical energy storage can only advance some fixed ratio of its length into the terrain, where the ratio is determined by the efficiency in taking bond energies of one sort to break bonds of a different sort. Based on these considerations, it appears unlikely that a completely self-contained subsurface vehicle could advance more

than perhaps a hundred times its own length. Unless nuclear power sources are considered (and they have been), this requires some sort of tether to the surface to provide a nearly unlimited source of energy. Another problem for subsurface vehicles is that rock tends to expand when it is pulverized (in a process called *communition*). Nonporous rock typically expands in volume by a few tens of percent when excavated, which means that fully self-contained subsurface vehicles have a severe *conservation of volume* problem. In principle the rock can be compressed back into its original volume, but this generally requires pressures much greater than the compressive strength of the original rock. The energy required to do this is much larger than the energy

required to excavate the rock in the first place and would become the dominant use of energy in an already energy-intensive effort.

As a result, it is generally assumed that any subsurface vehicle must keep some access tunnel open to the surface so that the excess volume of cuttings can be transported out. If this tunnel is available, then it seems that a means for getting power from the surface is also available, so that self-contained nuclear power is not needed. Subsurface vehicles with diameters as small as one or a few centimeters have been proposed that could potentially reach great depths within the mass and power constraints of feasible planetary robotic exploration missions.

45.5 Conclusions and Further Reading

Space robotics as a field is still in its infancy. The speed-of-light delays inherent to remote space operations makes the master-slave teleoperation approach that has been very useful in the undersea and nuclear industries problematic. Space robotics lacks the highly repetitive operations in a tightly structured environment that characterize industrial robotics. Hardware handled by space robots is very delicate and expensive. All three of these considerations have led to the fact that relatively few space robots have been flown, they have been very slow in operation, and only a small variety of tasks have been attempted. Nonetheless, the potential rewards of space robotics are great – exploring the solar system, creating vast space telescopes that may unlock the secrets of the universe, and enabling any viable space industries all seem to require major use of space robots. The scale of the solar system is not so great (a few

light-hours) that human intelligence cannot always supplement even the most remote space robot that becomes confused or stuck. Indeed, for the Moon (with only a few seconds of time delay) it seems that hazard avoidance and reliable closure of force–feedback loops is all that is required to make a highly useful robotic system. For Mars (with tens of minutes of time delay), along with hazard avoidance and force loop closure, it seems that robust anomaly detection (with modest reflexive *safing* procedures) and perhaps scientific-novelty detection are probably all that is needed. High levels of autonomy are enhancing but not enabling for work in the inner solar system and become more and more desirable for robots that are sent farther into the outer solar system.

For further reading, the following materials are suggested [45.92–97].

46. Robotics in Agriculture and Forestry

John Billingsley, Arto Visala, Mark Dunn

In agriculture and forestry, robotics has made a substantial impact. Farmers are conscious of their need for automatic vehicle guidance to minimize damage to the growing zone of their soil. Automatic sensing, handling, and processing of produce are now commonplace, while there is substantial instrumentation and mechanization of livestock procedures. In forestry, legged harvesters have not yet seen great success in their application, but the automation of trimming and forwarding with simultaneous localization and mapping techniques will change the industry in the future.

Some impressive developments in walking forestry harvesters are presented, including machines targeted towards the difficult terrain of the Scandinavian forests. More-conventional cut-to-length harvesters are also highly automated, while operations such as *delimbing* must be carried out at speed. Before complete autonomous harvesting becomes possible, some of the localization and mapping techniques that are described must come to fruition.

The combination of machine vision with global positioning by satellite (GPS) allows a tractor to follow a row of crops, performing a headland turn at the end of the row. The history of a series of projects is outlined, leading to the present outcome that is in the process of being commercialized. Another project that is based on machine vision relates to the location of macadamia nuts. To select which trees should be propagated, it is necessary to attribute fallen nuts to the correct tree. Color sorting and grading of produce is not a matter of sensing alone, but involves a measure of produce handling that puts it at the fringe of robotics.

Automated milking parlours have proved their worth. However success has eluded some other projects described here, such as automated sheep-shearing and an automated abattoir. Another project is presented that literally sorts the sheep

from the goats, using a swinging gate to separate different species using machine vision so that feral species are excluded from watering holes in the dry Australian outback.

Although robotics is making rapid inroads into these areas, they are still a fruitful source of application projects, some sufficiently demanding to require the development of new theoretical techniques.

46.1 Definitions

The boundaries of agriculture are not clear cut. Preparation of the soil, planting, cultivating, watering, spraying, and harvesting are evidently included, but how far into the post-harvest processes of trimming, sorting, and grading can we go before they merge with food preparation? Similarly, animal-based activities can extend beyond milking and shearing to slaughtering and butchering, at the start of a long chain of operations leading to the appearance of processed food or manufactured garments on the supermarket shelves.

Robotics made its first real appearance in the manufacturing industry with the adoption of the name *Robot* for the serial manipulator. Here manipulation and its related kinematics formed the core of the art, later developing into intelligent automation. When the essentials of robotics are applied to the much more significant industry of agriculture, however, the emphasis must be placed much more heavily on sensing than on manipulation. When a tractor is steered automatically or a gate is closed because a feral pig has been recognized, the answer to the question *Is this robotics?* is not cut and dried. Without including such applications, however, many of the advances in agricultural automation would be overlooked.

Forestry deals with the harvesting of wood. Forestry machines are today still mostly directly controlled by human drivers, with the help of distributed controller area network ([CAN](#))-based automation systems, but these machines will become more autonomous and robot-like in the future. The machines will have a perception system, which will map the trees and localize the machine. Information about the forest stand can thus be collected so that operation of the semiautomatic crane and loader becomes possible, together with steering and driving. Most of the forests in the Northern hemisphere are natural forests that are cared for. Particularly in Nordic countries, there is efficient and sustainable silviculture, the science, art, and practice of caring for forests for human exploitation. Stands of forest trees are thinned before clear cutting and replacement trees are either seeded

or planted. Autonomous machines for silviculture will be an important research area in the future.

46.1.1 Technological Developments

Perhaps the greatest impact on agriculture has been through the farmer's growing awareness of computer power. Mobile computing can log the yield during harvesting, relating it to a precision map of the property. Tasks that had been merely mechanized can now be synchronized and automated, such as the lifting of spray booms and implements when turning.

Global positioning by satellite ([GPS](#)) has been seized on for mapping and guidance operations.

Generic radio communication techniques use protocols that might be common to mobile telephone technology or networked systems such as [Zigbee](#) [46.1]. These systems allow remote monitoring of gates, livestock, or equipment and automatic replenishment of water troughs. They can equally contribute to fleet management and information transfer in a forestry situation. Other radio technology in the form of transponders can see each animal tagged and identified to support activities such as milking and tracking *from the paddock to the plate*.

Much farming machinery has long been hydraulically powered, but the addition of digitally controlled valves opens the way for automated steering and other robot operations.

With computing power comes the ability to analyze images from cameras, which are becoming ever cheaper. Vision sensing has pervaded sorting operations, but now it extends to vision guidance and the recognition of animals to permit or deny them access to watering points.

It is unlikely that large tractors will ever be allowed to roam unmanned because of the risk of legal repercussions, but the day when cooperating teams of small autonomous *farmhand robots* will be seen in the fields is drawing ever closer [46.2].

46.2 Forestry

46.2.1 Overview

Forestry has progressed from manual to machine harvesting, such that by the end of the 1990s some 95% of

the wood in Nordic countries was harvested with machines. Now the challenge of introducing robotics is being addressed. A typical harvester machine is shown in Fig. 46.1 and a forwarder, the machine that transports

Fig. 46.1 Cut-to-length (CTL) harvester made by Ponsse Oy Ltd. [46.3]

wood from the felling site to the roadside, is shown in Fig. 46.2.

Nowadays all new Nordic harvesters are controlled with a CAN-based distributed control system and information system, with GPS localization utilizing mobile communication networks to transfer data relating to harvesting. This forms a basic platform for adding more enhanced control functions. However, in a forest en-

Fig. 46.2 CTL forwarder by Ponsse Oy Ltd. [46.3]

vironment, GPS does not work well enough for the exact localization needed in machine control; simultaneous localization and mapping (SLAM) algorithms are needed.

A digital map of the forest stand and the target log assortments are downloaded to the harvester when the work begins. The diameter and volume of every log is measured when the log is *delimbed* and *bucked* (cross-cut) to the selected length. Information about the accumulated log situation is uploaded to a higher information system to manage the transportation of the wood from the side of the forest road to the mills. This logistics system incorporates trucks with digital maps and positioning systems, and is highly optimized in Nordic countries. The coordinates of every stack of different types of log are included in the information system and are delivered to the truck responsible for their collection.

46.2.2 Robot Locomotion in Forestry

Most current forestry machines use wheels as their locomotion mechanism. With active control, the machines can move in very difficult forest terrain if the slopes are not too steep. Much research and development has been performed in this area in order to stabilize and smooth locomotion with wheels over uneven terrain.

For locomotion in mountainous areas, new technological solutions such as walking are required. There are many areas in which mountainous terrain form a large

Fig. 46.3 Walking forest harvester prototype by Plustech Ltd., today part of John Deere

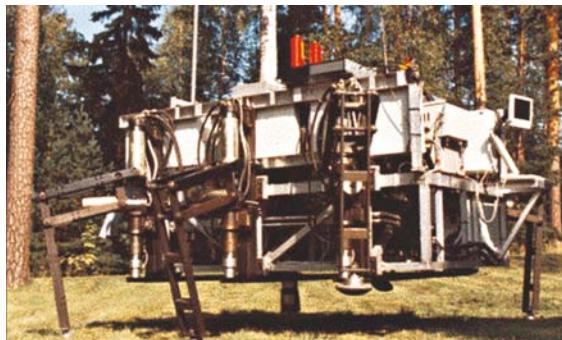

Fig. 46.4 MECANT walking machine by Halme et al. at TKK

proportion of the forest. Walking is perhaps the only safe form of locomotion on hillsides and mountainsides and has been an exciting research area in forestry robotic since the late 1980s.

In 1995, Plustech Oy published a prototype of a walking forest harvester, shown in Fig. 46.3. Plustech was owned by Timberjack Oy, which is today part of John Deere. Plustech Oy developed their walking machine independently, but most likely profited from the experience and results from a research project in which they had participated, MECANT 1989–1995. MECANT was developed at the TKK Automation Technology Laboratory led by Professor Aarne Halme [46.3]. MECANT, shown in Fig. 46.4, is a six-legged hydraulic remotely operated walking platform for studying locomotion in natural environments for work machines. Halme and Vainio at TKK published an article about forest robotics in 1998 [46.4], in which MECANT is also introduced. Newer research on locomotion at TKK has concentrated on combined walking with legs and wheels in each leg, rolling, developed in the Workpartner platform by Halme et al. [46.5].

In Japan, most of the forests are in the mountains and many research projects have been conducted on walking technology for forestry, for example at Tokyo University by Toshio Nitami and co-workers.

Operating walking harvesters on mountainsides could be risky for human operators sitting in the cabin of the machine. Such machines should be remotely controlled. Teleoperation is dealt with in more detail below.

46.2.3 Forestry Automation

Almost all cranes used in cut-to-length harvesters and grab loaders in the forwarders are today driven with

hydraulics. The control system of the crane or grab loader is based on CAN controllers with electrohydraulic valves. However, in spite of these technological possibilities, human drivers still control all movements. Some combined movements exist so that linear movements can be easily controlled, but commercial harvesters or forwarders do not have any automatic or even semiautomatic work cycles in their cranes and grab loaders.

Research to realize automatic or semiautomatic crane control has been underway since the 1980s. For example laser-pointer-assisted motion control of a forestry crane was implemented and tested in 1984 by Manninen and Halme [46.6]. The principles of interactive robotics, which could be used in connection with forestry cranes, were presented by Halme et al. [46.7]. The crane can easily be instrumented, since it resembles an industrial robot. Other enhancements can control swinging of the load.

During recent years, research has been performed to develop better control algorithms for motion control in the harvester head. The stem should be moved as fast as possible during delimiting, but no slip is allowed. The stem should be stopped at just the right place for cross cutting because the allowed tolerance in the length of the logs is only some centimeters. Koivo and Viljamaa et al. have developed well-behaved solutions for this problem [46.8].

46.2.4 Machine Perception and SLAM in the Forest Environment

In mobile robotics, simultaneous localization and mapping (SLAM) algorithms have been extensively studied. In forestry, the main task is to detect and parameterize the valuable trees among other plants and nonvaluable trees. This is a very difficult task due to illumination changes in general, bushes and young trees, and the branches of valuable trees. The perception must also work in winter-time, when there may be more than 1 m of snow that can cover the trees, and expensive forestry machines must be driven in almost complete darkness in the early morning and late evening.

With experience in using two-dimensional (2-D) laser scanners for measuring logs, work on modeling of the trees and forest on the basis of laser scanners has been performed since the 1990s. Figure 46.5 shows forest modeling results by Wernersson and Högström [46.9]. Similar work with a three-dimensional (3-D) scanner has also been undertaken at TKK by Halme and Forsman, as shown in Fig. 46.6 [46.10]. Modeling of the forest

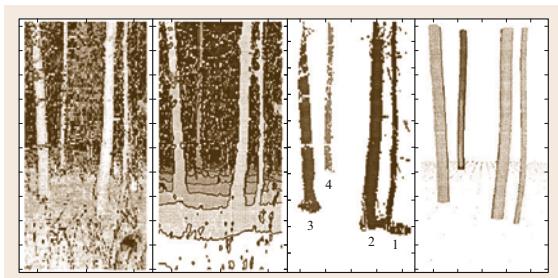

Fig. 46.5 Typical laser measurements of a typical outdoor forest scene, segmentation, and shape estimation by Wernersson [46.10]

on the basis of airborne 3-D laser scanners has been an important theme in remote sensing. However, because of the tops and branches of the trees, sufficient detail for forestry robotics cannot be measured from the air or space; this information must be supplemented with measurements in the forest terrain.

Autonomous **SLAM** capabilities are widely held to be one of the key features of outdoor mobile robots, including forestry robotics. Robot navigation has been an ongoing research topic for several years.

Navigation in outdoor environments is an open problem. The absence of simple features leads to the need for more-complex perception and modeling. 2-D laser range finders have become one of the most attractive sensors for localization and map building due to their accuracy and low cost. Most common laser scanners provide range and bearing information with sub-degree

resolution and accuracies on the order of 1–10 cm for 10–50 m ranges. Valuable work has been done, particularly in the University of Sydney by *Nebot* and *Bailey* et al. [46.11–14]. Web sources concerning forestry measurements by Australian National University are also useful [46.15].

The prospect of a fully autonomous forest harvester seems to lie far in the future. However, it is possible to advance step by step. A **SLAM**-based support system for the driver of the harvester seems to be reasonable and the benefits rewarding. In the ongoing Forestrix project by Visala et al. at Helsinki University of Technology TKK, forest and tree trunk measurement technologies, signal processing methods, and algorithms are studied in order to develop this kind of support system for the driver of a harvester. Semiautomatic control of forest harvesters for easy conditions is also being studied. In every forest stand, there are areas where only the human operator can control the machine. Advances in laser range finders and machine vision systems provide opportunities for new kinds of forest measurements.

46.2.5 Autonomy, Teleoperation, and Fleet Management

At Umeå University, a group led by Thomas *Helström* is developing autonomous driving of the *forwarder*. A human driver teaches the system by driving the route himself first [46.16]. This is a *real-world* study and results can be drawn from studies in the military sector.

Teleoperated loaders are already commonly used in mining. The main reasons for teleoperation are safety and efficiency, since one operator can operate several machines without being physically present in any of them. In mountainous forests, safety is a very good argument for the use of teleoperated machines. In relatively flat areas, as in Nordic countries, teleoperation can be advocated on the basis of increased efficiency. In Sweden a remote-controlled harvester operated by the driver of the forwarder has been developed by *Löfgren* et al. [46.17]. The trees are harvested directly to the cargo space of the forwarder. One remote-controlled harvester serves two forwarders.

True teleoperation over long distances requires efficient wireless communication, which can be a problem. For example live video links require quite high bandwidth, which cannot be implemented on the basis of mobile communication services existing today in the deep countryside. Teleoperated machines should there-

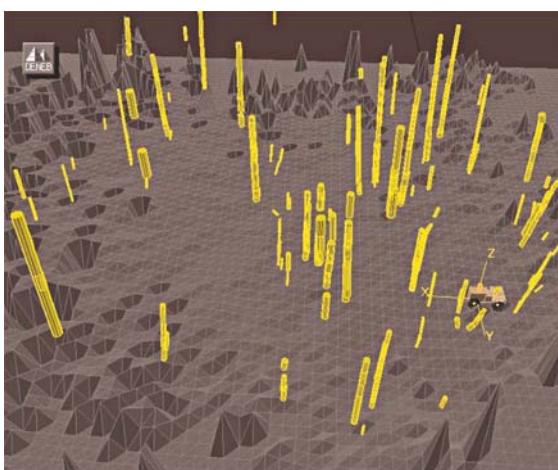

Fig. 46.6 A bird's-eye view into the combined 3-D elevation/feature model of a small forest area by Forsman and Halme [46.11]

fore be intelligent enough that less efficient wireless communication is sufficient.

46.2.6 Autonomous Robots for Silviculture and Treatment

In Nordic countries, after the final clear-cutting of trees the ground of the forest stand is usually prepared for planting of seedlings or seeds. Seeding can be combined with automatic tilling. Planting has been partly mechanized over the last few years, using harvesters in which implanting units are installed in the tip of cranes. Planting could be robotized so that the planting plan is realized with a group of small robots employing real-time kinematics (**RTK GPS**). However, there is much expertise and knowledge related to implanting it-

self, soil, and the planting site, which is difficult but not impossible to automate.

In order to automate weeding, more research is needed in this sector of forestry robotics. Pioneering research has been done in Canada by Petawawa at the National Forestry Institute [46.18].

46.2.7 Forestry Conclusions

Forestry is a demanding area for robotics. It is a harsh environment for all types of instrumentation. Reliable perception and measurement of essential objects and state parameters in real time is the bottleneck to developing more enhanced autonomous or teleoperated functions and operations in forestry machines.

46.3 Broad Acre Applications

46.3.1 An Overview of Automatic Guidance

Since the earliest horse-ploughing contests, farmers have aspired to straight lines. In Australia and other countries, this has been strengthened by the concept of *controlled traffic*. The belief is that if vehicles can be made to run in the same wheel ruts from year to year, the least damage will be done to the growing zone of the soil. These factors lend strength to the desirability of an automatic guidance system that has an accuracy of a few centimeters.

Methods that were considered included buried cables, but by the early 1990s it was clear that machine vision and the anticipated **GPS** offered the greatest promise. Workers at the University of Illinois had already researched means of deriving guidance information from row-crop images, but in those days computing power was limited and image capture interfaces expensive.

With a simple frame-grabber that captured a sparse binary image, researchers in Southern Queensland achieved automatic steering to centimeter accuracy. In a mere five years, low-cost video capture systems became available which enabled a color-based system to be developed, tested, and brought to market [46.19]. The central algorithm was based on a regression fit of lines to plants seen in *keyholes* that moved to track the rows. Discrimination of *plant/not plant* employed a variable level that tracked a farmer-entered estimate of percentage ground cover. Steering was implemented by a submodule with an embedded microprocessor that switched

valves in the hydraulic steering system, the loop being closed by a Hall-effect steering sensor. Figure 46.7 shows the row-fitting algorithm in action.

Despite great field success, the marketing effort through a major **US** tractor-maker saw few units sold. It is thought that the price was set too low, so that dealers were reluctant to take responsibility for high-technology equipment in sites that were mainly remote. Another handicap was the growing publicity for **GPS** guidance.

In those days, to achieve an accuracy that was claimed to be better than 10 cm **GPS** systems needed to be based on two-band receivers with a ground

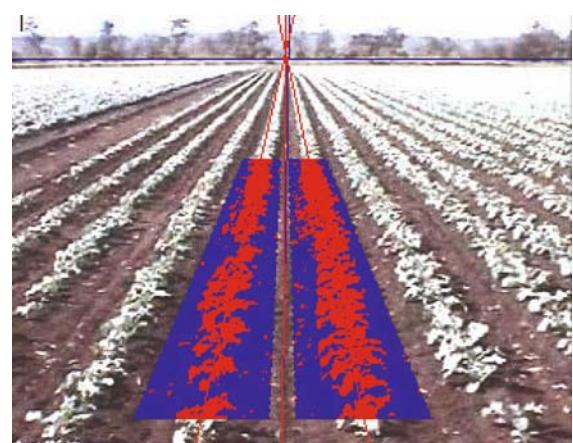

Fig. 46.7 Camera view with rows identified

base-station and **RTK**. Nobody could accuse the market-leading systems of being underpriced, with price tags of as much as 80 000 Australian dollars. However the initial products did not provide automatic guidance but merely displayed a guide bar for a human driver. The steering submodule that had been developed for vision guidance was sold in quantity to adapt the **GPS** systems for automatic operation. These *steering ready kits* sold for double the end-user price of the entire vision guidance system of which they had been a minor part.

With the convergence of computing and entertainment, cameras can now be directly interfaced through universal serial bus (USB) ports. Processing power and software are abundant. Differential carrier-based techniques allow low-cost **GPS** receivers to offer centimeter displacement tracking and the new generation of systems combine vision, **GPS**, and inertial sensors.

Whether tractors will ever be fully autonomous lies more in the hands of the litigation lawyers than in those of the engineers.

46.3.2 Sowing, Weeding, Spraying, and Broad-Acre Harvesting

When the individual operations are considered, the technologies vary in their importance. For spraying, 0.5 m accuracy is usually sufficient. Here, however, demands of speed are at their most important, so there is a trade-off between a **GPS** with a once-per-second update with inertial assistance and the 5 Hz **GPS** that is becoming more common. For yield monitoring, where the har-

vested yield might be apportioned into 5 m squares, **GPS** with 0.5 m precision is also sufficient.

When *listing up*, there is little or no visual reference in the field. Precision **GPS** and inertial sensors have a clear lead. However, when a good furrow has been formed, planting can employ a simple mechanical *furrow follower*, a ball or wheel trailed from an arm projecting in front of the tractor.

When seedlings have emerged, machine vision offers great advantages over **GPS** guidance. While cultivating, any dynamic positional errors at the planting stage will be added to steering positional errors; the blades must be set further from the row if the risk of destroying plants is to be contained. Vision can track the wander in the planted rows so that only one level of errors will be involved.

When a cotton crop is ready for harvesting, simple methods can again be used. Mechanical *stem feelers* are ideal for guiding the harvester precisely along the rows and these have been successfully field-tested by the National Center for Engineering in Agriculture (**NCEA**). For wheat, however, vision could still be supreme. The Illinois researchers have investigated visual ways of detecting the boundary of the previous cut.

A simpler robot already in widespread use is the center-pivot irrigation device [46.20]. These systems are self-propelled, irrigating an area of up to 600 acres per pass. Add-ons such as **GPS**, moisture monitors, and even imaging devices add sensory input for decision making. In this way, water and fertilizer may be applied to specific areas of the field at specific rates dependent on conditions [46.21, 22].

46.4 Horticulture

46.4.1 Picking of Fruit and Vegetables

Once we leave broad-acre crops, harvesting can require selection and sensing. Brute force *tree shakers* might be used for picking some citrus fruit, but hand-picking is still common. Intelligent picking has presented a challenge to many robotics researchers [46.23–27].

Picking can sometimes take the form of a location or localization task, deriving a target position for the picking actuator. At other times there is an additional requirement to determine which of the fruit are ready for picking and which must be left to ripen. At present, the *automation* consists of no more than conveyor belts extending each side of a tractor while hand-pickers walk

the field, choosing which to cut, be they broccoli, rock melons, or cauliflowers.

The gathering of macadamia nuts is performed by a manually steered vehicle with a *bristle roller* which gathers up the nuts from the ground. What brings it to the attention of robotics is a localization task associated with selecting for varietal strains. It is necessary to attribute each kernel to the correct tree, meaning that the absolute position must be measured.

Cameras inspect the rollers just before the nuts are stripped, as shown in Fig. 46.8, so that the pick-up location is known precisely with respect to the vehicle, but that leaves the task of locating the vehicle. **GPS** is unreliable under the tree canopy, so the system

Fig. 46.8 Macadamia harvester with cameras

combines odometry with tree-trunk location using both sideways-looking visual streaming and radio frequency identification ([RFID](#)) tagging [46.28].

46.4.2 Color Sorting and Produce Grading

Some tomato growers resort to mass-harvesting tomatoes that are still green and rock hard, relying on ripening them in a controlled atmosphere. The selection task is then transformed from a field operation to a color-sorting line.

The actuation aspect of a sorting line might be a simple tipping mechanism that ejects a fruit from a carrier to fall into an appropriate bin. Alternatively it can take the form of an air-jet that deflects a falling nut kernel, causing it to miss a catching scoop. An essential difference is the substantial delay until a conveyor system reaches the required station compared with the few milliseconds required to actuate a valve to deflect a falling nut.

In all cases there is the task of singulation, separating each item for individual inspection. Apples and tomatoes will roll into cup-shaped depressions, but nut kernels

need to be shaken onto a pair of contra-rotating rollers that form a chute down which the nuts can slide. As the nut falls through the viewing window a decision must be made within milliseconds to either let it fall or to deflect it with the jet.

Some applications hardly warrant the term *machine vision*. In an early nut sorter, light was separated by dichroic mirrors into two chosen wavelengths, to be measured by simple photocells. The transient was interpreted for color and for the presence of shell. A conventional camera would be ineffective, since the delay associated with the frame rate would be long compared with the time of flight. In a tomato sorter, on the other hand, the three conventional red-green-blue ([RGB](#)) color bands of a television camera suffice to determine both ripeness and size.

When an early investigation was made of the sorting of broccoli heads, image capture was a substantial hurdle to overcome [46.29]. The reward was the quality of information gathered, enabling grade boundaries to be adjusted when separating the produce for varying destinations. However the project was handicapped by the automation task of separating the heads from bins of produce, to load them into the inspection carriers.

One of the factors used to determine citrus quality is the texture of the skin, which is a combination of wrinkles, dimples and lumps, or flat spots. Previously, measurements were made using a stylus on the revolving fruit [46.30]. In the machine-vision solution, the rotating fruit is illuminated from the side, so that it appears as a *half-moon* to the camera mounted in front of it [46.31]. The *terminator*, dividing lit and portions in shadow, appears as a ragged vertical line, with a statistical distribution of horizontal *roughness* that is readily related to the texture.

Today the vision grading system could well be carried on the harvesting vehicle. There is a growing appreciation of the benefits of single-handling, with grading and packing being performed in the field as part of the picking operation.

46.5 Livestock

46.5.1 Robot Milking

Although matters have come a long way from hand-milking, the milking parlour still requires many operations. The cow must be identified, moved to the milking station, and restrained, then the udder must be

inspected and prepared, and the teat cups attached. The milk must be assessed to ensure that it can safely be added to the storage, the teat cups removed, and the udder treated post-milking.

According to a review paper [46.32] there were over 400 milking robots in operation by 1999, each capable

of tending 40–70 cows by performing these operations. It is now the cow's responsibility to determine the time of milking. The visit to the milking station is rewarded with grain feeding, but training is required to establish a routine.

46.5.2 Sheep Shearing

Without doubt, one of the most spectacular aspects of robotics research for agriculture was the University of Western Australia system for robot shearing, *Shear Magic* [46.33]. A hydraulic robot arm was developed to enable shears to be manipulated in an emulation of the blows that are actions of a human shearer. Innovative capacitance sensors enabled the shears to *float* accurately close to and parallel with the skin of the animal, so that nicks and cuts could be reduced below the level a human shearer might impose.

After spending many of millions of dollars, however, the project was discontinued. In an industry where contests are held for speed, the failure of the robot system to achieve similar speeds and cost efficiency left it without support.

A similar fate befell the two-armed system announced in 1985 [46.34]. This was developed for automatically shearing part of the sheep by the Merino Wool Harvesting Pty., which ran out of funding in 1993.

Nevertheless there have been valuable spin-off lessons. An aspect that makes shearing arduous is the need to manhandle the sheep. The robot demanded that the sheep be presented in a structured manner, and the sheep loading animal manipulation platform (**SLAMP**) sheep-handling part of the university research surely lent

Fig. 46.9 *Shear Magic*

concepts to systems such as *ShearExpress* [46.35, 36]. This is a system whereby the legs of the sheep are cuffed, presenting the sheep at various attitudes for the convenience of manual shearers who can now perform their task standing up rather than crouching, each specializing in a different part of the fleece.

ShearExpress also addresses the problem of bringing sheep and technology into the same physical location, taking the form of a complete mobile shearing shed. Even so, its future is also in question.

There has also been considerable *strategic* payoff from such research. Shearers have moderated their pay demands and industrial relations behavior since the technology was demonstrated. The progress of projects such as these has been hampered by the inability of the industry to gather sufficient investment capital against which to leverage external investment funds.

46.5.3 Slaughtering

Delegates to a Brisbane robotics conference in 1993 were taken on a visit to see a robotic slaughtering system installed at Kilcoy. They were able to compare the manual system, in which each beast is stunned and then hoisted by a hind leg to have its throat cut, against the Fututech system in which the stunning and exsanguination process were automated.

The emotional impact was striking, much more so than the economic factors. The dead animal was toppled onto a moving cradle, where it could be dismantled by human butchers. There were islands of technology, such as the skinning station and the saw that accurately split the carcase in two under sensory control. However the automation was made somewhat cumbersome by the centralized control, requiring extensive cabling to the control and computing booth. The actual saving in manpower was slight, with 30 or so butchers still required for jointing.

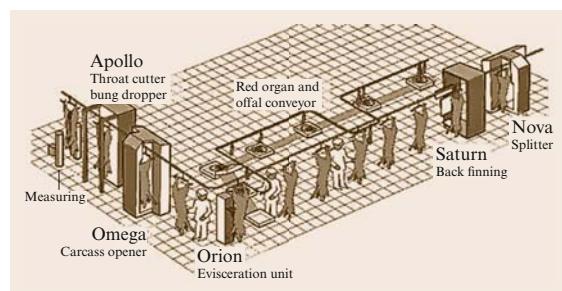

Fig. 46.10 Danish pig line

Fig. 46.11 Sheep with identifying outline

Soon afterwards, the project was wound up. In Hansard on 7 May 1996 [46.37] it was reported that Senator O'Chee said, *What became apparent as the trials went on was that the process was not working. The idea that these animals would be automatically killed just was not happening.* He went on, *That has seen the cost blow out from AU\$2.2 million, which was the estimated cost of the Kilcoy portion of the Fututech program, to \$20 million for that portion of the program. That is half of the \$40 million which was expended in relation to Fututech.*

Perhaps some of the problems lay in overoptimistic overall budget expectations and in the choice of animal to butcher. In Denmark, an automatic slaughter line for pigs claims a throughput rate of 78 000 pigs per week [46.38]. *Islands of automation* handle evisceration and back splitting with methods bearing a similarity to those of Fututech. This part of the US\$270 million DanishCrown Horsens plant was engineered by SFK Meat Systems at a cost of some 20 million dollars [46.39]. Production started in late 2004.

46.5.4 Livestock Inspection

As with produce, grading and classification of livestock carcasses is becoming more commonplace. Poultry [46.40] is one application where the advances in image sensors and filters for particular spectra combine to provide automatic detection of disease and contaminants in a poultry processing line.

An application involving individual recognition of production animals is in full commercial use by *Big Dutchman* [46.41]. In this circumstance, pigs are tagged with unique radiofrequency identification (RFID) ear tags. As each animal enters a feeding bay, the tag is read and an appropriate ration of food is delivered. This allows individualized diets and medication delivery to improve the bottom-line cost/benefit for pork producers.

Another novel method of identifying and controlling animals is being developed in Southern Queens-

Fig. 46.12 Robocow with horse and rider

land [46.42]. Using machine vision, each animal proceeding along a laneway towards water is classified at the species level. An automated gate then either allows or denies access to the watering point. The same technology can be used to remotely draft production animals based on a condition score into several different categories.

46.5.5 Robotic Animals

The Robotic Sheepdog [46.43] was initially developed to herd ducks, with the expectation that it could be applied equally to herding sheep. The robot was controlled by a remote personal computer (PC) using a fixed television (TV) camera to locate both the flock of ducks and the physical robot. The duck behavior was modeled and fed back to the robot position control to herd the animals from one end of an arena to the other.

At the fringes of agriculture can be found country sports such as *cutting contests* and *camp drafting*. Both are contests of horsemanship, requiring a small beast to be manoeuvred by moving the horse relative to the beast. In fact the horse must take many of the decisions. It must be trained to react appropriately to the beast's actions, requiring hours of interaction with a steer or heifer.

The beast is prone to lose patience rather quickly and simply wander away from the horse, so Robocow was developed as a training aid [46.44]. As seen in Fig. 46.12, the steer-shaped body is mounted on a steered tricycle that can spin on the spot or accelerate rapidly on rough ground. Originally programmed to *dance* a chosen pattern, there is a new project to add *bovine intelligence* by enabling it to react directly to the movement of the horse.

46.6 Unmanned Vehicles

There is a rise in the use of unmanned aerial vehicles (**UAVs**) to address tasks in agriculture. The most advanced applications are already at a commercial stage. Helicopters from Yamaha [46.45] can be programmed to take aerial photographs over a specific flight path. Manual override control allows user interruption, with the capability of resuming the flight path from where it left off. This type of vehicle offers unprecedented availability of a stable platform for image sensors and hyperspectral sensor devices.

UAV collaborative, which has a cooperative research agreement with the National Aeronautical and Space Administration (**NASA**), uses long duration flight time

UAVs such as the Pathfinder [46.46] to perform unmanned flight operations. The applications range from testing coffee ripeness in Hawaii, to real-time acquisition and distribution of thermal images over a controlled fire in California.

While full-sized tractors may never be fully autonomous, there is scope for smaller, cooperative vehicles to perform set tasks. Many researchers are currently investigating various platforms, including several approaches from researchers in Illinois [46.47]. The idea behind smaller units will be that they can work cooperatively and constantly, thus providing the same amount of horsepower with much reduced risk.

46.7 Conclusions and Future Directions

Robotics is percolating into all aspects of agriculture. The applications are many and various, but there is still great scope for further innovation. A constant grumble is the shortage of manpower for farming, both skilled and for seasonal harvesting operations. Intelligent robotics will be welcome in this most essential industry.

The main challenge facing robotics in forestry is the harsh environment. This is due to a combination of both weather conditions and rapidly changing illumination. Improvements to forest machines are ongoing and some recent results in this direction have been reported by the research project Forestix [46.48, 49].

In agriculture generally, there are a number of issues that must be confronted.

- The ongoing loss of expertise in the industry;
- New robust reliable sensors and actuators will be required to withstand the environmental extremes that are the basic working conditions in many agricultural areas;
- A unit-cost barrier exists due to the small profit margin of many agricultural areas. This will require either a generalized methodology for robotic system, or some other measure to lower unit costs.

Robotics in Construction

Kamel S. Saidi, Jonathan B. O'Brien, Alan M. Lytle

This chapter introduces various construction automation concepts that have been developed over the past few decades and presents examples of construction robots that are in current use (as of 2006) and/or in various stages of research and development. Section 47.1 presents an overview of the construction industry, which includes descriptions of the industry, the types of construction, and the typical construction project. The industry overview also discusses the concept of *automation* versus *robotics* in construction and breaks down the concept of robotics in construction into several levels of autonomy. Section 47.1 also presents traditional and advanced concepts for sensing systems in construction, which enable the use of robots and various forms of automation. Section 47.2 discusses some of the economic aspects of implementing robotics in construction, and Sect. 47.3 presents examples of robots from various construction applications. Section 47.4 discusses unsolved technical problems in construction robotics, which include interoperability, connection systems, tolerances, and power and communications. Finally, Sect. 47.5 discusses future directions in construction robotics and Sect. 47.6 gives some conclusions and suggests resources for further reading.

Construction is a ubiquitous human activity that relates to the creation or realization of physical artifacts or custom-made capital goods. It is distinguished from manufacturing in that the production activity normally occurs in a field setting and is undertaken in the open air, on natural terrain, and often with naturally occurring materials. Typically, building and construction products are large in scale and unique in form. Moreover, the environment or field setting is typically unique and requires a, rather ad hoc, *factory* to be synthesized on site.

Over the centuries, various forms of machines and mechanical engineering systems have been intro-

duced into the construction engineering domain and into the building and construction industry to increase production efficiency. In common with the fields of agriculture, mining, and forestry, the long-term trend has been for these fields to become increasingly mechanized [47.1].

In the last few decades, with the decrease in the relative cost of machinery to labor and with the globalization of markets, the construction industry has become significantly more capital intensive and large-scale machinery systems and pieces of construction plant – such as tunnel-boring machines and very large tower

cranes – have become commonplace. This trend to mechanization is likely to continue with the progressive introduction of computer-controlled construction machinery and flexible manufacturing concepts into the industry.

With the relatively recent development of the microprocessor and the availability of low-cost computer and sensing technology, construction robots have become a technical and economic possibility and this form of technology is now gradually being used in the industry.

47.1 Overview

The application of robots in construction traditionally falls under *construction automation*. As the term implies, the field of construction automation is focused on automating construction processes, and the use of robots is but one aspect of automation. Construction processes also fall within several categories best described through a brief introduction to the construction industry.

47.1.1 Industry Description

In the USA the value of construction put in place in 2002 was approximately 8% of the national gross domestic product (GDP) [47.2], employing over 7 million workers in 2005 [47.3]. According to data from a 2003 US Census Bureau report, approximately half (48.25%) of those workers were employed by firms of four employees or fewer, and roughly 60% of all construction workers worked for specialty trade contractors who accounted for roughly 60% of construction firms [47.4] (specialty trade contractors are usually subcontractors on a project and are not responsible for the overall outcome of the project). In the European Union (EU), construction accounted for 5.7% of the EU's gross value added in 2004, and the construction industry employed over 11 million workers [47.5]. Worldwide, construction industry spending is estimated at approximately 11% of the world's GDP [47.6].

Construction is considered by many to be technologically behind other industries, such as manufacturing. In manufacturing, a product is designed for mass production, whereas construction products (or projects) are

usually one-off and unique [47.7]. Thus the efficiencies achieved through mass production are not easily achieved in construction.

Other often attributed reasons for the construction industry's technological lag are the industry's fragmentation and aversion to the risks associated with the introduction of new technologies [47.7, 8]. In addition, unlike their manufacturing counterparts, construction sites are for the most part unstructured, cluttered, and congested, making them difficult environments for robots to operate in. Furthermore, human workers are also present in large numbers on a construction project, making safety a paramount concern.

Types of Construction

Construction projects are usually classified as residential, commercial, industrial, or civil. Residential construction generally involves single-family homes or large apartment buildings; commercial focuses on building structures such as office and retail space, warehouses, and so on; industrial is involved in building factories, power plants, and other similar structures; and civil construction focuses on public infrastructure such as highways, bridges, tunnels, and dams.

In the USA (as of 2006), residential construction accounted for a little over half of the total construction value put in place [47.2]. Among nonresidential construction activities, commercial, civil, and industrial projects accounted for approximately 26%, 17%, and 4%, respectively, according to census data for the 4 years between 2002 and 2005 [47.2]. According to the same census data, approximately 78% of all construction activity in the USA is undertaken by private firms.

In the EU (as of 2005), civil construction accounted for 20% of the total construction put in place, nonresidential construction for 31%, renovation and maintenance for 23%, and new residential building for 26% [47.9].

The Typical Construction Project

A construction project typically goes through six major phases, as shown in Fig. 47.1. Some projects may

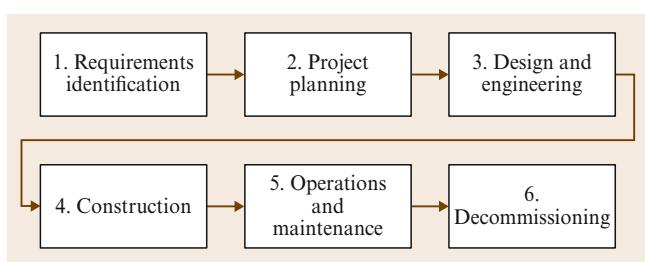

Fig. 47.1 Phases of a typical construction project

go through different variations of the sequence shown, but most projects include planning, design, construction, and operation phases [47.4, 7]. Phase 1 begins when a need for a project arises and the requirements are identified. Phase 2 involves developing alternative project plans that could meet the identified needs and evaluating the technological and economic feasibility of each alternative. Phase 3 develops detailed engineering designs and specifications for the plan selected in phase 2. The construction of the facility from ground-breaking through to final inspection takes place in phase 4 of the project. The facility is occupied and commences operation in phase 5 and continues operating until it is time to shut down and dismantle the facility once it becomes obsolete (phase 6).

The actual physical work (building, operating, maintaining, and dismantling) on a construction project takes place in the last three phases. Although these are the only phases in which machines are used, construction automation can also take place during the other phases of a project, as described in Sect. 47.1.2.

During the various phases of a construction project, several stakeholders may be involved at any time. The major stakeholders include the following: the *owner* and *operator*, whose needs initiated the project; the *architect* and *engineer*, who have the task of translating the owner's needs into an aesthetically pleasing and structurally sound design; and the *general contractor*, whose task is to translate the design into a physical structure. In addition several other stakeholders may be involved either independently from the above stakeholders or as part of their organizations; for example, the constructor may employ a project manager, a construction manager, a site superintendent, and others, and he/she will typically subcontract major activities such as excavation and concrete pouring. The subcontractors and sub-stakeholders are often the ones who use a new technology and can either *make or break* its implementation.

Although the builder is the most likely user of robots on a construction project, the actual work on site is often conducted by subcontractors who often are reluctant or financially unable to use advanced technologies which have not been entirely adopted by industry. A constructor's goal is often to meet the owner's requirements by the most efficient *and* least risky methods possible. Hence, traditional construction methods that have stood the test of time are preferred. Nevertheless, it has often been anecdotally reported that the owner has the *power* to require the use of certain technologies on a construction project, since that shifts part of the risk and cost associated with the use of the technology to the

owner. This phenomenon may be partially responsible for the widespread penetration of laser scanning technology into the construction industry that is currently taking place [47.10].

47.1.2 Automation in Construction

Construction automation describes the field of research and development focused on automating construction processes, and the use of robots is but one aspect of that field. In short, construction automation deals with applying the principles of industrial automation to the construction sector, whether in building construction, civil engineering (roadways, dams, bridges, etc.), or in prefabrication of construction components [47.11]. This can be viewed as an extension to research in field service robots generally designed to replace or assist humans in a specific construction-related task or function.

From a historical perspective, research in construction robotics and automation started in the 1980s with the introduction of single-purpose robots (principally remotely controlled, or teleoperated, machines). The Japanese led this effort, driven primarily out of concern for societal demographics, which showed a significant future shortfall in personnel available for the construction labor pool [47.12]. In the US the principal related work involved developing remote control or teleoperated machinery for hazardous work that required modified construction equipment. Example applications include robots developed for rapid runway repair and unexploded ordinance removal. In the EU, research was focused on the development of large-size masonry (brick laying, assembly) robots for residential and industrial building construction.

During the next decade, as research on task-specific construction robots continued, large Japanese construction firms introduced on-site *factories* for high-rise construction. These construction systems included just-in-time delivery of components, automated part tracking and material handling, robotic connection and assembly, and centralized control in an enclosed or semi-enclosed environment. It is reported that the systems enable better working conditions (weather invariant) and reduced project completion time [47.13]. Other benefits include improved productivity and quality, though overall construction costs are not necessarily lower [47.14].

Advanced concepts in integrated residential construction automation were developed as part of the EU FutureHome project. In this construction concept, each structure consists of several high-quality, prefabricated three-dimensional (3-D) modules and two-dimensional

(2-D) panels which are assembled *production-style* on site [47.15]. An analogue of this approach for automated residential construction has been commercialized in Japan [47.16].

New methods for collecting, processing, analyzing, and communicating construction information are a significant area of construction automation research [47.17]. This research includes data interoperability and exchange through the design, construction, operations, maintenance, and decommission phases of a capital project [47.18]; advanced sensors for assessing the status of the construction process [47.19–21]; visualization systems for planning construction events, verifying constructability, and maintaining site situational awareness [47.22–24]; and information models which extend traditional computer-aided design (**CAD**) modeling to combine both the physical (geometric) and functional characteristics of building components [47.25].

Finally, three notable, large-scale, ongoing EU projects are attempting to integrate construction automation into the way construction projects are executed: the ManuBuild (open building manufacturing) project deals with, among other things, the development of mobile field factories, including robots, for on-site modular construction [47.26]; the I3CON (industrialized, integrated, intelligent, construction) project deals with the indoor automation and robotization of buildings [47.27]; and the Tunconstruct project deals with the robotization of inspection and maintenance operations in tunnels [47.28].

47.1.3 Robotics in Construction

Construction robotics is an advanced form of mechanization (automation) in which an endeavor is made to automate some industrially important operation and thereby reduce the cost of this operation by either removing a human operator *from the control loop*, or enhance operational efficiency through machine control systems. Due to the nature of construction work, most robots which have been developed for the construction industry are either mobile or relocatable systems. Some platforms, such as floor-finishing robots and machine-controlled earthmovers require mobility as a specific function of the work process to be performed. Others, such as wall and ceiling panel manipulators, require some level of mobility to extend their operating workspace.

Robot terminology can vary depending upon the research discipline. For this chapter three general cat-

egories of construction robots are introduced. The first class is *teleoperated systems*, which for simplicity includes *remote control systems*. The general distinction between the two terms is whether or not the equipment must be operated in line of sight from the human controller [47.29]. The second category, *programmable construction machines*, includes most construction equipment that is outfitted with sensors and mechanisms to augment operation by an onboard human operator. The final category, *intelligent systems*, relates to unmanned construction robots which operate either in a semi- or fully autonomous mode. In Sect. 47.3 this classification will be expanded to include examples based on various generic activities, materials handled (operand types), levels of onboard intelligence, levels of commercialization, and levels of system integration and computer integration.

Teleoperated Systems in Construction

In established engineering terminology, the term *teleoperation* refers to the remote control of machines and systems. In teleoperation (loosely referred to as telerobotics) the control of the machine is accomplished by the use of remote control means such as an umbilical cord or wireless control. Teleoperation ideas and methods are used extensively in the space and nuclear industries (Chaps. 45 and 48, respectively).

In telerobotics, the machine does not operate autonomously but is under the control of a human. Data sensing and interpretation and cognitive activities such as task planning are done by the operator.

Recently, many telerobotic devices have appeared in the construction and mining industries. These machines have evolved in response to industrial situations where there is danger to the operator and where remote-controlled machinery is necessary (e.g., teleoperated small compactors). Situations of this kind occur in the construction, demolition, and mining industries and in other hazardous locations.

The technology for telerobotics in construction is well established, with a number of excellent examples of such activity available, for example, a sophisticated model-based supervisory-control-type distributed teleoperation system for the construction of a trench for a diversion dam in a lava field in Japan using a fleet of heavy earthmoving machines [47.30].

Programmable Construction Machines

A software-programmable construction machine is what most people would consider to be a robot. The operator of this type of machine is able to vary the task to be ac-

accomplished within certain constraints either by choosing from a preprogrammed menu of functions or by *teaching* the machine a new function. Variations in the task to be accomplished could be as simple as slight changes in the driving speed based on the current load for an automated forklift, or as complex as a change from being able to pick and place steel beams and columns using an autonomous crane to being able to deliver concrete autonomously using the same crane.

Generally, software-programmable construction machines are identical to traditional construction machines (such as an excavator), but have been modified to be controllable through a computer [similar to the way in which traditional manufacturing machines – such as mills and lathes – evolved into computer numerically controlled (**CNC**) machines].

Software-programmable construction machines can make use of an electronic representation of a portion of the construction site where their work is to be conducted in order to control all or part of the machine's operation. A commercialized example is *stakeless grading*, where data from a 3-D model is used in combination with global positioning systems (**GPS**) and/or laser measurement systems to automate the blade control for bulldozers and motor-graders.

Intelligent Systems in Construction

As opposed to a teleoperated or a software-programmable construction machine a fully autonomous construction robot is expected to accomplish its task, within a defined scope, without human intervention. A semiautonomous construction robot would be expected to accomplish its task with some level of planning interaction conducted with a human supervisor [47.29]. In each case the construction robot is expected to adapt to its sensed environment, formulate plans for the execution of its task, and replan as necessary (with possibly some human assistance in the semiautonomous mode). The intelligent construction robot should also be able to determine when its tasking is not executable and request assistance.

Example research in intelligent construction systems includes autonomous excavation [47.31, 32] and autonomous crane operations [47.24, 33–35].

47.1.4 Sensing Systems in Construction

Field measurements are an integral part of the construction process. The *tape measure* and the *transit* have been used in construction for decades for measuring distances and angles, respectively. However, construction meas-

urements are not limited to distances and angles, but can also include measurements of installed quantities, percentages of completion of activities, and so on. All of these measurements are necessary to be able to lay out the site where a facility is to be built, to measure the conformance of the as-built facility to the intended design, and to monitor safety, productivity, and progress.

Traditional Sensing Systems

In addition to the tape measure, transit, and level, all of which are still in use [47.36], more modern sensing systems are now considered commonplace (or traditional) at a construction site. These include total stations [or digital theodolites – a combination of a theodolite and an electronic distance measuring (**EDM**) device], **GPS**, and laser planes, levels, and plumb bobs. Although **GPS** is commonplace in construction (and many other industries) and may be considered a traditional sensing system at this stage, it is and will continue to be a significant enabler for construction automation.

Advanced Sensing Systems

More advanced sensing systems are also beginning to have some impact in the construction industry. Some of these technologies are, and will become more so in the future, key enablers for the introduction of automation and robotics onto the construction job site by providing real-time situational awareness of site conditions. Some of these advanced sensing systems are described below.

Real-Time Positioning Systems. Traditional **GPS** relies on line of sight (**LOS**) to Earth-orbiting satellites and cannot currently track a moving object at much better than 20 cm unless ground-based stations are used. For applications where **LOS** to the **GPS** satellites is not available (such as indoors) or where higher real-time accuracy is required, two technologies currently exist: laser-based (also often referred to as indoor **GPS**) and ultra-wideband positioning systems. Indoor **GPS** (**iGPS**) relies on **LOS** to a series of laser transmitters (beacons) to measure and track the position of an optical receiver at up to 100 m away from the closest beacon [47.37]. Ultra-wideband (**UWB**) relies on **LOS** to a series of radio receivers to measure and track the position of a radio transmitter (working in the microwave frequency) at up to 200 m away from the closest receiver. Both technologies are similar to satellite-based **GPS** in that multiple objects can be tracked using the same infrastructure created by a few fixed beacons or receivers and that tracking can be quickly regained following a break in the **LOS**. (In the case of **UWB**, direct **LOS** is not always necessary

since the **UWB** signals can travel through many common construction materials, albeit at the possible cost of degradation in the positioning accuracy.)

Laser-Based 3-D Imaging Systems. Laser-based three-dimensional (3-D) imaging systems use lasers to measure the range to points on objects within their field of view, as well as the bearing (angles) to those points within the instrument's coordinate frame. These systems usually output a *cloud* of points (or *point clouds*) with 3-D coordinates (usually *X*, *Y*, *Z* or angle, angle, range) associated with each point. In addition, many of these systems also output the intensity of the returned signal from each measured point on the objects as well as the red, green, and blue (**RGB**) color information from each point. Laser-based 3-D imaging systems are commonly also referred to by some of the following names: laser scanners, laser radar or laser detection and ranging (**LADARs**), and light detection and ranging (**LIDARs**).

The use of laser-based 3-D imaging systems is rapidly penetrating the construction industry due to its efficiency in capturing the existing conditions of a construction project (during or after construction) in great detail [47.10]. Gathering as-built conditions is essential for facility redesign, maintenance, repair, and upgrade and the ability to efficiently and accurately measure the condition of the existing facility and can have significant time and cost savings.

Ground-Penetrating Radar. Ground-penetrating radar (**GPR**) uses electromagnetic radiation at the microwave frequency (also known as *ultra-wideband*) range to measure reflections from objects buried underground or within structures (similar to traditional RADAR). In construction, this technology has been used to locate buried utilities before digging [47.38], to measure pavement layer thickness [47.39], to inspect concrete bridge decks [47.40], and to measure soil water content [47.41].

Structural Health Monitoring Systems. Structural health monitoring technology uses *in situ*, nondestructive sensors [e.g., strain gages, ultrasonic sensors, optical fibers, micro-electromechanical systems (**MEMS**) sensors] in order to detect structural damage or dangerous conditions [47.42]. These sensors are best deployed as a network of wireless sensors and can be used to monitor the state of a structure as it is being built, to monitor its health during normal operation, and to help determine structural integrity after an extreme event.

Equipment Health Monitoring Systems. Similar to structural health monitoring, these systems allow equipment operators to monitor the state of the machine (e.g., peak loads, tire pressures, engine temperature, hours in operation, crane tilt). The systems can also suggest when a machine needs maintenance and can even safely shutdown a machine should dangerous or undesirable conditions occur.

Concrete Maturity Meters. Concrete maturity meters use disposable sensors that are embedded in the concrete before it is poured in order to measure the internal temperature of the curing concrete and determine the developed strength [47.43]. Other systems use the dielectric properties of wet concrete to estimate the developed strength [47.44].

Radiofrequency Identification. Radiofrequency identification (**RFID**) is a relatively new addition to the construction sector. With the complete acceptance and adoption of **RFID** by some of the world's largest retailers (such as Walmart and Target) and by the **US** Department of Defense, this technology is evolving rapidly and the construction industry is poised to benefit from it.

The implementation of **RFID** technology involves the combination of **RFID** tags and tag interrogators. Each **RFID** tag has a unique identification number permanently stored on a microchip [usually in read-only memory (**ROM**)] embedded within the tag. Tags can be passive, semiactive (or semipassive), or active. An interrogator transmits a radio wave at a specific radiofrequency (**RF**) and waits for returned signals from tags that are within range. For passive tags, an onboard capacitor accumulates enough of the interrogator's **RF** energy (due to current induced in the tags antenna) to transmit the tag's unique identifier back. For active tags, an onboard battery powers the transmit function and can be used to maintain data stored in random-access (volatile) memory (**RAM**). In semiactive tags, an onboard battery is used to maintain data stored in **RAM**, but the transmit function still relies on the induced current to charge a capacitor.

Applications of **RFID** technology in construction to date have been in the research and development domain. Pilot projects have been conducted to test the effectiveness of **RFID** for tracking the delivery of construction components (e.g., pipe spools) to the construction site and to maintain an inventory of available parts and tools on site [47.45–48]. The application of **RFID** technology is likely to benefit the construction industry significantly in the short term (since projects are often plagued

47.2 Economic Aspects

47.2.1 Scope

In general, construction system designers are interested in the development of efficient production systems using available technology. Typically, such systems designers use new processes and technologies as they become available and as they prove to be economically viable. In relation to automation technology, such technology will not be introduced if only *islands of automation* are implemented with little overall system benefit [47.49].

47.2.2 Motivation

Apart from the pursuit of economic efficiency, construction robotics has technical features that have the potential to add value to the construction process and to product timeliness and quality, for example, there are work quality benefits such as in the quality and reliability of welding and inspection tasks. Furthermore, automated performance monitoring systems can give construction agencies hard-copy data for quality control and quality assurance purposes. The provision of historical compaction data in the construction of roads is a good case in point [47.50].

As a unique technical feature, construction robotics has the potential for reducing of occupation health and safety (OH&S) risks by removing workers from danger zones and high levels of noise or air pollution [47.51]. Construction can be a dangerous activity with a relatively large number of people being killed or injured annually (when compared to other industries).

Robotics has a major potential for allowing construction work to be undertaken in very cold or very hot weather and in areas subject to extreme radiant heat (such as building or bush fires or near blast furnaces) or nuclear radiation, for example, an early use of tele-robotics was the remote control of concrete pumps in the encasement of the Chernobyl nuclear power plant in the Ukraine. Likewise, the remote control of underwater bulldozers and other types of underwater equipment is an obvious area for the technical attributes of construction robotics.

47.2.3 Barriers

Technical and Commercial Barriers

While technology researchers and developers may be interested in construction robots for their own sake,

the typical purchaser of such systems is a contractor or construction agency who is predominantly interested in machinery systems as an instrument of purpose or as a *tool-of-the-trade*. For a particular application, robotic or automated systems or machines must compete with existing labor-intensive solutions and alternative technological solutions.

As a generalization in 2006, it is fair to say that currently available construction robotic solutions do not undercut traditional labor-based solutions except in special niche areas. This is in contrast to the widespread use of robotics in the manufacturing sector.

Some of the economic difficulties associated with the application of robotics in construction stem from the characteristics of the industry. Because it is primarily concerned with the production of large-scale custom-made capital goods that are specifically designed to fit a site, the construction industry is characterized by unique products and low production volumes and in situ development processes in open-air environments. Historically, the construction industry has proven substantially unsuited to the hard-automation methods that have been successfully developed in the large-volume repetitive applications in the manufacturing sector [47.52].

Using manufacturing industry terminology, construction may be categorized as a *jobbing-type* industry. Typically, the construction industry has very low levels of repetition and normally has *job lots of one*.

To increase the level of internal repetition, methods of product standardization have been introduced. Over the last 50 years, standardization and extensive experimentation with systems-building methods have occurred in the industrialized building sector (in places such as the old Union of Soviet Socialist Republics) and in attempts to produce manufactured homes and buildings. Such attempts have largely failed due to a lack of product and process flexibility and to market acceptance of the products [47.53].

Potentially, the emergence of robotics and flexible manufacturing methods will have a great impact on the construction industry since product and process variety can be accommodated much more easily than with hard-automation methods.

Because the construction industry is fully established and has its own methods and techniques, the likelihood is that it will robotize its own forms of equipment rather than simply move industrial robots from the factory to the site.

Sociological and Industrial Barriers

Apart from commercial barriers many people are concerned that there will be substantial industrial or worker

resistance to the widespread introduction of on-site robotics. The possible reason for worker resistance is potential job losses through displacement of labor.

47.3 Applications

Applications of robots in construction span a wide and diverse range. While certain robots with limited intelligence are slowly finding their way onto construction sites around the world, others remain scaled-down prototypes under development at universities and research organizations.

Classifying the extent of construction robot applications using a single scheme would be a daunting task, especially since some robots are being developed for multiple applications. Classification could be by level of commercial success, type of task performed, industry sector, physical scale of device, degree of technical complexity, level of onboard intelligence, and so on. Classification could also be by type of actual construction activity involved.

From a purely physical-world and practical point of view, construction may be viewed as being comprised of a finite number of elementary processes [47.55–58], which may be summarized by the following list [47.8]:

- Attaching
- Building
- Coating
- Concreting
- Connecting
- Covering
- Cutting
- Digging
- Finishing
- Inlaying
- Inspecting
- Jointing
- Measuring
- Placing
- Planning
- Positioning
- Spraying
- Spreading

Most of these processes can also be grouped into three predominant types of functional operators as follows:

1. materials handling (by bulk and unit load)
2. materials shaping (cutting, breaking, compacting, and machining)
3. structural joining

These functional operators are typically each applied to multiple operands. Common operands in building and civil engineering are steel and other metals, concrete, timber, earth and rock, masonry, plastic and glass, cement, aggregate, epoxy resin, bitumen, and other bulk and formed materials.

In the interest of brevity, the applications presented in Tables 47.1–47.10 have been loosely organized into two categories: (1) construction and (2) maintenance and decommissioning. Within these categories, robots are organized by the type of construction activity that each performs, but not necessarily following any of the classification schemes presented above. The list of applications is not comprehensive, but is meant to be a fairly representative sample of the types of robots currently being used in, or developed for, the global construction industry. (Although certain commercial construction equipment are included in this section, the inclusion of such information should in no way be construed as indicating that such products are endorsed by the National Institute of Standards and Technology (NIST) or are recommended by NIST or that they are necessarily the best equipment for the purposes described.)

47.4 Currently Unsolved Technical Problems

47.4.1 Interoperability

A recent study found that the US construction industry does not realize approximately 15 billion US dollars per year in potential savings due to inadequate interoperability related to information exchange and management practices [47.73]. Although the lack of interoperability between the various information systems used in construction is a significant source of inefficiency for the industry, it is also a roadblock to the use of automated systems in construction. Automated systems need electronic information on past, current, and/or projected future states of a construction project to function efficiently.

For example, in order for a robotic crane to pick a steel beam from the site and deliver it to its target location, the robot must be able to know that the steel beam has been delivered to the site, as well as its current position and orientation. While information on the current inventory of parts on a site may be available on paper, it is rarely available electronically unless someone enters it manually into some computer system, which in

turn may not be compatible with other systems used in that project. In many of the examples of automated construction technologies presented in this chapter, custom electronic databases and/or data formats have to be devised to demonstrate the robot's operation. In some cases, the electronic information had to be entered manually from paper into a computer for the robot to work correctly.

In addition to information exchange and management, many of the measurement instruments and sensors used in construction are not interoperable. This problem is not limited to the construction sector but is a relatively large problem in many robotic applications where different types of sensors are used. Several efforts are underway to make sensors interoperable [47.74] and construction equipment in general [47.75], but the issues have yet to be resolved.

47.4.2 Structural Connection Systems

Traditionally, structural member connections in construction have been designed for human installation.

Whether using bolted, welded, or other types of connections, manual labor is usually involved in guiding the mating parts together and in establishing the connection.

For example, in structural steel erection, workers perched on the structure typically guide a crane operator through visual or auditory cues in order to maneuver a steel beam (or column) into place. The workers must then physically manipulate the beam in order to align corresponding surfaces for bolting or welding. Once the correct beam pose has been achieved, it must be maintained while the workers temporarily fasten the beam to the structure. The workers then release the beam from the crane and permanently fasten the beam to the structure at a later stage.

For automated (or robotic) construction to work, new connections that are more amenable to automation must be designed. These connections need not mimic traditional, human-installed connections, but should be optimized for use with robots instead. For example, the Lehigh University Advanced Technology for Large Structural Systems (ATLSS) Center designed a gravity-load-only shear steel connector [47.76] back in the early 1990s that is more suitable for automated construction (Fig. 47.2). This type of male–female connector for automatic assembly of building modules allows, together with an adequate control strategy, small tolerances, which permit assembly by automatic cranes [47.77]. An example of a nonstructural connector that is more amenable to automation is the piping and electrical connector developed for the FutureHome project, shown in Fig. 47.3 [47.15].

Although automated welding has been applied in some limited form in construction, it is generally used to replace manual welding without changing the design of the parts being welded. In other words, no significant change in the way in which construction components are designed has occurred as a result of automated welding. Moreover, apart from a few examples of automated welding applied at the construction site, most of the other limited applications are done at the component fabrication facility.

47.4.3 Tolerances

Specifications for tolerances in the construction sector exist for most types of construction, however, they are not always achieved in practice [47.78]. For example, it has been stated that one of the biggest sources of problems in structural steel erection in the US is that fabricated pieces are often out of tolerance, and that this is only discovered during installation at the construc-

Fig. 47.2 A drop-in, shear-load-only, steel connection

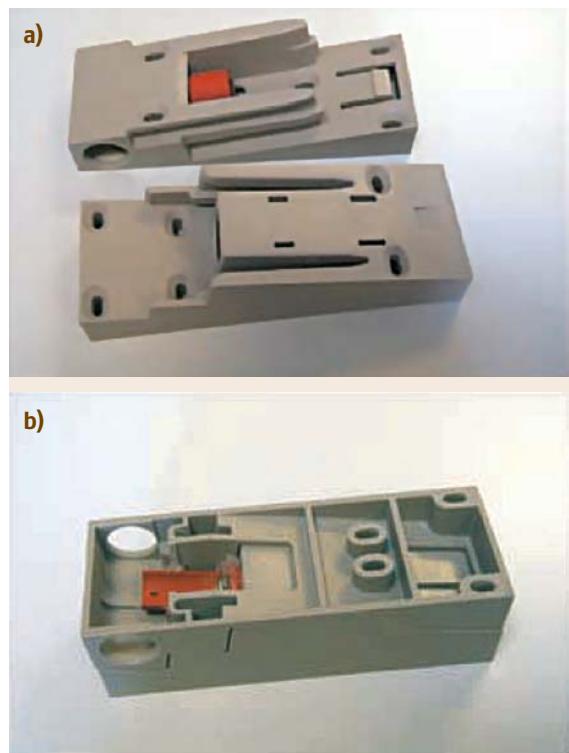

Fig. 47.3a,b A piping and electrical drop-in connector shown (a) disassembled and (b) assembled

tion site [47.79]. However, since the finished facility must meet the design tolerances before it is accepted, this shifts the burden to workers and supervisors dur-

ing construction. The workers are expected to handle problems as they come up rather than expect all fabricated construction components to be within tolerance. Since most construction projects are under tight schedules, it is often preferable to fix these kinds of problems on site rather than wait for replacement components to be fabricated and delivered.

However, tolerance problems are not all due to fabrication errors. Installation problems are also responsible for out-of-tolerance problems, for example, anchor rod installation has been an area of concern for structural steel erection. (Anchor rods (or bolts) are the connection interface between the concrete foundation and the structural steel columns. The rods are usually installed by the concrete foundation crew before the concrete is dry.) The situation of anchor rod patterns that do not match the hole patterns in a mating column is an identified problem in construction [47.20, 80].

Given the relatively loose achievable tolerances in construction, the application of robotics in construction faces an uphill battle. This, in addition to the unstructured nature of the construction site environment, requires that robots either be highly intelligent in order to correctly interpret and react to their surroundings or to be human assisted. However, site structure and tolerances are expected to improve as pressures to reduce costs and improve productivity continue to rise. Improvements in site organization and construction tolerances have already been proved to be achievable in a few cases, as

has been demonstrated in Japan [47.53]. However, the economic case for these demonstration projects has yet to be made.

47.4.4 Power and Communications in the Field

Unlike manufacturing environments, in which specially designed factories are outfitted with the necessary power and communications installations, a construction project often begins before such resources have been installed at the site. Therefore, robots with large power requirements that need to communicate with supervisory systems located off site would be challenging to implement without significant added cost.

Although communications technologies have advanced significantly in the last few decades, it is still considered difficult to maintain a reliable local-area network at a construction site and to connect that network to the Internet. The use of cellular telephones with a press-to-talk (the digital version of the traditional two-way radio communication method) feature has largely replaced the traditional two-way radios that also revolutionized on-site construction communications. However, in order for construction sites to become more automated, reliable interference-free high-bandwidth networks must be able to carry data transmission between sensors, machines, and supervisory systems.

47.5 Future Directions

As previously discussed, developing new methods for collecting, processing, analyzing, and communicating construction information is a significant area of construction automation research, and will dominate near-term efforts. As this construction information becomes more readily accessible, automation of processes can be enabled directly from the combination of design information and current site status that is accurately captured and shared. Resource tracking will become ubiquitous and just-in-time delivery of needed materials and equipment will happen throughout the site.

Advances in mobility (humanoid robotics, smart cars, legged locomotion, etc.) will enable ever more

automated material handling on the job site. These advances will require better control systems for the construction robots that can provide high payload and good positioning accuracy. The increased use of robots at the construction site will also drive research into safety systems for construction robots working around human workers and other machines.

Perhaps most important, more extensive automatic design systems will enable more prefabrication of building components and new methods of assembling those components on site, which in turn will provide the promise of faster, better, and cheaper construction robotics first envisioned in the 1980s.

47.6 Conclusions and Further Reading

The application of robotics to construction has yet to catch up with other industries such as automobile manufacturing. Construction presents a unique challenge for robotic applications. The construction environment is cluttered, unstructured, and teaming with human workers. In addition, construction processes are usually labor intensive and have to accommodate wide margins of error in the constructed facility. The application of robotics in construction to date has been limited to commercial teleoperated and programmable machines. Autonomous or semiautonomous machines are currently mostly limited to research projects within various nonconstruction organizations. With the increase in competition throughout the global construction market, construction companies are on the lookout for ways to improve productivity, quality, and safety. The use of automation and robotics is one answer that the industry is slowly turning toward. However, before these potential solutions can be successfully applied, much work is needed to improve construction tolerances, develop

standards, and achieve real-time site status monitoring.

The International Association for Automation and Robotics in Construction holds an annual conference (the International Symposium on Automation and Robotics in Construction) at which researchers can present the latest developments in the field. The proceedings from this conference hold a wealth of information on the state of the art of the field and are accessible to the general public through IAARC's website (www.iaarc.org).

There are several journals that publish articles on various aspects of automation in construction. Most notable of these are *Automation in Construction*, *Computer-Aided Civil and Infrastructure Engineering*, the *Journal of Computing in Civil Engineering*, and the *Journal of Construction Engineering and Management*. In addition, some journals publish special editions on robotics in construction. Some examples are *Autonomous Robots* and the *Journal of Advanced Robotic Systems*.

ations, removing high-level nuclear contamination, reactor decommissioning, tunneling through rock falls, and most landmine and unexploded ordnance problems still present many unsolved problems.

48.1 Operation in Hazardous Environments: The Need for a Robotics Solution

Hazardous environments present special challenges for the accomplishment of desired tasks depending on the nature and magnitude of the hazards. Hazards may be present in the form of radiological or toxicity dangers to potential explosions. When the magnitudes of hazards reach the point that human exposure would either represent a direct threat to life or long-term health consequences, some form of remote operations that separate humans from the hazards must be employed. An

extensive example of such operations is environments involving nuclear radiation; in fact many of the technical roots of modern robotics technology can be traced back to nuclear remote handling manipulators and support systems. Remote handling and operations concepts using engineered systems that allow humans to work effectively from a safe environment have evolved over the years. Today, such remotely operated systems are used widely in many areas and recently they have become rou-

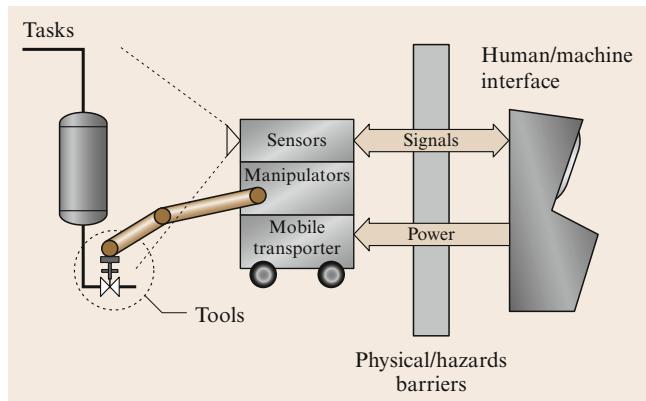

Fig. 48.1 Basic subsystems of a remote handling system

tinely used in explosives disposal, security operations, and handling of dangerous biological materials.

A remote handling system will generally involve subsystems for mobility, manipulation, tooling, sensing, and human–machine interfacing (Fig. 48.1). Nominal operations involve the collective workings of these subsystems to accomplish remote operational goals. Any remote handling system will eventually experience some aspect of off-nominal operation that may be the result of unexpected environmental events or system malfunctions. The fundamental idea is to connect the human operator to the remote environment via a power and signal infrastructure that allows effective operation in

the remote environment: mechanized devices and sensor systems that allow the human's perception and action capabilities to be *projected* into the hazardous environment to perform remote operations. The more realistic this projection, the more natural and effective the human remote control will be.

Because of their inherent complexity and the very nature of remote operations, operator training is a major challenge that requires the use of simulations and cold testing facilities that provide operators with comprehensive and realistic training. Such training will typically encompass all aspects of nominal and anticipated off-nominal operations.

Remote handling systems themselves will eventually experience equipment failures. Remote maintenance/operation of failed remote maintenance systems must be an integral part of their basic design and operational features. Hardware/software features must be provided for the analysis of, recovery from, and correction of problems.

Robotics researchers have worked hard to realize a long-awaited vision: machines carrying people from burning buildings or tunneling through collapsed rock falls to reach trapped miners. In this chapter we review progress. Researchers still have many challenges ahead of them but there has been remarkable progress in some areas.

Technology that specialized engineering companies can develop and sell without active help from researchers

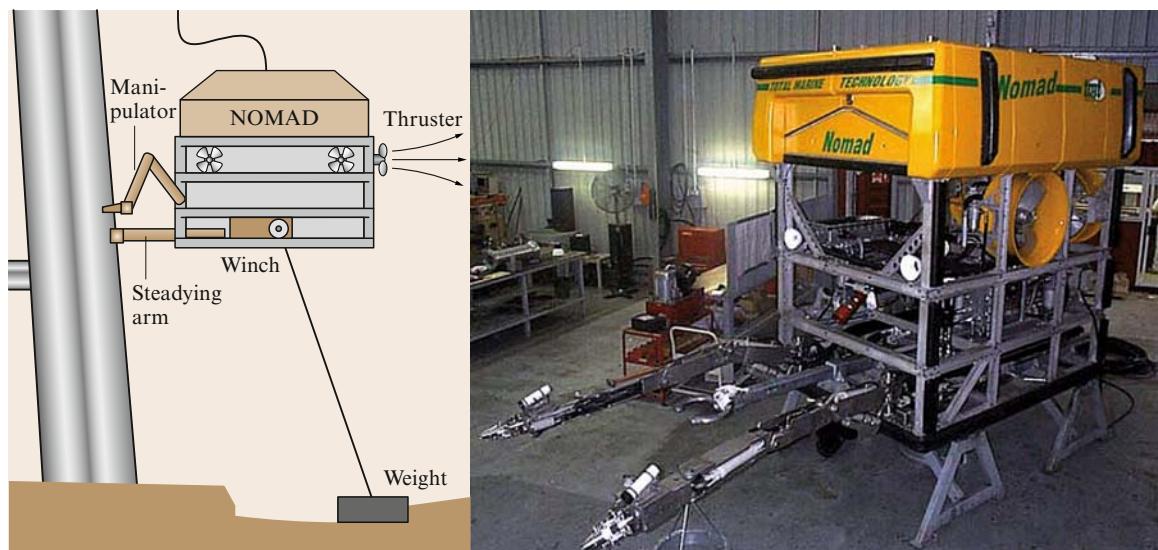

Fig. 48.2 NOMAD remotely operated vehicle for underwater engineering work (Total Marine Systems Pty Ltd, Fremantle, Australia)

marks the frontier of feasibility. Just inside this border lie teleoperated robots for explosive ordnance disposal (EOD) [48.1, 2] and for underwater engineering work. The necessity for people to wear protective suits in these situations limits their endurance and dexterity. Even with the typical tenfold reduction in manipulation performance imposed by the limits of today's *telepresence* and teleoperation technology, robots usually offer a more cost-effective solution. Figure 48.2 illustrates the elegant simplicity of the NOMAD remotely operated vehicle (ROV) that pulls itself deeper with a simple electric winch. It can be left in place overnight or during rough weather. Free-swimming robots are much more complicated and expensive and have to be hauled out of the water when not under active control.

Limited autonomy or autonomous operation for a restricted time can relieve operator fatigue and allows

unmanned aerial vehicles (UAVs) to fly extended reconnaissance missions with occasional precision weapon delivery. Such missions would be too hazardous or too politically sensitive for manned aircraft.

Most hazardous applications lie far beyond the frontier, although researchers managed to establish some limited inroads by the turn of the 21st century. Fire fighting, rescue operations, removing high-level nuclear contamination [48.3], reactor decommissioning, tunneling through rock falls, and most landmine and unexploded ordnance problems still present many unsolved problems. Attempts to use first-generation mine rescue robots reported in the press in 2000 and 2001 merely created distractions for the people who regularly have to risk their lives saving their trapped colleagues (e.g., the Australian Numbat robot [48.4]).

48.2 Applications

Applications of robotic systems in hazardous environments encompass an extremely wide spectrum. The solutions for these different environments are equally diverse. In general such applications involve unique challenges associated with the uncertainty and unstructured nature of the associated tasks. In this discussion, two application areas that are very different have been selected to give the reader a deeper sense of technology evolution, accomplishments, and remaining challenges. Landmine eradication, sometimes referred to as demining, is a current application domain with humanitarian importance and extremely difficult and dangerous outdoor conditions. Hazardous materials and operations is a decades-old problem area that has had a strong influences on many aspects of robot manipulation and mobility research and development.

48.2.1 Eradicating Landmines

Efforts to construct a practical robotic device to help with landmine clearance have met with only limited success. While remote control technology has enabled some existing machines and vehicles to be used in hazardous situations, we are still a long way from achieving reliable robotic mine clearance. It is instructive to understand why many expectations have turned out to be hopelessly optimistic.

Landmines, a simple type of victim-activated explosive device, were used extensively in Europe and North

Africa during the Second World War between 1939 and 1945. Extensive clearance operations in 1945 and 1946 removed nearly all of the landmines then in use ([48.5], part 1, pp. 15–25).

Landmines were used extensively in subsequent decades. Along with antipersonnel cluster bombs, they caused extensive civilian and military casualties in Vietnam and Cambodia from the 1960s onwards. However, it was not until their widespread use in Afghanistan, Angola, Cambodia, and several other countries in the 1980s that they were recognized as a major humanitarian problem. Landmines blocked aid efforts needed to rebuild communities following civil conflicts.

The Red Cross and the International Campaign to Ban Landmines (ICBL) successfully promoted a ban on the use of landmines that came into effect in 1997 as the Ottawa Treaty. The knowledge that thousands of children were losing their legs, even their lives, motivated hundreds of researchers to develop new technologies to help eliminate this threat. By 2000 ICBL estimated that over 80 countries were affected by landmines and other explosive remnants of war such as cluster bombs. Although many countries that have not signed the Ottawa Treaty still have extensive stocks of landmines, the treaty has been effective in restricting the use of landmines as much through peer pressure as enforcement. A few countries and several nonstate actors continue to deploy landmines according to recent reports. However, explosive remnants of war such as cluster bombs and

other munitions have become, yet again, an increasing problem in Iraq and Afghanistan.

There are several basic types of landmines and unexploded ordnance (**UXO**) that continue to cause problems in many countries.

Antipersonnel (**AP**) blast mines, made predominantly of plastic with small metal firing pins and detonator cases, typically contain between 20 g and 100 g of explosive (Fig. 48.3). These mines only cause extensive injuries when they detonate within a few centimetres of a person. Typically they lie buried just below the ground surface and are activated when the victim steps on top of the mine. Shattered fragments of bone pass through the flesh of the leg at high velocity. If the victim survives long enough to reach hospital, amputation above or below the knee usually saves his or her life but the victim will need prosthetic legs, replaced at regular intervals.

Antipersonnel fragmentation mines contain similar quantities of explosive with a thick metal case that breaks into high-velocity fragments when the mine explodes just above the ground surface. Older fragmentation mines were mounted on posts; more recent varieties lie buried but jump into the air when activated and explode at waist height, killing or seriously wounding victims up to 200 m away. These mines are much easier to de-

tect so they are often protected by nearby antipersonnel blast mines to deter theft.

Antivehicle (**AV**) or antitank mines (**AT**), made predominantly of plastic with small metal firing pins and detonator cases, are large versions of the **AP** blast mine and typically contain 5–10 kg of explosive. Some have a thick metal plate on top that can penetrate 50 cm of armor plate on the underside of a tank. These mines cause significant damage even to mine-resistant vehicles which have blast-resistant hulls, offset wheels, and additional protection for occupants.

Air-dispersed munitions such as cluster bombs (**CBs**) were not intended to be victim-activated. Several hundred are released from a single canister and they are designed to explode on impact with the ground. Typically between 5% and 25% failed to explode immediately and lie in a partially triggered state either on or just below the ground surface. Some will detonate in response to electromagnetic fields from metal detectors, and others will detonate with the slightest movement. Most explode like powerful fragmentation mines with a lethal radius of up to 200 m.

Improvised explosive devices (**IEDs**), often in the form of roadside bombs, are increasingly used by insurgent groups fighting organized military forces (asymmetric warfare). They are often made from large **UXOs** fitted with remote controlled detonators. Ironically the **UXO** is often unintentionally donated by the same organized military forces who become the targets of these devices.

Evolution of Landmine Clearance Techniques

Removing landmines is difficult. It is important to distinguish between humanitarian mine clearance and military mine clearance methods (sometimes called *breeching*). Military mine clearance has to work fast, in all conditions (even under fire), and therefore it is unrealistic to aim for 100% clearance. In humanitarian operations there is less time pressure and work can be suspended in unfavorable conditions, and the aim is 100% clearance. Recent political expectations of low casualties often demand very high clearance standards even in military operations.

Humanitarian mine clearance typically starts years, perhaps decades, after the mines were laid. The mines lie buried or hidden from view. They deter people from entering the land so vegetation often grows thickly. Drainage systems rapidly become clogged, denying access in wet conditions.

The traditional *manual* method for removing landmines has been to use a metal detector to locate metal

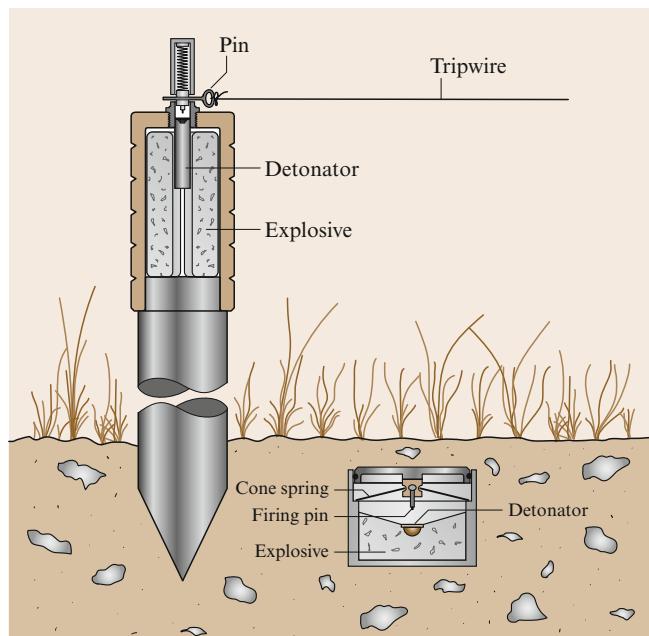

Fig. 48.3 Antipersonnel fragmentation mine (left) and buried blast mine (right)

Fig. 48.4 Typical ruined house overgrown by vegetation in a village in northern Croatia, possibly containing mines or booby traps. The entire village population was forced to leave in 1991 and the houses were looted and intentionally severely damaged. Vegetation problems like this must be taken into account in considering practical mine and UXO clearance devices. August 1999 (photo J. Trevelyan)

fragments close to the ground surface and then to carefully check each metal fragment to see if it is associated with a mine or explosive device. Any tripwires and vegetation have to be removed, with great care, before a metal detector can be used. In many areas deminers have to investigate hundreds or thousands of metal fragments for every mine found. Manual mine clearance also requires careful organization and marking of the ground

to ensure safety and thorough clearance. Currently it is still the method that guarantees the lowest risk of residual mine contamination but it is expensive, typically costing US\$1–\$5/m².

Armored mine clearance machines using hammers mounted on the end of rapidly spinning chains (flails) first appeared in the 1940s but have not been able to neutralize mines with sufficient reliability for most humanitarian applications [48.6].

In the late 1990s commercial mine clearance organizations operating in thick vegetation in Bosnia Herzegovina and Croatia realized that flails spinning just above the ground could rapidly remove vegetation and trip wires to prepare the ground for manual clearance, often assisted by mine detection dogs. Clearance costs have been reduced by up to 80% (particularly in thick vegetation) using different combinations of machines, detection dogs, and manual clearance.

Ground milling machines use metal drums studded with hard cutters that shred buried objects. They require more power than flails but can operate with greater levels of reliability. Both flails and ground milling machines have been extensively used in Croatia to recover large areas of formerly productive agricultural land. Both kinds of machines can withstand a limited number of AT and moderate-size UXO explosions before main bearings and other components need to be replaced.

Naturally, machines operate best on flat or gently sloping ground, which is also the land that is most val-

Fig. 48.5 Flail machine using hammers on the ends of spinning chains to clear vegetation and tripwires. This machine will also detonate a proportion of buried mines (inset) (photos Scanjack AB, Sweden)

able for agriculture and human habitation. Thick forest and mountainous terrain still requires traditional manual clearance and in most countries will not be cleared of mines for a long time, if ever.

Mechanized clearance methods continue to evolve with improvements to machines and techniques. Machines can be used for survey, risk assessment, and risk reduction tasks to help determine the need for more expensive manual clearance methods. Mine action programs are gradually shifting from an emphasis on total clearance in the 1990s to one of progressive prioritized risk reduction involving a series of measures including high-security fences, mechanized survey and risk reduction methods, and selective manual clearance ([48.5], part 4). Protective measures applied to agricultural machinery offer cheaper alternatives in low-AT-risk areas [48.7].

Evolution of Demining Research Priorities

Technological development in landmine clearance from within the demining community has mainly been driven by the search for improved productivity. Many of the comments in this section are based on numerous discussions with experienced demining personnel who have tried new technologies in the field. References have been cited where further detailed written information is available.

In the mid-1990s there was the expectation that, with sufficient research, advanced technology detectors could replace eddy-current metal detector technology that had been in use since the 1940s. Metal detectors also react to metal fragments in the ground. A detector that could confirm the presence of explosive, it was thought, would save having to investigate all these false alarms. The most promising line of research seemed to be data fusion: combining signals from a metal detector, ground-penetrating radar, infrared detectors, thermal neutron detectors, and even acoustic detectors. Astute observers at research conferences have pointed out that these signals were often well correlated, even in the presence of false alarms: producing a reliable detector was going to be hard work. Their forecasts turned out to be very accurate. Only one such detector is currently in operation: the handheld standoff mine detection system (HSTAMIDS) detector used by US military forces in Afghanistan employs a combination of ground-penetrating radar and eddy-current metal detection. Little information on its effectiveness has been released and no independent trials have been reported. Experienced research groups report that ground-penetrating radar requires accurate alignment of the detector with the ground surface (to

eliminate ground surface returns) and also with the target center point to enable the target to be characterized reliably. If the principal metal component of the landmine coincides with its geometric center, a common feature of minimum metal mines, the metal detector can be used for alignment. However this is not always the case and one cannot guarantee the absence of other metal fragments near the mine. Ground-penetrating radar provides confusing returns in very dry or very wet conditions and is also susceptible to false alarm indications from underground discontinuities such as stones, sticks, animal burrows etc. Publishers mostly downplay these difficulties and prefer only to report positive results, not false negatives. These issues only emerge from discussions with developers who have seriously evaluated technology in field conditions.

The major performance improvements in sensing have been obtained by compensating eddy-current metal detectors for soil magnetization, enabling them to work in a much wider range of soil conditions. Improvements in sensitivity can help with minimum metal mines but can also result in a large number of false alarms from smaller metal fragments. Metal detector arrays have been fitted to vehicles to speed up clearance of paved areas and roads [48.8].

By the late 1990s slow progress with sensors had become more apparent and research priorities after 2000 gradually turned to mine detection dogs and large demining machines.

The Afghanistan Mine Action Center (**MACA**) started using mine detection dogs around 1993 but it was not until 1998 that this program was running effectively. There were several difficulties. The first challenge was that close association between humans and dogs was socially unacceptable in Afghanistan. The second challenge was to devise ways to use dogs and manual mine clearance in an effective combination providing reliable clearance with high productivity. This was much the greater challenge, but by 1998 the cost of clearance using dogs was around one-third the cost of manual clearance. It was then that the problems started to appear: the occasional missed mine that could not be explained by lack of organization or failure to follow procedures. At the same time, carefully controlled trials of mine detection dogs in Bosnia had returned highly variable results. On several occasions dogs had walked past blocks of trinitrotoluene (TNT) lying almost visible in the ground. Yet, at the same time, a number of commercial demining agencies were routinely declaring land free of mines using similar dogs. In late 1999 the Bosnian Mine Action Center ran a carefully controlled test in which around 80% of

the dogs failed to achieve the required performance standard. The results were hotly contested at the time and the international community organized a systematic trial of mine detection dogs through the Geneva International Center for Humanitarian Demining (**GICHD**).

By 2001 it was apparent that there had been little scientific research on the fundamental physiological mechanisms that enable dogs to locate sources of explosive vapor. Dogs had been able to find mines using explosives (such as high melting point explosives (**HMX**)) with vapor pressure far below measurable detection thresholds. The mechanism by which TNT vapor and its breakdown products reach the ground surface was the subject of considerable scientific debate. By 2003 a systematic trial in Afghanistan, scientific studies at SANDIA Laboratories in the USA and in Scandinavia, explosive trace detection studies with dogs at Auburn University, and several other investigations provided some insight into this problem for the first time [48.9]. However, the precise physiological mechanisms for canine explosive detection remain unclear, especially for lower-vapor-pressure explosives. We do not know for sure whether dogs are reacting to vapor, minute particles of explosive suspended in the air, biochemical breakdown products, or a combination.

In 2003 a **US** company, NOMADICS, demonstrated the FIDO detector, the first that could reliably measure the presence of TNT vapor with greater sensitivity than a highly trained dog. However field trials showed that TNT vapor could be detected everywhere in a mine contaminated area. An explosive vapor sensor was just the beginning of the story and warns of a complex task ahead.

By 2004 the international community realized that the early confidence in a breakthrough resulting from advanced sensor technology, demining machinery, and mine detection dogs had been misplaced. **GICHD** commissioned the first serious study of manual demining to see whether productivity improvements could be made. A systematic series of trials were conducted in Africa to determine the effectiveness of several innovations such as magnets and rakes. The final report, issued in 2005, revealed that greatly improved productivity was possible but would depend more on improving contracting arrangements, management, and training than technology.

The New York attacks in September 2001 have fundamentally changed research priorities. Removing unexploded ordnance, particularly cluster bombs, became the top priority for the next 12 months in Afghanistan (Fig. 48.6). Since then the deteriorating

Fig. 48.6 Unexploded BLU-97 cluster bombs in Afghanistan early in 2002. Two of the small yellow canisters with parachutes still attached lie visible in the foreground. Others lie in the houses in the distance. Some may lie up to 40 cm below the ground surface. Some can detonate when a metal detector or mobile phone is used nearby. These devices have a kill radius of 200 m and can sometimes be set off by a strong gust of wind. They readily attract the curiosity of children (photo G. Zahachewsky and N. Spencer)

security and political situation in Afghanistan has focused mine clearance agencies more on maintaining security for their own workforce than trying to improve productivity and safety.

Resistance to the **US** and international occupation of Iraq and the easy availability of explosives both from former Iraqi armed forces and unexploded ordnance from **US** military operations led to the proliferation of improvised explosive devices (**IEDs**) to attack organized military forces and police. These have now become the main threat and the focus for much of the funding, and operational and research expertise formerly available to support mine clearance operations. This development has also placed ordnance disposal teams at the front line for the first time, rather than working in well-protected secure areas. Iraqi insurgent groups attack ordnance disposal teams both because they are attempting to disarm some of the insurgents' most effective weapons and also because they remove the main sources of explosives available to insurgent groups.

Improvised explosive devices, when detected, are often investigated and neutralized using remotely operated robots. While there are nondestructive methods to neutralize **IEDs**, the fastest method usually involves placing a small demolition charge on the device. Operational details remain confidential to reduce the risk that **IEDs** will be modified to defeat current neutralization methods.

Paradoxically it is this development that has enabled robotics to make a greater contribution to

Fig. 48.7 Bozena teleoperated demining vehicle (Way Industry, Slovakia)

the problem by contributing improvements in remote manipulation technology. These improvements come more in the form of low-cost commercial off-the-shelf components (mobile platform, motors, TV cameras etc.) than from fundamental research advances. Improvements are still being made: improved remote manipulation, blast survivability, operator interface improvements, and mobility improvements have all contributed significantly to performance and reduced operating costs.

Advances in Demining Robotics Research

In a brief survey it is not possible to mention every contribution. We have attempted to provide a sample of research reports that illustrate the main achievements and we present brief technical discussions on mobility and manipulation dexterity.

Fig. 48.8 Gryphon experimental robot on trial in Croatia (Photo S. Hirose) [48.10]

Teleoperation remains the only robotics technology that has been used in practical application in field conditions [48.11, 12]. Robotics research has not yet been able to make a significant contribution to mine and unexploded clearance work. However, the problems posed by landmine clearance have stimulated new research results that could have other applications.

Robotics researchers started their efforts in the early 1990s, for example, Stephan Havlik and *James Trevelyan* independently proposed suspended cable robots to work in minefields [48.13]. However, both have later argued in favor of alternative solutions [48.11, 14].

Nicoud [48.15] wrote one of the first surveys exploring the possibility of using robotics technology for landmine clearance. Developments in robotics research since the mid 1990s have been motivated both by a genuine desire to help combat a serious humanitarian issue and also by a desire to find a justification for more fundamental research. However, most researchers still have not learned lessons from the field such as the need to remove vegetation and the variety of situations in which deminers find themselves [48.16].

One of the most prolific research areas justified in part by humanitarian demining problems has been path planning for autonomous agents [48.17]. Probabilistic approaches were explored by [48.18]. Some researchers have proposed multiple robot solutions, even swarms of robots [48.19] and so-called *immune systems* [48.20]. Autonomous search and mapping algorithms have also been explored [48.21], including even three-dimensional search techniques for locating underground chemical sources [48.22].

Landmine clearance has also stimulated developments in autonomous robot vehicles, with many examples in the literature [48.23]. Tracked vehicles have been proposed for working in rubble and built environments [48.24]. Walking vehicles have been proposed, particularly for difficult terrain in countries like Bosnia and Afghanistan [48.25] even to the extent of examining how damaged robots with missing legs could extricate themselves from a mined area [48.26].

The desire to keep human operators away from the risk of handling unexploded ordnance has stimulated research on artificial hands and telemanipulation [48.27]. Purely mechanical devices have also been explored [48.28]. Several researchers have provided detailed results of tests with manipulators mounted on autonomous vehicles [48.10].

Robotics solutions have also been proposed partly to overcome the limitations of handheld sensors such as ground-penetrating radar. A robot manipulator can

control the motion of the sensor so much more precisely, opening the possibility of synthetic aperture techniques for both metal detection and radar [48.29].

Military research agencies in the United States, Australia, Britain, and Canada devoted large research budgets to the problem of road clearance after military casualties in Somalia and Bosnia. Insurgent forces had demonstrated that they could bring organized military forces to a complete standstill overnight simply by laying antivehicle mines in a few road potholes. With most roads in poor condition there was no easy way to detect that the mines had been laid. Insurgents would typically use mines to stop leading vehicles in a convoy in order to increase the effectiveness of an ambush.

Most research teams proposed one or more vehicles carrying multiple sensors including ground-penetrating radar, metal detector arrays, passive and active infrared, and even some acoustic arrays. Some sensor arrangements were designed to look forward sufficiently far to allow the carrier vehicle to stop before reaching a mine. Others were to be carried by lightweight remotely controlled lead vehicles. Military planners calculated that search speeds of approximately 30 km per hour would be required to be able to check roads daily in time for supply convoys to use the roads in daylight hours. Many different arrangements have been reported [48.30]. Other teams proposed teleoperated devices for landmine and explosive ordnance detection and neutralization but few anticipated the requirement to operate under armed attack. Typical requirements envisaged secure rear area mine clearance in combat situations and peace-keeping on roads and tracks [48.31] or force protection roles [48.32]. Most of these efforts were initiated in the late 1990s but by 2005 it had become apparent to military planners that vehicle protection rather than mine detection was a more practical solution. Much of today's vehicle protection technology originated in southern Africa with further development in Australia, the UK, and other countries, stimulated in part by South African expatriates.

One way to reduce the distance between researchers and field problems, at least in terms of geographic distance, has been to promote research in landmine-affected countries such as Sri Lanka and Colombia [48.33]. However this is not easy. Most countries affected by landmines have been disrupted by social conflict and destabilization that led to the military conflicts in which landmines were used. This makes it difficult for local people to create sufficient economic and physical security for researchers to pursue their work.

Future Prospects For Robotic Demining

What are the challenges for robotics researchers working on landmine clearance and other hazardous applications in the future?

We need further advances in mechatronics design, sensing, and accurate understanding of the problems to be solved using robots.

The best starting point for research is to witness people undertaking hazardous work in several different situations. Nuclear accidents, mine disasters, and burning buildings are usually off-limits to researchers. However, mine clearance operations are readily accessible in many countries. It is unfortunate that many researchers think a visit would be far too hazardous and, as a direct result, have failed to appreciate the practical difficulties involved. Photographs taken at mine clearance operations are available to provide researchers with a web site for reference purposes, partly in answer to this need to understand the practical realities [48.34].

One of the main motivations for robotics researchers has been the perception that mine clearance is a hazardous occupation and that it would be more preferable for robots to be exposed to minefield risks than human beings [48.35]. While mine clearance is certainly a hazardous occupation it is not necessarily dangerous. Accident records show that mine clearance in Afghanistan in 1998 resulted in about half the rate of injury of the United States forestry industry and about one third the rate of injury for the United States building construction industry per 100 000 working hours. Mine clearance agencies use advanced techniques to improve safety when possible [48.36]. In terms of deaths, demining is considerably less hazardous than mining, construction of building foundations, and especially offshore drilling rigs ([48.37], pp. 11–14).

Another motivation for research is to reduce deaths and injuries among local people who have to live with the daily threat of landmines and unexploded ordnance. Again, there are misperceptions of risk. The incidence of death and injury from mine explosions is often very small compared with disease, for example. The main priorities for local people tend to be improvements for water and food supplies, education, sanitation and physical security: landmine clearance is usually a much lower priority and it is often hard to justify significant local resources.

It is also important that robotics researchers intending to contribute to the solution of this problem understand the relatively small size of humanitarian demining operations, which have been funded from a combined international humanitarian aid budget of

approximately US\$400 million. These programs spend an estimated \$20 million annually on all equipment needs. The market for specialized humanitarian demining detectors is therefore very small and manufacturers cannot afford research and development specifically to support humanitarian demining solutions [48.38]. Adapting technology developed for other purposes, such as military equipment or civil engineering construction machinery, is more likely to be feasible.

The last 10 years has seen significant improvement in mine clearance techniques but progress is still slow and robotics may well provide the final solution in the long term. There is plenty of time to develop robotic techniques that could ultimately provide the only cost-effective method for removing this menace.

48.2.2 Hazardous Materials Handling and Operations

The oldest application of robotics-related technology to hazardous environments is various aspects of remote nuclear operations dating back to the beginning of serious work on atomic physics in the early 1940s. This section discusses hazardous materials and operations in the context of nuclear applications and some extrapolations to other domains. These applications run the spectrum from low- to high-fidelity manipulation and multiple mobility modes.

Many variations of remote handling systems have been in use since man has attempted to cope with hazardous environments. In the 1940s, research in atomic physics led to a new era in remote handling as scientists sought to explore the nature of materials involving ionizing radiation. As experiments became more complex, mechanical manipulator systems were created which allowed operators to perform increasingly complex tasks safely behind thick biological shielding. These mechanical systems then evolved into electrical systems that allowed larger work volumes to be considered. Incredible engineering achievement occurred in a 15 year period within the Remote Control Division of the Argonne National Laboratory. Even though this era represented tremendous technical achievement, it went further in illustrating the intrinsic complexity of remote operations. The equivalent work performance achieved with sophisticated teleoperated remote systems is poor in comparison to what human workers can achieve with direct contact operations and common tools. Typically, this form of teleoperation (i.e., manual control over a physical distance or barrier) is ten to hundreds of times slower than conventional contact operations. Remote

operations are extremely expensive and time consuming and have been the continual target of engineering improvements over the years.

Many research and development efforts have focused on different avenues for improving the work efficiency of teleoperated remote operations. These efforts have included the development of better manipulators, control stations, control algorithms, etc., all intended to enhance reliability and maintainability. In the late 1960s and early 1970s, as digital electronics became more cost effective, interest began to emerge in the integration of automation with teleoperation as a scheme to effectively increase remote operations work efficiency. It was around this time that industrial robot concepts were also introduced. Combining selective automation of specific subtasks with traditional teleoperation offers the potential to reduce labor requirements and to improve the quality of repetitive task executions. This integration of automation with teleoperation became the foundation of what is now termed *telerobotics*. From the 1970s until today, telerobotics has been an active area of research and development in many different domains that include nuclear, space, and military applications. Unlike manufacturing automation, remote operations in hazardous and unstructured work task environments necessitate human-in-the-loop control, or teleoperation, as a backstop to assure safe operations. Teleoperation related to hazardous materials and operations, in the most general sense, involve mobility and the use of manipulators to handle objects and tools to accomplish useful work in predominantly unstructured and uncertain environments.

Over the years, there have been numerous papers, books, and reports written concerning technical challenges, issues, and solutions. Readers will find *Vertut* [48.39] and *Slutske* [48.40] provide comprehensive and general information about manipulators and systems. The performance and design of effective teleoperated systems are strong functions of human factors and *Kraiss* [48.41] and *Johnsen and Corliss* [48.42] provide good discussions of key principles. Finally, control system hierarchies and structures are explained in depth by *Sheridan* [48.43].

Past Perspectives

Initially, science and experiments involving dangerous radiation levels were accomplished through the innovative use of shielding walls, long-handled tools, and mirrors. As the tasks became more difficult, mechanical arms that could do a better job in emulating human motions were pursued. These ideas represented schemes

whereby human sensing and handling capabilities could be more completely *projected* into the remote work environment [48.44]. One of the first challenges that the Argonne group tackled was the development of the mechanical master–slave manipulator. The basic concept was to create a mechanism that would have a master controller side where an operator could provide position and orientation commands to a slave-side mechanism/linkage system that would *replicate* motions and forces in the remote work area. It was felt that force reflection to and from the master and slave systems was essential for the operator’s sensory awareness of the task execution. Experimentation has repeatedly verified the significance of both kinesthetic and tactile feedback in performing more complicated tasks [48.45].

Today, master–slave manipulator (MSMs) are used around the world in nuclear, biological, and other types of hazardous remote experimentation and operations. The remote work efficiency of a dual-arm MSM with shielded-window viewing is around 5–10 times slower than equivalent contact operations. Because the master and slave sections of MSM’s are mechanically coupled through the metal-tape drive transmission, the physical separation that can exist between the safe operating area and the hazardous remote work area is limited to a maximum of approximately 10 m. Because of this characteristic and their kinematics, MSMs are restrictive in many applications and often have constrained the physical design of remote cells. The Argonne group and others recognized that it would be much better to have the equivalent of a fly-by-wire MSM in which the physical separation of the master and slave could be larger. This need led to the development of electrical master–slave manipulators (EMSs) that are commonly called electrical servomanipulators [48.46, 47]. Research and Development on the EMS began in the late 1940s and continued into the early 1950s.

The Argonne group was at that time limited by the available electrical control technology. Nonetheless, they made noteworthy progress toward integrated systems, as depicted in Fig. 48.9. The prototype system shown is a dual-arm anthropomorphic system with head-aiming remote television viewing and bilateral force reflection. After the Argonne Remote Control Division was disbanded, limited research and development occurred until the 1970s when commercial nuclear power growth was driving a number of research programs in the US, West Germany, France, and Japan. During this time, the programs in the US and France were focused on electrical servomanipulator systems which incorporated emerging microprocessor technology. The Central

Research Laboratories model M2 system, shown in Fig. 48.10, was jointly developed with the Oak Ridge National Laboratory and was the first force reflecting servomanipulator system to use distributed digital

electronics to implement position–position force reflection with multiplexed serial communications between the master and slave. The model M2 system was used over the years to explore remote operations for military, space, and nuclear applications.

The development of the advanced servomanipulator (**ASM**) followed the M2 in an effort to improve the remote maintainability of the manipulators themselves. This work was one of the earliest modular robotics efforts. The motivation for this work was to reduce maintenance technician radiation exposure and to increase the overall availability of the remote maintenance system. The **ASM** was designed from the beginning to provide a foundation for telerobotics in addition to effective teleoperation [48.48] (Fig. 48.11).

At the time of the M2 and **ASM** developments, Jean Vertut and his colleagues in the Commission de Energie Atomique (**CEA**) focused their research on the development of telerobotic functionality for their MA-23 electrical servomanipulator systems. This

research appears to include some of the earliest experimental demonstrations of telerobotic functions [48.39]. They called their concept computer-assisted teleoperation and it included both operator assists and robotic teach/playback functions. Operator assists included software jigs and fixtures designed for the improvement of the remote operation of tools such as saws, drills, etc.

In the 1980s and 1990s as nuclear power activities began to decline, nuclear remote operations technology was migrated into other areas such as space and the military. Nuclear remote operations experience with teleoperation influenced the Space Shuttle remote manipulator system and the short-lived Flight Telerobotic Servicer program.

In the mid 1990s, substantial interest developed in the application of remote handling systems to deal with problems in hazardous site/facility remediation, such as those associated with defunct nuclear facilities in the **US** and in Eastern Europe. The intrinsic complexity of remote clean up operations continues to drive research and development in all aspects of teleoperated and telerobotic systems. Challenges and accomplishments in this application area are discussed in the next section.

Hazardous Site Clean Up Applications

Robotic and remote systems have been used in assessing the status of sites contaminated with hazardous materials. These surveys are essential in planning and executing subsequent clean up operations. Such systems have been used most extensively in nuclear waste sites around the world because remote techniques are more common in many nuclear operations. There has been some use of robotic survey systems in chemical and biological hazard situations as well.

Survey Systems. Numerous robotic survey systems have been developed and used. The basic idea is to integrate a sensor suite, appropriate for the contaminants of interest, with a suitable mobile platform that incorporates remote and/or autonomous driving functions and requisite navigation and control functions. The desired output of the survey process is a *precise* map of contaminant locations and concentrations. Such systems have been developed for both outside and inside operations.

It was common practice in many industries for a number of decades to bury hazardous wastes in earthen trenches in isolated burial sites. Usually, useful records of what materials were buried at what locations either did not exist or were not accurate. In fact, the general conditions of such buried waste sites are often unknown to the extent that human entrance is not allowed. As a result, the first step toward remediation is to quantitatively

Fig. 48.12 Prototype buried waste survey robot (courtesy of Los Alamos National Laboratory)

assess the physical and hazard conditions of the site. The mobile robot shown in Fig. 48.12 is an example of a survey system used to evaluate nuclear waste buried waste sites. The robot's location is monitored with Global Positioning System (GPS). The suite of sensors includes eddy-current probes and ground-penetrating radar that reveal density contours, radiation detectors, and gas emissions monitors. This system was an initial prototype that could be operated from a remote driving station or operated in autonomous programmed trajectory mode. The system was controlled using a radio communication link. Its unique feature is that it was designed with minimal use of ferromagnetic materials to minimize interference with the magnetic subsurface sensors.

The mobile characterization system shown in Fig. 48.13 is a similar concept for radiation survey of floored areas. This particular system uses a Cybermotion commercial mobile platform, triangulation of optical

Fig. 48.13 Mobile characterization system (courtesy of Oak Ridge National Laboratory)

fiducial markers for localization, and operates primarily in a full autonomous mode. The objective in this application is to reduce labor costs and eliminate error-prone tedious human operations.

Excavation Systems. The actual remediation of buried wastes ultimately leads to digging and object-handling type operations. Various types of systems involving integrated mobility and manipulation-like functions have been developed. One of the most popular and low-cost approaches has been to retrofit conventional excavation equipment with sensor and actuators that allow remote and robotics operations. Such systems have been used in explosive ordnance disposal also. The system shown in Fig. 48.14 is called the teleoperated small emplacement excavator (TSEE) and is a prototype remotely operable backhoe for such applications. The unit included a multicamera remote viewing system that is the primary basis for teleoperation. Radio and tether communica-

Fig. 48.14 Remotely operated excavator (courtesy of Oak Ridge National Laboratory)

tions connections are used to allow the human operators to be displaced up to several miles from the hazardous operations.

Deactivation and Decommissioning Systems. In recent years, one of the most complex forms of hazardous operations is the deactivation and decommissioning (D&D) of defunct facilities where nuclear radiation or toxicity hazards preclude human presence. D&D can be thought of as remote demolition for the most part. Some operations are crude such as knocking down building structures and debris removal. Other operations may involve careful disassembly of equipment and devices, size reduction and packaging of handling/storage. These operations are essentially the inverse of remote maintenance and require the dexterous use of tools and handling of objects. Tools include saws, hydraulic shears, impact wrenches, and the like. Planning and situational awareness are very important in demolition-type operations because the physical layout and stability of the basic environment is changing during the process. Effective remote viewing (adjustable multiview capabilities) and acoustic sensing are essential. Audio feedback from the remote environment provides the human operator with the ability to monitor the normalcy of tooling operations such as sawing. D&D applications require manipulators that are both dexterous and massive. Experience has shown that payload capacities on the order of 100 kg are needed to deal with debris handling, typically with manipulators of the type shown in Fig. 48.15. Figure 48.16 is a frame view from one of the remote viewing cameras used to operate a similar system that was used to D&D an old experimental nuclear reactor. A manipulator is being used to teleoperate a conventional circular saw to segment a large-diameter aluminum tank. This operator view of the remote environment provides a realistic perception of the task environment lighting conditions and complexity.

In recent years, numerous remote manipulation systems for nuclear applications have been developed

Fig. 48.15 Dual-arm D&D manipulator system (courtesy of Oak Ridge National Laboratory)

Fig. 48.16 Operator's view of a remote sawing task (courtesy of Oak Ridge National Laboratory)

around industrial robots. These systems are augmented with sensors and master controller arrangements to facilitate teleoperation. This approach offers significant cost savings and the level of teleoperation performance achievable in complex task environments has steadily increased [48.49–53].

48.3 Enabling Technologies

There are a number of technology issues that are key to the design and implementation of mobile robots that can operate effectively in different types of hazardous environments. A few of them are touched upon here to give the reader additional insight into the foundational aspects of this class of robots.

48.3.1 Mobility Issues

Hazardous application such as fire fighting, EOD, and demining naturally include uneven ground in indoor and outdoor environments where a normal wheel-type robot cannot easily operate. It is critical to have a mobile

mechanism with a good negotiability in uneven ground conditions. Most mobile mechanisms are classified into wheel type [48.54–57], track type [48.58–63], and leg type [48.64]. For negotiability in uneven ground, the wheel and track types need additional linkages with ground adaptation. There are two kinds of this adaptation: active and passive adaptation. Active adaptation uses an additional actuator to alter the linkage's motion while in passive ones the linkage motion is controlled by the ground conditions and gravity effects.

Stability Conditions

Stability should be considered in the design process to prevent rollover on uneven ground including stairways, steps, and natural terrain. Stability can be investigated in terms of three parameters: *center of mass*, *supporting area*, and *stability margin*. Stability requires that the center of mass remains inside of the supporting area, as shown in Fig. 48.17. The supporting area is a polygon built by the edges connecting each projection point on the horizontal plane. A conventional vehicle has limitations in rugged terrain due to a fixed center of mass with respect to the body coordinates. The center of mass greatly affects the stability margin (the minimum length between the center of mass and edges of a supporting area). If the center of mass is located out of the supporting area, rollover occurs. The stability margin of a conventional vehicle is mainly determined by the inclination of landform. Many vehicles are designed to have a low center of mass, thereby obtaining a large stability margin on a slope. Furthermore, a vehicle is often designed to have multiple bodies to overcome this limitation. For a multiple-link mechanism, the center of mass varies and the relative motion of links when traveling over the landform also alters the supporting area.

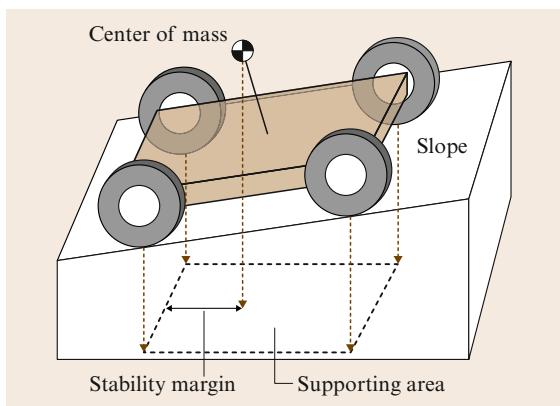

Fig. 48.17 Stability condition

Active Adaptation Mechanisms

An active adaptation mechanism uses an additional actuator to generate motion of the adaptation linkage on rugged ground. Although additional actuators and linkages are required, the adaptation mechanism can overcome variously shaped rugged landforms.

It is known that a vehicle can negotiate an obstacle which is smaller than radius of a wheel. One may think that a vehicle which has large wheels can pass over rough terrain like a monster truck. However, most applications require a small vehicle to drive between obstacles.

A deformable wheel or its equivalent mechanism can be adopted: insufficiently inflated wheels, as shown in Fig. 48.18a, adapt to irregular terrain by deformation of wheels. However, their size should be big enough to negotiate rough terrain, so this concept still has size limitations. Their equivalent mechanisms are relatively compact and yet they need sophisticated articulation mechanisms, as shown in Fig. 48.18b. Two wheels are attached to a link that rotates about a main body. Therefore, revolution and rotation of wheels are made as shown in Fig. 48.18b. If rotation is provided by actuators at the main body (i.e., an active mechanism), the vehicle has an equivalent wheel whose radius is equal to that of the rotation. The vehicle in Fig. 48.18b can pass a sill via carriage rotation, although the radius of a wheel is smaller than the height of the sill.

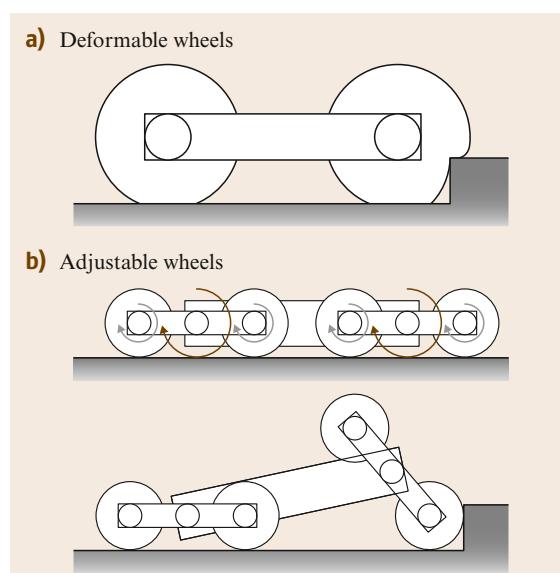

Fig. 48.18a,b Wheel configurations (a) deformable wheels, (b) adjustable wheels

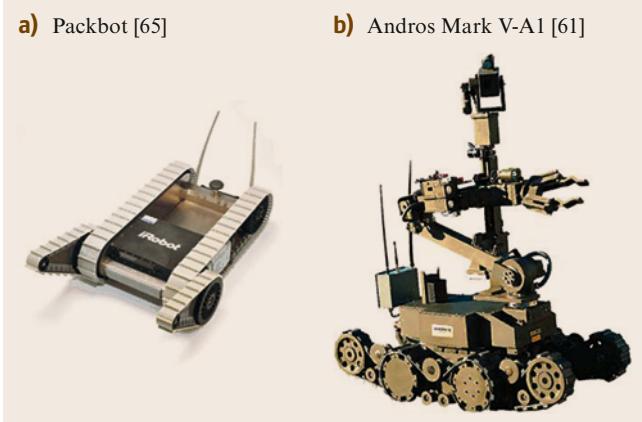

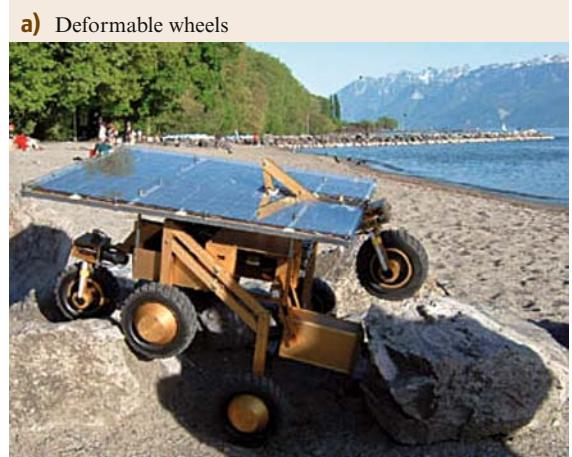

Fig. 48.19a,b Mobile robots with active adaptation mechanisms
(a) Packbot [48.65], (b) Andros Mark V-A1 [48.61]

Many track-type mechanisms have multiple linkage structures with active adaptation [48.60–63, 65]. When traveling over uneven ground, these mechanisms can negotiate rugged ground by changing the configuration of multiple track mechanisms, for example, typical multiple-tracked robots with active adaptation such as *Andros* [48.61] and *Packbot* [48.65], as shown in Fig. 48.19a and b, commonly uses a small active additional track called a flipper. By using the flipper when spinning on the ground the robot reduces undesired friction torque between the ground and the track by lifting up the flippers. When climbing up stairs, touching the flippers down to the ground can increase the stability by enlarging the supporting area. Snake-like robots use active interconnecting joints [48.62] and have the potential for mobility and manipulation.

Passive Mechanisms

Passive adaptation mechanisms do not use any additional actuators; rather they simply utilize the gravity effect to generate adaptation to irregular ground. This approach is less adaptive but enables the operator to drive the robot easily because he (or she) does not have to take care of controlling the adaptation mechanism. Passive mechanisms usually include various kinds of passive linkages activated by irregular ground conditions.

For the wheeled vehicle shown in Fig. 48.18b, a passive mechanism can be designed in which no additional actuators are needed, for example, when a wheel meets a sill whose height is greater than the radius of a wheel, it will become stuck. Then high torque is exerted at the wheel since the stall torque is usually greater than the normal rotation torque of the wheel. In this case,

a) Deformable wheels

b) Adjustable wheels
Fig. 48.20a,b Mobile platforms with passive adaptation: (a) Soleo-Shrimp [48.57] and (b) Robhaz-dt3

a closed linkage without any actuator except the driving wheels can generate a passive motion to climb over the sill [48.55], for example, a smart mobile robot with passive adaptation called *Soleo-Shrimp* (depicted in Fig. 48.20a) can climb up an obstacle by lowering the instant center of rotation of the passive four-bar linkage when coming into contact with the vertical surface of the obstacle [48.57].

Similarly, multiple bodies with tracked and chained passive joints can also adapt to irregular landforms. The track type is inherently insensitive to the unevenness of ground. Thus passively chained multiple-tracked bodies can provide greater reliability and better capabilities in ground adaptation. For example, a mobile robot with a passively chained double-tracked mechanism called *Robhaz* (shown in Fig. 48.20b) is a practical design with

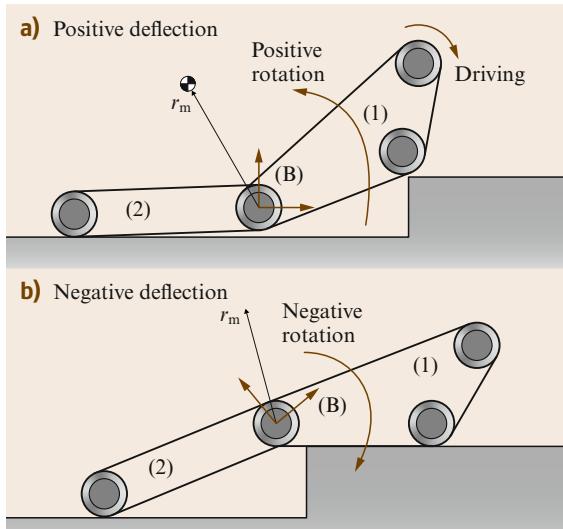

Fig. 48.21a,b Passive adaptation of double-tracked mechanism: (a) positive deflection and (b) negative deflection

simply adapted multiple tracked bodies with passive joints [48.63]. As depicted in Fig. 48.20, two tracks of the Robhaz rotate positively or and negatively according to the contact situation between the track and the stair surface. Based on this behavior, in terms of the lower center of mass (Fig. 48.21a) and the supporting area (Fig. 48.21b) better stability in stair climbing than that of a single-tracked vehicle can be achieved.

48.3.2 Manipulator Design and Control for Hazardous Object Handling

Manipulation is essential for EOD missions. Generally, EOD missions have two phases: (1) approach, and (2) object manipulation to achieve ordnance neutralization. The second phase is generally controlled by teleoperation. Both the human's careful control and innate intelligence, plus appropriate manipulator design and control, are needed for such dangerous tasks.

Design Requirements

Unlike industrial manipulators, the design of manipulators for many robots in hazardous environments does not require very fast movement. Instead, high payload, lightweight, and compactness are more important. Therefore, many manipulator designers locate actuators and reducers, which typically have high weight and large volume, on the base or lower links. This reduces the weight of the moving parts of the manipulator

Fig. 48.22a,b Hazardous application robots with manipulator: (a) Packbot with manipulator and (b) Robhaz-dt2 with manipulator

and offers better stability and dynamic control properties. Consequently, they have a thin profile, as shown in Fig. 48.22a,b. This characteristic is usually associated with explosive ordnance disposal-type robots that require access to congested areas and normal human living spaces. Mobile robots used in other hazardous environments can be much larger, depending on the specific applications. Refer to Sect. 51.2.2 for examples.

48.3.3 Control for Hazardous Tasks

In most cases, the operator does not have much information about the environment around the robot and the manipulator. He may have very limited vision, and unexpected collisions between the manipulator and obstacles can easily happen, even if he (or she) tries to be very careful. The robot should be able to handle these risks by appropriate design of the manipulator and good con-

trol algorithms. There are several ways to solve these problems.

Proximity sensors that detect objects around the robot and/or mounted on the manipulator can be used to avoid a collision before it occurs [48.66]. However using many proximity sensors necessitates large wiring bundles and complex manipulator design. Force control is also a good way to handle collisions. When a collision occurs, the manipulator can move away from the collision point by using force/torque sensor data. Often a six-axis force sensor attached at the end-effector of the manipulator is used for the force control [48.67]. Many researchers have developed stiffness/compliance/impedance control methods for a manipulator with a force sensor. However, this method can only handle a limited collision zone – only the end-effector or the manipulator *hand* – because the sensor cannot sense contact with intermediate links, while a collision could occur at any point on the manipulator. For this reason, some manipulators use joint torque sensors at all of their joints [48.68]. When using a joint torque sensor, contact at any point on the manipulator can be sensed, however, gravity compensation and errors in the transformation from the joints to the Cartesian space introduce further difficulties.

The stability of telerobotic systems, particularly when force feedback or reflection is involved, remains a critical issue. Systems involving significant data communication time delays are even more difficult. National

Aeronautics and Space Administration ([NASA](#)) groups have studied stability and bandwidth issues numerous times over the years; one of the more recent studies is provided by *Uebel et al.* [48.69]. Energy methods have been applied to this problem, resulting in new ideas entitled *passivity* control that show promise for enhanced stability and performance [48.4, 70].

Master Controllers for Teleoperated Manipulation

In teleoperation, the robot is designed to be a faithful slave to deal with a dangerous task while the operator uses a control interface to direct the slave from a safe location. The user interface usually provides a means for

- sending position commands to the manipulator
- providing contact force feedback or force reflection to the user

Ideally, the design goal of a user interface is to make it *transparent*, so the operator feels as if he or she is directly manipulating the object handled by the slave manipulator. To achieve this transparency, there are several design issues

- Simplicity:
 - All indicators are unified as one scene.
 - All input button and joystick are integrated into one haptic device.
- Intuitiveness:
 - High-level command by speech recognition.
 - Human-friendly feedback such as graphical displays and human voice.
 - Motion command matching between the haptic device and the slave in Cartesian space.
- Portability:
 - Small/lightweight and human-friendly design for wearability
 - Tetherless operation without communication lines and additional power.

An example of wearable multimodal user interface is provided by [48.71], as shown in Fig. 48.23. The operator wears a head-mounted display (**HMD**), head tracker, and headset to interact with the slave. A six-degree-of-freedom haptic master is attached on his waist together with the standalone controller, and the operator grips its handle to telemanipulate in Cartesian space. All the control hardware including the batteries are packed into one backpack, so that the user can walk around to gain a better view during teleoperation. It includes radiofrequency (**RF**) and wireless local-area network (**LAN**) modules enabling completely

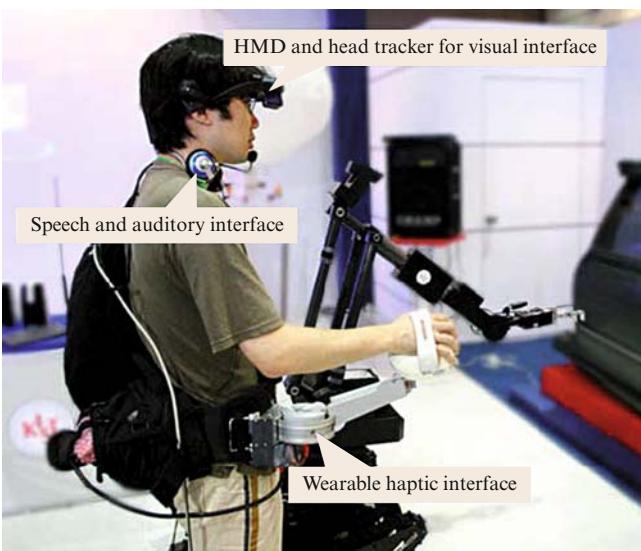

Fig. 48.23 Appearance of proposed wearable multimodal user interface

wireless communication. It is composed of major three interfaces.

Speech and Auditory Interfaces

An operator usually sends two types of commands to the robot: selection and continuous motion commands. For example, the selection between mobile and manipulation mode, the reset of the robot arm and mobile base, the on/off and reset of pan-tilt motors, speed selection for the mobile platform, selection among installed cameras are defined in the selection commands. It is convenient if the operator can issue these commands by speaking to the controller. When the operator says a word that has been predefined as a command, the speech interface can sense that word and, if the speech recognition system successfully recognizes it, the recognized command pops up on the **HMD** for confirmation. Finally, the operator decides whether to execute or cancel the command with a confirmation button on the haptic master.

The auditory interface synthesizes the human voice using a speech synthesis engine. It can warn of the approach of an obstacle by sound, or reveal the distance and direction to a laser-designated object nearby.

Wearable Haptic Interfaces

A wearable haptic device is shown in Fig. 48.23. The base linkage is designed as a serial RRP mechanism to measure a translation, and an RRR z-y-z rotation mechanism is attached at the end of the base linkage.

Figure 48.24 shows a wearable haptic master device for teleoperation of mobility and manipulation systems. It has six degrees of freedom for motion input and three degrees of freedom for force feedback.

To achieve a compact design and reduce its weight, a tendon-driven mechanism is designed into each joint.

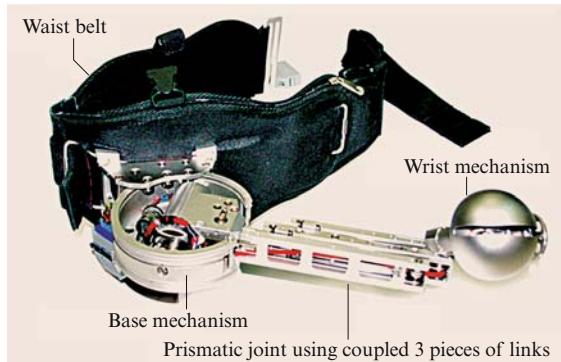

Fig. 48.24 Picture of wearable haptic device

Due to weight constraints, only three actuators are installed for force feedback, and each actuator is specially designed to fit the joint. Because a passive actuator is better than an active actuator with respect to power density (power per unit volume or weight), small magnetorheological (**MR**) brakes have been developed. They are installed at each joint of the base linkage for force feedback. Also a compact brake drive with current feedback capability has been designed, which reduces the response time of the **MR** brake. The controller is packed into a bag that is attached to the back side of the waist. Because it includes brake driver module, satellite controller, wireless **LAN** module, and battery, it can operate without cable connections.

Visual Interfaces

The visual interface integrates the robot's view, the status of sensed data, and the status of speech commands. Since the slave includes a stereoscopic camera, the user sees a three-dimensional view on the head-mounted display (**HMD**). The operator wears the head tracker and it generates a pan/tilt command from the two-degree-of-freedom head motion. In the integrated system, head tracker data is used to command the direction of the remote viewing camera, thus the user easily

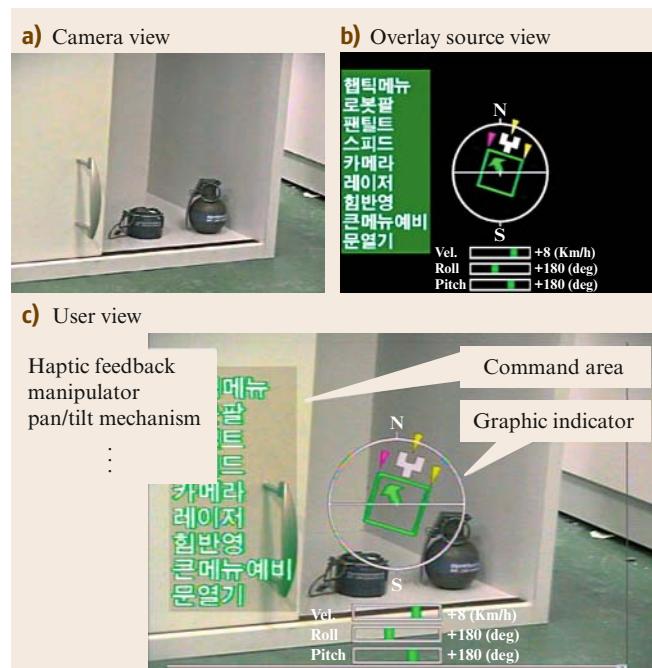

Fig. 48.25a–c Appearance of integrated visual interface: (a) camera view (b) overlay source view (c) user view

looks around the environment of the robot, as shown in Fig. 48.25.

Moreover, the head tracker is useful to indicate an object as a target. The operator moves his head and looks at a target to get information of direction and distance, then triggers a laser displacement sensor that is placed in parallel with the pan–tilt camera. The vision information is sent via a **RF** channel while the sensed data is fed back via an independent wireless **LAN** channel to reduce the data communication traffic. A source for video overlay is prepared with the reported data, as shown Fig. 48.25. The recognized speech command is highlighted on the left for confirmation. When an ultrasonic sensor detects an obstacle, it shows a round robot icon in the middle of the scene. Other useful and important information (i. e., velocity, heading direction, view direction, arm posture, etc.) are shown by bar graphs. These are overlaid on the remote video source pictures and unified into a single scene. Finally the operator sees the stereoscopic picture and the status of the robot at a glance on the immersive **HMD**. The overlaid view is shown in Fig. 48.25c.

48.3.4 Data Communications

Robots used in hazardous environments are almost always mobile so that they can move about an area of interest with flexibility. The combination of mobility and intrinsic operation across a physical or hazard barrier introduces unique problems with respect to bidirectional data communications (refer to Fig. 48.1). Communications from the operator location to the robot is necessary to achieve remote control or teleoperation. Communications from the robot to the operator are essential to

connect the operator's perceptive skills into the remote environment. The transmission of the electrical and/or optical signals comprising such data communications can be quite complex due to a host of factors such as penetration of physical barriers, signal transport delays, signal attenuation, and data throughput requirements. As summarized in Table 48.1, data throughput requirements are dominated by the feedback of visual imagery or remote camera views from the mobile system. Channel capacity necessary for audio feedback and control are small in comparison. If the mobile system involves precision manipulation with force feedback, bidirectional data channels on the order of 1 Mb/s are required.

For a mobile robot with high-fidelity manipulation, multichannel remote viewing, and other sensors, on the order of hundreds of megabytes per second are required for the data communications path from the remote environment to the operator station while on the order of ten megabytes per second are needed for the bidirectional control link. Communications at these data rates are straightforward with the use of retrievable hardwired cabling or tethers. Tethered systems complicate mobility and reliability significantly. Tethers that combine signal and power conductors are difficult to pay out even with servo-controlled deployment/retrieval reels and are often snagged on obstacles such as debris. Free-space radio or microwave signal transmissions at these rates in the cluttered environments often associated with hazardous robots are much more difficult and require specially designed systems. Data throughput requirements can be reduced through data compression and reduced frame rate schemes with effective results in many cases.

Table 48.1 Example data communications requirements

| Type | Single channel | Typical system |
|--------------------------------------------------------------------------------------------------------|--------------------------------|--------------------------------------|
| Standard black-and-white remote television: 600 × 400 pixels 30 frames/s 12 bit gray scale | ≈ 10 Mb/s per viewing channel | 30–50 Mb/s for 3–5 channels |
| Color remote television: red, blue, and green = 3× black and white | ≈ 30 Mb/s per viewing channel | 90–150 Mb/s for 3–5 channels |
| Control 12 bit resolution input and output 200 Hz sampling rate | ≈ 4.8 kb/s per control channel | 48 kb/s - ten control servo channels |
| Audio feedback 15 kHz signal capture 12 bits resolution | ≈ 180 kb/s per audio channel | 540 kb/s - three remote microphones |

48.3.5 Energetics

Another key challenge in fielding mobile robots in hazardous environments is in the area of energetics including power supply, consumption, conversion, and management. The specifics of the given environment often restrict the types of power supply/conversion that are permissible, for example, the use of combustible fuels and internal combustion engines is seldom allowed within nuclear facilities but are entirely acceptable in demining and most outdoors operations. The most common power systems used today are electrochemical batteries and electric motor drives. The power and energy density map [48.72] given in Fig. 48.26 shows the fundamental situation for mobile robots used in hazardous environments. For perspective, a small passenger automobile is estimated to need a minimum of 200 Wh/km to meet road demands, which in turn translates into 500 Wh/kg. This is why hybrid electric vehicles that combine spark ignition engines with battery-powered electric motors are becoming popular. A large mobile robot with dual manipulators operating in the payload range of hundreds of kg would have power requirements similar to these and would be well above the 100–200 Wh/kg range that batteries can provide. A force-reflecting six-degree-of-freedom robot manipulator with a 20 kg payload will have a peak power consumption on the order of 10 kW. If a particular application domain is amenable to the use of spark ignition

engines, the order of magnitude power density compared with any type of battery-powered system makes implementation feasible. If pure battery power is necessary, then considerable attention must be given to the design, including state of charge monitoring and mission provisions for recharging. In the future, emerging fuel-cell technology may provide better solutions for mobile robot power systems.

48.3.6 System Architectures for Real-Time Mission Control

Because of the intrinsic nature of hazardous environments where uncertainty and lack of geometric structure are prevalent in the task environment, shared control architectures are commonly used. The degree of human interaction runs the gamut from pure teleoperation (manual control) to high-level intelligent control operations (autonomous). For example, most low-cost EOD type robots utilize simple manual control architectures, while at the other end of the spectrum, the MARS Rover robots operate as autonomous agents responding to mission-level commands from human operators on the earth. The basic architectures for real-time mission control are summarized in Fig. 48.27 [48.73]. Also, see *Sheridan* for a comprehensive discussion of architecture principles and design [48.43]. Between the manual and autonomous control exist combinations of computer assistance and semiautonomous (i.e., selective and in situ task automation) functions intended to improve remote work performance by either reducing operator workload or allocating tasks more suitable for computer control to autonomous execution. It is important to recognize that, as one moves from manual control toward autonomous control, the data throughput rates for communication and control are reduced because high-level commands are comparatively small packets of information while force-reflection manual control of a manipulator, for example, requires visual feedback and high-bandwidth control interconnection of the slave and master controller. The data communication bandwidth available has great bearing on the type of architecture that must be used. Untethered undersea applications usually require semiautonomous architectures because of the bandwidth limitations of acoustic communications links.

As intelligent systems research advances, it is expected that, for hazardous situations, robots will employ semiautonomous and autonomous architectures to a greater degree as a fundamental approach to overall performance optimization. Operators will be able to choose the control mode based on the task needs

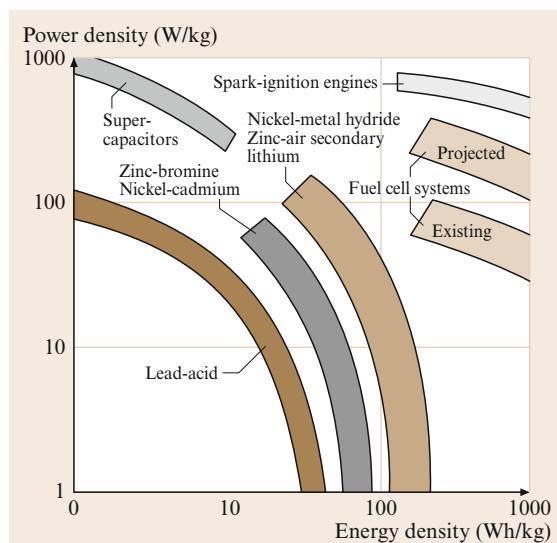

Fig. 48.26 Power and energy density for various power storage and supply systems

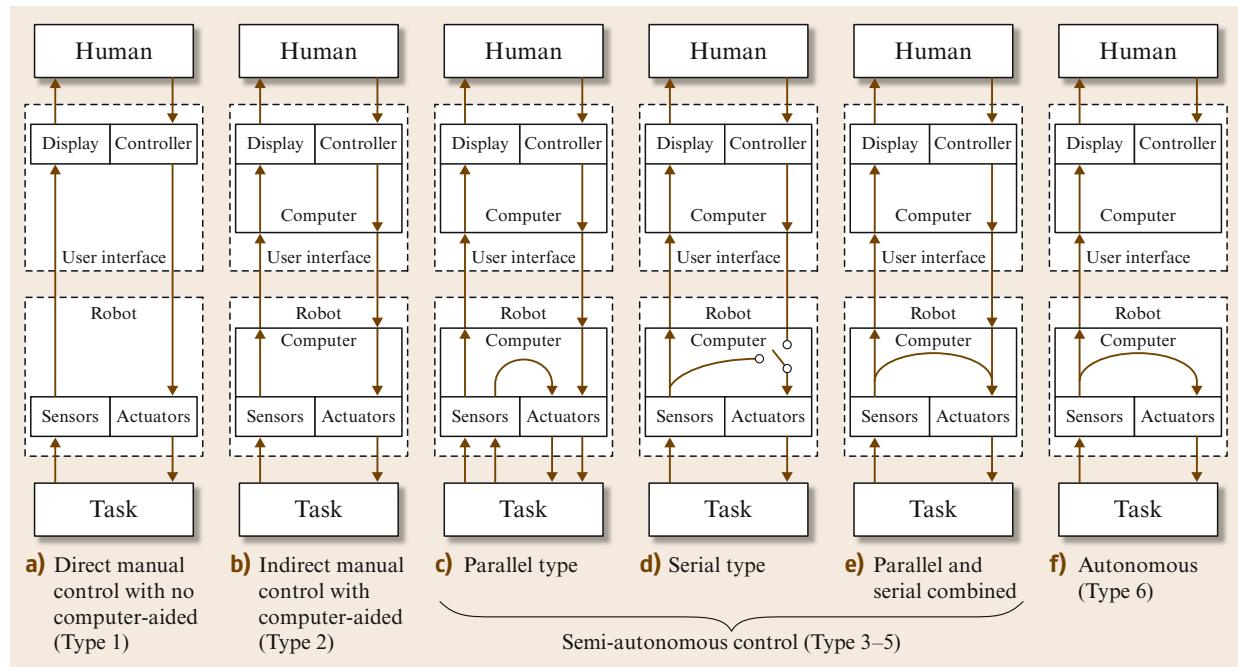

Fig. 48.27a–f System control architectures

and the likelihood that autonomous execution can be reliably achieved. In this human-centered way, task

execution mode will be matched to best achievable performance.

48.4 Conclusions and Further Reading

If we are to learn anything from the experience of the last decade we must appreciate that robotics research is just one step in the development of tools that extend human capabilities. This search for improved tools is as old as humanity itself so great patience is required [48.74].

Researchers need to make significant advances on four different fronts: mechatronics design, sensing, machine intelligence, and problem understanding.

- Mechatronics designers have to trade gains in precision, dexterity, mobility, and strength for losses in endurance and reliability. We are mostly well short of biological (e.g., human) capabilities except for high-precision applications. Machines have much the same environmental tolerance as people. Machines need special precautions against heat and cold outside the temperature range of 0–35 °C, and operation beyond –60 °C or +60 °C is usually impractical. Dust, radiation, low or zero air pressure,

fumes, biological agents, even insects can be fatal for machines without special design features, which may result in performance reductions. Maintenance or repair work may necessitate decontamination before people can work on the machinery.

- While electronic sensors can go far beyond biological capabilities, hazardous applications still present problems far beyond present capabilities as we have seen in the case of landmine applications. Radiation levels that are lethal for humans can also quickly kill electronic sensors. Extreme heat or cold limits performance, as can contamination, and even insects.
- Advances in usable machine intelligence have been much more difficult than many expected. The only real progress has been achieved with capabilities often associated with clever people: logic, mathematical manipulation, and playing games. Even the least intelligent animals have capabilities that still defy present-day understanding. However, teleoper-

ation and supervisory control can make up for this deficit in the medium term. Shortcomings in machine intelligence represent less of a barrier than the other three fronts.

- Understanding the intended application and economic factors has proved to be equally important for researchers. Early applications rely on exploiting particular opportunities with specific applications to generate confidence that inspires others to persevere with more difficult problems. Failures in understanding, particularly with economic factors, undermines confidence, and leads to disappointment and disillusioned researchers. Attempts to develop landmine clearance robots provides a useful case study that illustrates some of the difficulties in developing robots for hazardous applications.

There is no question that future teleoperators will become hybrid telerobotic systems that allow seamless transfer between manual and autonomous operations. Specific tasks will be selectively automated by operators for the purposes of enhancing quality and/or reducing

subtask execution times. Early systems will continue to incorporate high levels of human interactivity to accommodate the limitations of current intelligent systems technology. Low-cost embedded computational power will continue to track Moore's Law, making real-time execution of complex control algorithms and virtual-reality-like graphics engines (which are really useful) routine. Robust machine learning that allows human task execution skills to be captured through learning by observation will become realizable. Through micro-electrical mechanical systems (**MEMS**) and engineering miniaturization, all types of sensors particularly imaging sensors will be more powerful and less costly. In the next decade, telerobots for hazardous environments will become smarter and their relationship with their human operators will become more cooperative and less interactive. Human operators will supervise the operation of multiple telerobots. However, telerobots will remain subordinate and the need to assure human-takeover capabilities through teleoperation will always be present.

49. Mining Robotics

Mining Robo

Peter Corke, Jonathan Roberts, Jock Cunningham, David Hainsworth

Mining is the process of extracting mineral resources from the Earth for commercial value. It is an ancient human activity which can be traced back to Palaeolithic times (43 000 years ago), where for example the mineral hematite was mined to produce the red pigment ochre. The importance of many mined minerals is reflected in the names of the major milestones in human civilizations: the stone, copper, bronze, and iron ages. Much later coal provided the energy that was critical to the industrial revolution and still underpins modern society, creating 38% of world energy generation today. Ancient mines used human and later animal labor and broke rock using stone tools, heat, and water, and later iron tools. Today's mines are heavily mechanized with large diesel and electrically powered vehicles, and rock is broken with explosives or rock cutting machines (Fig. 49.1).

Mining remains hard and hazardous work and the scope for the application of robotics is very high. Mining requires the handling of enormous quantities of material in a cost-effective and safe manner. High operational costs, the need for greater productivity and improved health and safety outcomes are powerful drivers for robotics. Existing approaches to improving productivity

and safety through training, work practices, and larger and improved machine design are providing diminishing returns. The industry is close now to a tipping point where robotics and automation will provide the next step change in productivity and safety. A review of the global status of robotics in operating mines as of 2006 can be obtained from [49.1].

49.1 Background

For the purposes of this chapter, mining may include minerals, coal, salts, gemstones, tar-sands, shale oil, and construction material, which we will refer to collectively as commodities. Commodities may be exposed at or close to the surface, or deep underground. They may be concentrated into seams or veins or evenly dispersed

so that a significant amount of waste material must also be extracted and dealt with. Economic black coal is always found as a monolithic seam, a consequence of the manner in which it is formed by vegetable matter accumulating on the floor of ancient seas and lakes. Gold can be evenly disseminated or found in seams of quartz that

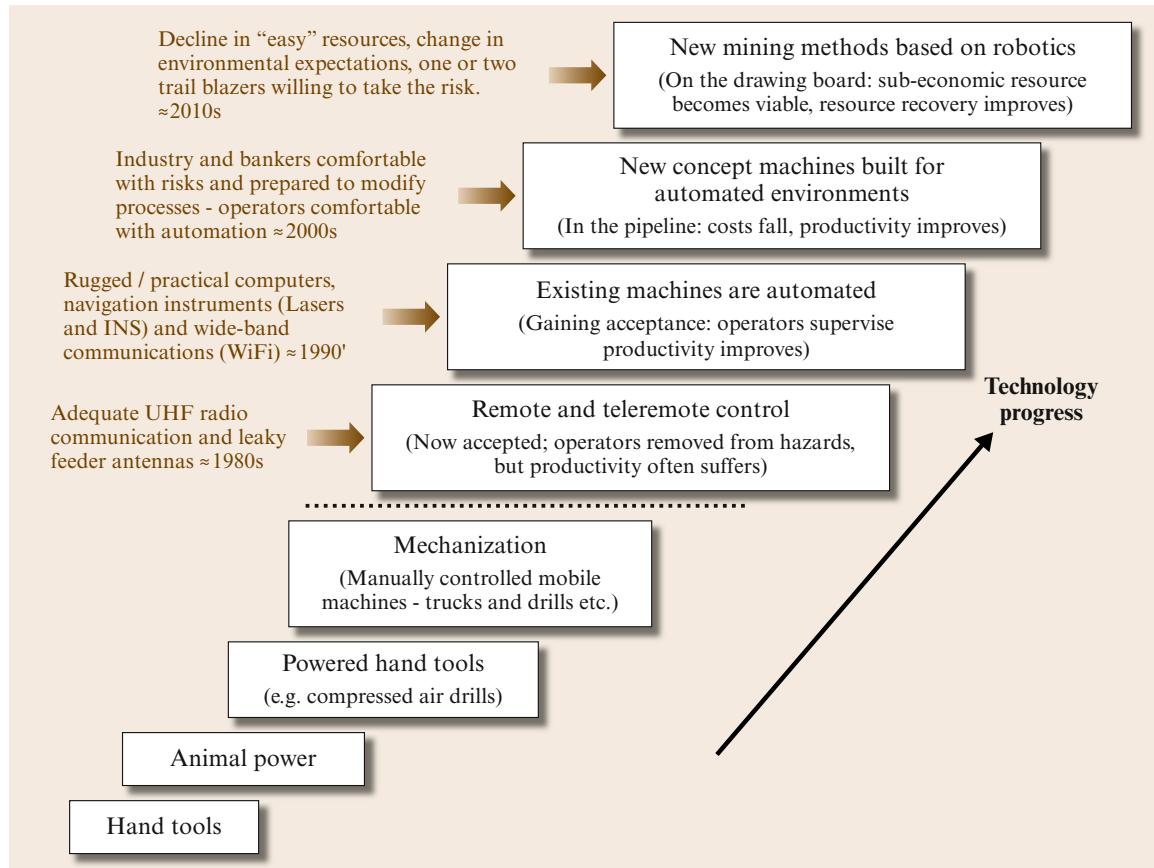

Fig. 49.1 Evolution of mining technology

was long ago forced through fissures in the surrounding rock mass. Some mineral deposits such as Canada's Sudbury nickel, are speculated to have come from me-

teorite impact so the resource is distributed around what seems to be an extremely large crater. The extraction of petroleum and natural gas is not generally considered as

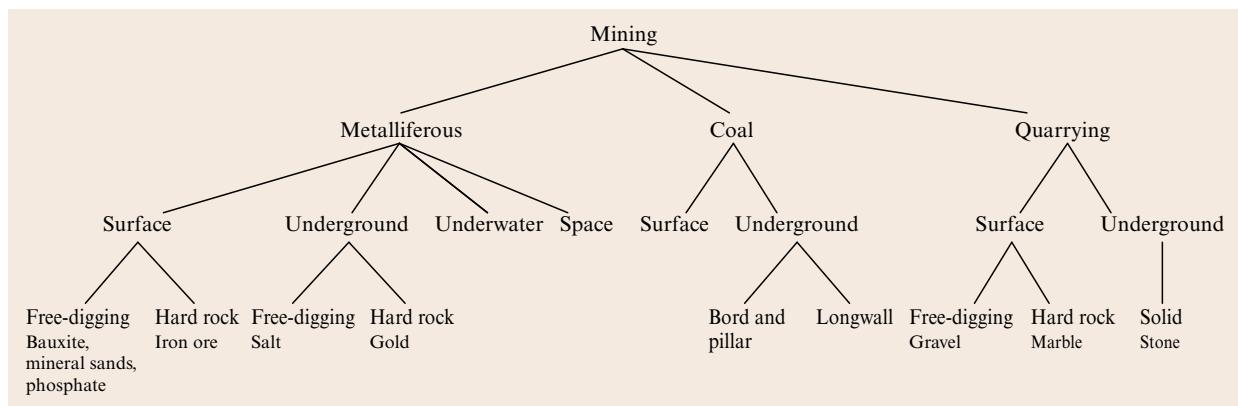

Fig. 49.2 A taxonomy of mining

mining and will not be discussed in this chapter. Mining may occur on land, below the surface, on the ocean floor, and in the future in space. A taxonomy of mining is presented in Fig. 49.2 as a framework for discussion. The first row distinguishes the different broad class of material that is extracted. Metalliferous refers to metal-bearing ores. Coal is found as black coal, a hard black *rock-like* material, or softer wetter brown coal. Quarrying refers to the extraction of stone, gravel or sand which is used as a building material or for use in concrete and road base.

The second row in the taxonomy differentiates the location of the material. Those on the surface of the Earth are extracted using large open-pit operations such as shown in Fig. 49.3. Underground mining methods are more expensive but are used for deeper material and this requires excavation of shafts and tunnels. Mining of deep ocean trench, black smoker sulphide resources is just beginning. The grade, or mineral concentration, of these resources is very high by terrestrial standards and mining methods are just being developed. The cost of reaching these resources is extremely high, and concern about fragile underwater ecosystems has acted as a brake on their exploitation.

The third row differentiates the physical state of the resource. Free digging materials such as bauxite, mineral sands, oil shales or salt can be simply *scooped up*. Harder materials need to be fragmented, typically by placing explosives in holes drilled into the ore. Rock cutting methods are sometimes used but this is applicable to only a small range of materials and the cost of cutting tools and power to drive the cutting process are often limiting factors. Development in this area is driven primarily by advances in hard materials for the cutting teeth.

Fig. 49.3 An open cut coal mine with a dragline excavator (US Bureau of Land Management, Washington)

A marked difference between current techniques for free-digging materials such as coal and hard rock (metalliferous) mining is the continuous nature of the former compared to the cyclical nature of the latter. Soft material can be extracted and conveyed to the surface continuously, whereas in the case of hard rock mining the process is generally not continuous, requiring breakage through blasting then loading and hauling on a cyclic basis.

49.1.1 Robotics in Mining

In this chapter we distinguish between several related technologies: automation, teleoperation and robotics. We define automation as conventional computer- or programmable logic controller (PLC)-based control systems, and teleoperation as remote control of equipment by an operator using information provided by video cameras and graphical display of machine state. This section discusses various aspects related to the introduction of robotics in mining.

Differences from Factory Robotics

Existing mining equipment is typically hydraulically actuated and either diesel or electrically powered. Work tools or end-effectors are often located at some distance from the operator and power source. Loads and masses are high and the equipment is expensive. In robotic terms, equipment is heavy, compliant and mobile. Localization, particularly absolute localization, is extremely difficult. The operating environment may also be extreme, in terms of high temperatures, salty and acidic water, and exposure to rockfall and robust treatment. The equipment may also be hazardous to humans, and in the transition period before fully robotic mines, the issue of human safety is paramount. Current prototype mining robots are essentially converted mining machines, but over time they will evolve to be purpose-built robots.

Acceptance by Mine Owners

To date, there have been few successful and practical robotic applications that have met the difficult operational requirements. There are some good reasons for this. Unlike traditional areas that have high uptake of robotics/automation such as factories and even mineral processing plants, the mining environment is not stable and is in a constant state of evolution. Machines and people must be adaptive and flexible and engage the natural terrain where they find it. Mining environments are difficult to alter to suit the easy application of automated machines. The design and configuration of factory and

process machinery can easily be optimized and integrated into a well-performing and stable system. Before finance can be raised to establish a mine, the resource needs to be well defined and valued. This is essentially a geoscience-intensive statistical process resulting in some uncertainty. This may leave little tolerance to accept risk in the downstream activities such as mine design, construction, and equipment selection which are predominantly engineering focused. Mine designers and ultimately investors like to use data and experience from existing successful operations. Therefore, any introduction of technology, including new mining methods is likely to be incremental, evolutionary, and undertaken with minimal disruption to existing production.

Many in the mining industry have little familiarity with robotics or its potential. Mining engineering is a combination of mechanical engineering, geomechanics, geology, finance, and management. It is critical that other disciplines work closely with production-focused mining engineering staff so that the technology will be fit for purpose and/or the uptake will not be inhibited through a lack of understanding of business needs. Significant progress is often made by adapting technology developed for other markets and disciplines.

The Need for Integration

When a mine is in operation, there can be many unexpected conditions that present challenges to conventional robots that excel in well-controlled environments. The inability to manage exceptions will usually negate any superior performance that might be expected based on operation under controlled conditions.

Robotic machines must be integrated with manual operations and their effects on up- and downstream processes must be properly considered, for example, if an automated machine requires an isolated area for safety reasons, and the same area requires regular or periodic access by people, then the benefits may be lost. To capture the benefits, other mining processes need to be modified to suit and a *systems* approach is recommended.

Remote control is often a good first step towards automation. The use of remote control either within line of sight or with the aid of video cameras/sensors (teleoperation) is now accepted by the mining industry, although it has yet to achieve market saturation. At the time of writing, a range of existing machines are being converted to *robots* through the application of automation technologies. Most notably these include highwall mining machines, load haul dump vehicles (LHDs), rock drills, and haulage trucks.

There are few suppliers of this specialized equipment and they are experiencing significant demand beyond their production capability. Robotic conversion of draglines and coal shearers is now possible and prototype systems are being installed. New concept machines, such as for the robotic installation of ground support and explosives, are at prototype stage or undergoing early field trials. New mining methods that are designed from the outset for robotic machines (see, for example, Sects. 49.2.3 and 49.3.3) are currently on the drawing board waiting for finance and trials.

The wide diversity of mining operations, methods, and environments will also be discussed because these affect the selection, design, and limitations of robotic applications.

Productivity

Productivity gains from consistency of operation, rather than an increase in basic production rates, is a priority. Because of the inability of current automated or robotic mining systems to match the sensing and control functions of operators, such systems are unlikely to match the peak performance of the best operators. However the strength of automation systems is their ability to maintain consistent equipment operation over extended periods of time. In an essentially continuous process this brings real benefits. Moreover, equipment operation can be constrained to always lie within performance bounds, conferring benefits in enhanced equipment reliability and improved product quality translating to availability and thence to productivity.

The largely batch nature of metalliferous mining and the time taken to change shifts often provides an opportunity to automate equipment so that it operates continuously during meal breaks and shift changes. Typically, two to three hours can be saved each shift in this way, especially if machines can be controlled from a centrally located control room. Access to the machine can then be limited to regular servicing or relocation. Hot-seat changeover is also used to address this issue, although this often results in increased labor costs and longer or overlapping shifts. In the case of LHDs, improved productivity of 20% has been experienced through automation.

Health and Safety

When considering safety, it is self-evident that there are potential benefits if people can be removed from the hazardous environments near a mining face or equipment. Here, injuries from explosive atmospheres, noise, dust, rockfalls, and moving equipment are commonplace.

In China, there have been more than 5000 fatalities per year in the coal mining industry, although the numbers are falling steadily. Figure 49.4 shows the declining number of fatalities in the Australian mining industry from statistics published by the Minerals Council of Australia (MCA). Further examination of this data identifies two categories of fatal injury that are significantly higher than all other categories: *vehicles or mobile plant* (31%) and *slides, cave-ins or rockfalls* (25%). When some of the other equipment-related incidents involving entrapment or machine faults are included, the *vehicle and mobile plant* category increased to approximately 36% of mining deaths over that period. The third most significant category relates to *falls, slips, and trips* (10.5%). Similar category distributions were found in the US mining and quarrying industry (National Institute for Occupational Health and Safety (NIOSH) statistics). It is obvious that people cannot be hurt by mobile equipment if they are not close by. Hence removal of operators from the area using robotic technology with compatible procedural controls is a viable solution.

In both coal and metalliferous underground mining, access tunnels must be supported by one or more methods including rock bolts, sprayed concrete, and steel mesh. There is always a period of time and location where ground support has not been installed following blasting or cutting and there is a risk of rockfall. Installation of ground support involves manual and mechanized activities and is a hazardous task. According to Potvin et al. [49.2] there has been a significant reduction in injuries from metalliferous mine rockfalls since 1998. From Potvin's report, mining procedures and training have played a significant role in the reduction. However, the majority of rockfall deaths still occur in access tunnels (drives) less than 10m from an active mining face. Two-thirds of these deaths occurred during the installation of ground support or explosives charging. Again the logical way of reducing or avoiding fatalities and injuries is by removal of operators from the immediate vicinity where possible.

In order to make a significant further reduction in the number of mining fatalities and injuries without changing mining methods, the following areas need to be addressed as a priority with the introduction of robotic technology and proximity protection:

- Mobile equipment (LHDs, trucks, longwall equipment)
- ground support installation processes (including scaling and coal mine roadway development)

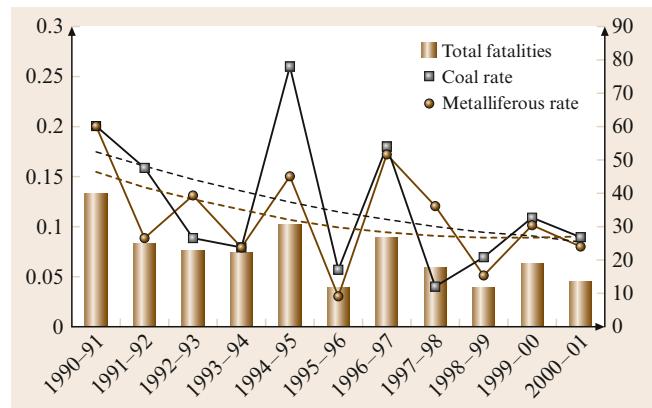

Fig. 49.4 History of fatalities in the Australian mining industry. Left x-axis is Fatalities per 1M man hours. Right x-axis is number of fatalities

- explosive placement
- rock drilling

It also needs to be acknowledged that some early introduction of close-range remote control and automation of existing mining equipment has actually resulted in deaths and injury. This was largely caused by a heavy reliance on procedural controls to maintain isolation from people. Operators were killed or injured by accidentally running over themselves or being caught in machines during maintenance. Poor design of control systems and interlocks may also have contributed to these incidences and has led to the development of industry standards. Failsafe engineering controls are critical to any robotic installation.

Acceptance by Miners

Despite the clear health and safety benefits there are perceptions in the workplace that these technologies will impact adversely on job security. The effect of this should not be underestimated but it can be managed. Consequently the current thrust of robotics and automation development in mining is to employ these systems to remove operators from direct roles in the most hazardous operational areas to safe-area supervisory and backup involvement. The robotics challenge is to develop the sensors necessary to replace the functions currently carried out by operators in the hostile operating environment, making their work easier.

There are many undesirable, monotonous, and hazardous tasks that can be addressed as a priority with general acceptance of the workforce if correctly introduced. Removing people from these activities to

a role that involves supervision of a process instead of moment-by-moment operation will generally be well received by operators because it makes their work easier and safer. Robotics also enables a reduction in the mining workforce as productivity improves and this can cause resentment in some mining communities. This can be managed through natural attrition as the workforce ages and people are less inclined to seek employment in the industry. Over the longer term the skill base will change and new jobs will be

created in knowledge-intensive areas associated with development and maintenance of robotic equipment. In Western countries with ageing populations, the shortage of skilled workers willing to live the hard and often remote lifestyle will drive robotics. Robotic mining could also keep mines open longer when it becomes uneconomic to mine using existing methods, mirroring the effect observed in the automotive industry where robotics has kept factories open rather than displacing workers.

49.2 Metalliferous Mining

For the purpose of this chapter, *metalliferous* is defined as all mined materials apart from coal, oil, and gas; for example, targeted materials may include, copper, lead, zinc, silver, gold, diamonds, iron, and aluminium. Several mining methods are used to recover metalliferous ore and references can be consulted for more detail about each [49.3–5]. Mining methods can be broadly categorized into surface and underground. Variations on the methods relate to the type of ore body or rock rather than the commodity or mineral they hold. For example, components of interest can be *disseminated*, that is distributed relatively evenly through a large volume of terrain. Here the boundaries of the ore body must be defined by the economics of mining. Such ore bodies are typically extracted using *mass mining* techniques. Ore can also be distributed in veins or tabular shapes ranging from a few centimeters to many meters thick. The boundaries of these ore bodies are typically defined by geology and they favor methods that are more selective, especially for underground mining.

Ore types can also be defined by hardness and the stability of the rock mass. Hard-rock ores usually require *drilling and blasting*. In some circumstances they can be made to cave-in if a large enough slot of rock is removed from below the volume of ore. Unconsolidated materials such as phosphate, salt, mineral sands, and bauxite are usually mined using excavators, rippers, shovels, and even dredges. Little or no explosives are used except where the ore is capped by hard, barren rock. These ore bodies are free digging and often alluvial in origin. Mineral sand is often mined using dredgers that float on an artificially created pond in the mineral zone. Sand is sucked up by a dredge and pumped to a processing plant. Another example of alluvial ore is presented by surf-zone marine deposits of diamonds which are located off

the southern coast of Africa. Here, the heavier diamonds are separated from sand through wave action and they become trapped in rock crevasses under the surf zone of a beach. Such deposits are mined using what is essentially a giant vacuum cleaner.

The following discussion of mining methods and infrastructure is made with the emphasis on aspects that are important for the design and application of robotics.

49.2.1 Underground Hard-Rock Metalliferous

The cost of underground mining can be between two and ten times greater than for surface mining. Therefore ore needs to be relatively rich to be economically viable for underground mining.

With some exceptions, metalliferous mining is a batch process involving a sequence of physical operations including:

- exploratory drilling
- geological and geotechnical mapping
- developing access roadways or tunnels (development)
- drilling and blasting of areas containing the ore (*stopes*)
- extraction and haulage of the broken ore
- back fill of extracted zones and rehabilitation

There are a large variety of different metalliferous mining methods that will weigh these separate process steps differently. Each has different opportunities for automation and robotics. Metalliferous mining has a significant reliance on explosives. However, new rock cutting technology is now emerging that will see a shift

away from explosives, at least in the development of access roadways and for some surface mining [49.6]. Rock cutting applications will benefit from a high level of robotic control. In metalliferous mining there is a strong emphasis on total extraction of the resource, which often means that voids left by mining must be filled to ensure geological stability.

Figure 49.5 shows one example of an underground mine layout. Here, the mine has progressed from a surface mine to an underground mine as the easily available ore is depleted (e.g., the Kiruna mine in Sweden). In some cases, underground mines can also evolve into surface mines (e.g., the Kalgoorlie Consolidated Gold Mine in Australia).

Layout and Environment

Access to underground is either by a declining tunnel (decline) or shaft or sometimes both. A decline is a descending tunnel with a typical gradient of 1:7 which is also known as a ramp. Cross-sectional dimensions are typically between 5 m and 6 m and the road surfaces consist of compacted gravel, often mixed with finer material such as tailings to assist with consolidation. Road maintenance is a critical task that significantly affects the productivity of heavy vehicles. The Kiruna iron mine in Sweden is an exception because it has a bitumen decline roadway that is suitable for normal highway vehicles. A typical decline will consist of a series of straight sections between 200 m and 400 m long which are joined with a relatively tight 180° spiral turn to keep the tunnel in close proximity to the ore body. In some mines the decline is a continuous spiral for its whole length. Exits are placed periodically to give access to mine working levels, which consist of a network of tunnels. Tunnels are often called *drives* where they run roughly inline with the ore body and *crosscuts* where they cut across the ore body. The terminology is not strictly defined. Usually the roadways are one-way and contain periodic passing bays. The traffic is mixed, with light four-wheel-drive (4WD) service or utility vehicles operating together with large haul trucks that may have a gross vehicle mass of up to 110 t.

Virgin rock temperatures can reach 80°C, so operating areas including stope are ventilated using air pumped from the surface. Sometimes air must be cooled and this is usually done near the operating areas using water that has been chilled at the surface and piped underground. Ventilation circuits are well managed and monitored to ensure operating areas are not downstream of any dusty, radioactive or fume-laden areas. This repre-

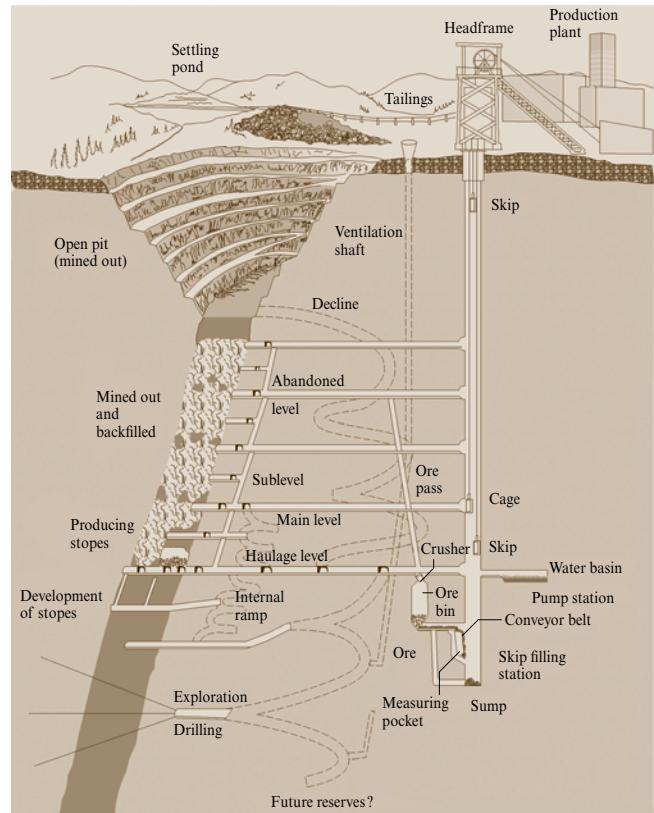

Fig. 49.5 Typical hardrock mine layout also showing transition between surface and underground mining [49.5]

sents a significant cost which can be mitigated through the use of robotics that can operate in poorer quality atmospheres.

Often mine workings intersect aquifers, giving rise to wet areas that must be drained. Mine water is often more salty than sea water and can also be extremely acidic. Electronic enclosures must be well sealed or drained and sometimes cooled. Developers also need to be aware that enclosures that are sealed in humid conditions may experience internal condensation if subsequently exposed to cooler conditions.

Block Cave Mines

The block cave underground mining method (Fig. 49.6) is the lowest cost underground method because once in production, the rock collapses and fragments under its own weight [49.5]. This minimizes the amount of explosives, equipment, and unit operations. Typically the ore bodies are large, disseminated, highly fractured or with low-tensile-strength rock. They may take a num-

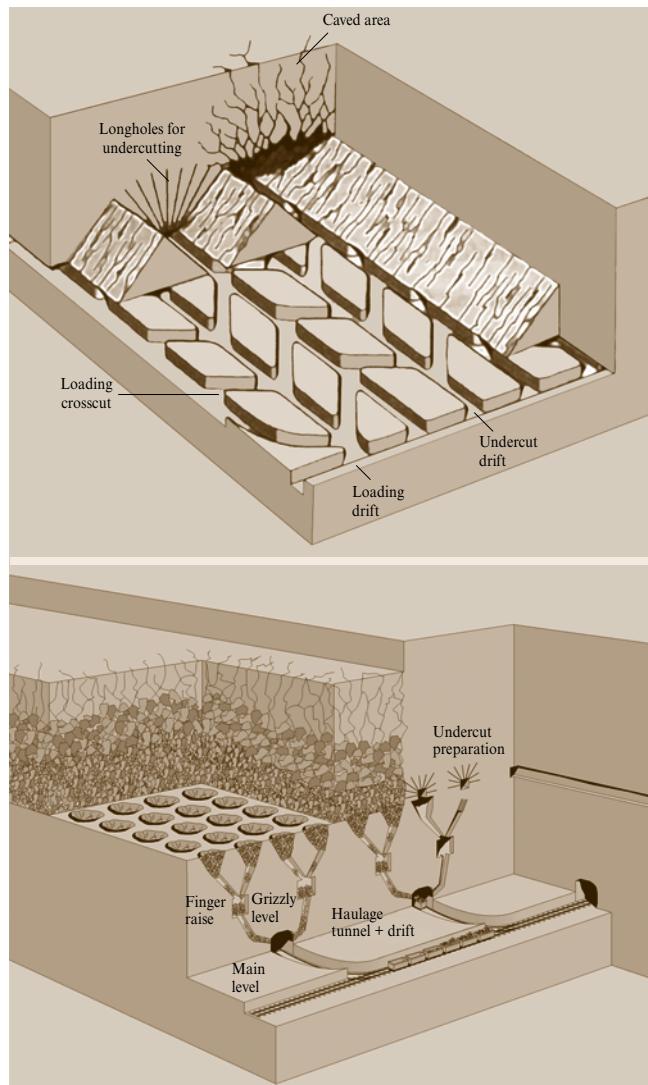

Fig. 49.6 Typical block cave underground mine

ber of years to extract, so a high level of infrastructure can be justified. This method approaches a continuous operation and is well suited to automation and robotics.

To create the cave, a large horizontal slab of ore called an *undercut* is removed at the base of the ore. The virgin rock can then no longer support itself and it caves. The broken ore flows downward and continues to fracture until it reaches a series of draw points which are linked to a tunnel network. Underground loaders (LHDs) pick up the ore from the draw point and take it to an underground crusher. There are several activi-

ties in block caving that may be suitable for robotics are

- automated loading and haulage
- ore hang-up clearance (including blasting)
- survey and inspection
- secondary rock breakage to clear large rocks

Stoping and Sublevel Caving

There are several other commonly used mining methods that have unique characteristics that differentiate them from a mining engineering perspective. However, for the application of robotics, they can be grouped together because they share similar challenges and equipment. These methods include:

- room and pillar
- narrow vein
- vertical crater retreat
- sublevel caving
- sublevel open stoping
- cut and fill

A classic example of a sublevel stope method is shown in Fig. 49.7. Examples of the other methods can be found in [49.3–5].

For these methods, access is gained to the ore body at various levels and the ore is fragmented, either entirely by drill-and-blast or in combination with caving (sublevel caving). These methods involve drilling holes for explosives and loading the explosives. Unlike block caving, these other mining methods are highly mobile, infrastructure is short term, congestion is heavy, and through traffic is common in the active areas. Careful consideration is required for isolation of any robot from manual traffic.

Activities similar to those mentioned for block caving are also suitable for robotic application with the addition of production and development drilling and ground support. For these mining methods there is a significant amount of tunnel (roadway) development, which is often a rate-determining step. The activities involved are all undertaken close to an active face and are therefore hazardous. This is a cyclic process with different heavy equipment continually deployed and replaced as the tunnel progresses.

Communication Infrastructure

Underground radio communication is challenging because of the wide variation in rock conductivity

and the geometry of mine voids. Radio communication propagates with high attenuation through tunnels and voids and is significantly affected by vehicles and steel infrastructure. Currently the most common form of communication remains very high-frequency (VHF)/ultrahigh-frequency (UHF) radio which is propagated through *leaky feeder* coaxial antennas throughout the mine workings. VHF/UHF radio is used mainly for voice but also for serial data communications. For equipment teleoperation, UHF systems can also carry analog video on amplitude-modulated (AM) frequencies. Frequency-modulated (FM) video is rare because of the cost and the unusual effects caused by the highly dispersive nature of the mine terrain. If an unfortunate choice of wavelength is made, the tunnels and voids may act as waveguides and filters. This produces a complex and unstable performance for both AM and FM that can result in signal strength variation of 60 dB over tens of centimeters and significant interference from vehicles and other infrastructure.

With the relatively recent evolution of Ethernet and WiFi technology [49.7], such systems are gaining popularity and will soon be common. WiFi systems are now in common use by advanced mines and they usually include a fibre-optic trunk link from the surface to distributed access points underground. Because of the Ethernet protocol, radio propagation anomalies result in reduced and variable data rates and communication is less deterministic compared with analog communication. This variable and significant latency means that caution is required when using WiFi for control and alternate and independent safety systems are thus required. Radio transmitters are usually power limited or are otherwise isolated to avoid accidental ignition of detonators and other explosives. WiFi systems suitable for safety-critical control applications are emerging.

Through-rock radio communication is also available but it can only support data rates of tens of characters per minute in one direction (base to field). This mode of communication modulates low-frequency electromagnetic fields (a few kHz) generated from a long loop antenna located near or around production areas. The antennas carry high current at low voltage and communication shadows often exist near highly conductive ore. This communication mode can be used for issuing simple messages to personnel or simple control commands (off/on) to equipment. New technology for bidirectional through-the-rock communication is under development.

49.2.2 Scope for Robotics

This section will review aspects of underground metalliferous mining with a focus on the opportunity for, or impact on, robotics and automation.

Underground Transport

In all types of underground metalliferous mining, material must be moved from where it is mined to the surface. The movement of the material can be achieved using either conveyors, haulage vehicles or hoisted bins (*skips*). Conveyors and hoists have been largely automated using factory automation technologies.

Mobile vehicles are used to carry ore out of the mine along the declines, or to move ore from the face to loading points underground. Underground haul trucks are typically diesel powered and ascend at about 6–10 km/h, fully laden, and descend at about 20 km/h. Electric haul trucks are rarer and use pantographs to tap overhead power and are usually faster than diesel trucks, ascending at 18 km/h and descending at 24 km/h. Mobile haulage vehicles are normally used where a high

Fig. 49.8 A load haul dump (LHD) vehicle

level of flexibility is required and in particular at a mining face.

For almost all underground metalliferous mining, load-haul-dump (LHD) vehicles are used in the ore transport process. LHDs (Fig. 49.8) are configured like front-end-loaders with a large bucket but are articulated so that they can manoeuvre in relatively small spaces and through tight corners. The vehicles are *trammed* between the pick-up and dump points, which could either be a temporary stock pile, crusher, chute, shaft or haul truck. LHDs are rarely used to carry material for a distance beyond 600 m. Their maximum speed is ap-

proximately 20 km/h and they may have a clearance of less than 1 m to the tunnel wall either side. This is a tedious and hazardous task for manual operation. These vehicles can be diesel or electrically (via a trailing cable and onboard winder) powered.

The two obvious motivations for automating haulage vehicles are improved efficiency and safety. Improved efficiency can result from reducing labor costs, increasing operating duty, reducing wear and hence maintenance costs. Automation can be approached in a staged manner with each level of sophistication bringing benefits as shown in Fig. 49.9. The operation of LHDs is hazardous because the vehicle must venture into areas that are potentially unstable with a relatively high chance of rockfall. Traditionally LHDs are manually operated for the tramping cycle but operated by line-of-sight remote control while they operate in hazardous areas. Regularly changing the operating mode is time consuming and hazardous. Accidents have occurred where an operator has been crushed by the LHD as it returns from the stope by remote control. To avoid this risk, many mines now use teleoperation for the entire tramping cycle [49.8, 9]. However, this typically leads to slower tramping times than if the operator was onboard, which is due to the reduced perception and lack of feedback to operators that naturally occur when they are no longer on the vehicle. Hence, onboard vehicle navigation is the obvious solution to remove the operator from the hazard and maintain high-tramping speeds and productivity.

The automation of LHDs has been investigated by a number of researchers over the past two decades. Early systems used buried wires in concrete roadways as guidance infrastructure for LHDs [49.10]. However, concrete roadways are not common in metal mining operations and so this solution is of limited use. A common approach was to use an optical marker placed on the center line of the roof along the length of the tunnel. An upwards-facing camera was then used to track the lights and estimate the offset of the vehicle, which was fed into a steering controller. Early systems used either a painted white line [49.11] or retroreflective tape [49.12, 13]. Another system used a row of lights suspended from the centerline of the tunnel roof [49.14, 15].

Following painted lines, lines of retroreflective tape, lines of lights or wires buried in the ground has its limitations. The lack of longitudinal information (along track data) means that the speed of the LHD must remain low as the vehicle does not know when a corner is coming up. Solutions to this are to provide additional means of measuring along-track position, which could

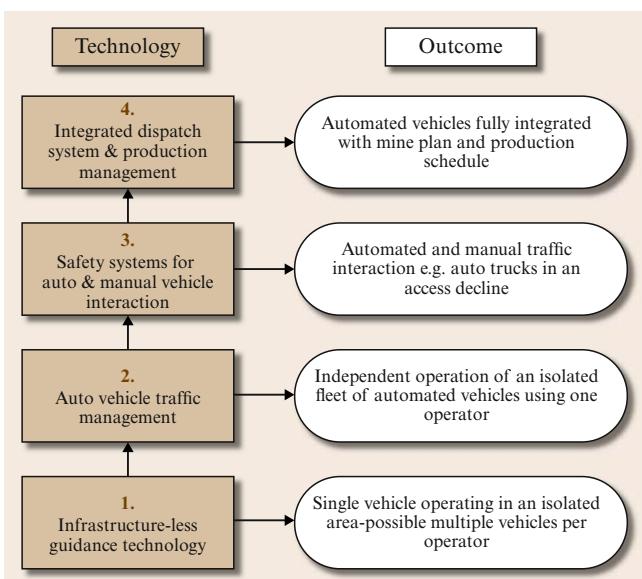

Fig. 49.9 The evolution of automated mining vehicle technology and the outcomes that could flow from each stage

be odometry and some other absolute system such as radiofrequency identification (**RFID**) tags to correct the drift of the odometry.

The availability of the two-dimensional (2-D) laser scanner in the mid to late 1990s saw the development of new-style LHD guidance systems. Some of these systems worked by using reflective markers placed along the mine walls at regular intervals (tens of metres) [49.16]. The LHD localized itself using a map of the beacons and the observed range and bearing readings to the beacons as observed by a 2-D laser scanner. This data was fused with odometry information and inertial data (such as heading rate and acceleration). Another system used the detected free space ahead of the vehicle, as determined by a 2-D laser scanner to reactively steer the vehicle [49.17]. This system also used the topology of the mine, again as determined by the 2-D laser scanner data, to localize the vehicle for high-level navigation purposes such as speed setting, turn decision making at intersections, etc. This approach was successfully demonstrated in a production mine in mid-1998, was subsequently commercialized and is now available as a product. Other approaches to feature-based localization underground are described in [49.18, 19]. Automated trams systems for LHDs are available commercially from Tamrock, Caterpillar and Atlas Copco and market uptake is growing rapidly [49.1].

Traffic control is another important issue particularly in *mixed fleets* of human-driven and robotic vehicles. Currently each mine vehicle is equipped with VHF/UHF radio and local communication procedures are adopted to manage traffic. In some mines a decline is divided into segments or *blocks* and traffic lights (block lights) are used to indicate that a segment is occupied. A set of rules is used to give priority to ascending vehicles and heavy vehicles. A common control for autonomous vehicles is segregation of autonomous and manual equipment operations through the establishment of safety barriers to exclude people from the operational area. However these barriers are quite extensive and difficult to maintain, and cause significant operational constraints. Reliable collision and pedestrian detection is required.

Drilling

Semiautomated drilling of blast holes for the purpose of roadway/tunnel development or in open stope mining is now a reality. Drilling machines are available that can drill a ring of holes autonomously with little supervision over periods of a shift or more. There are strong control challenges with this class of machine due to the large outboard mass of the drill, the long telescoping

arm which is compliant, combined with flexibility in the hydraulic actuators and the mobile base.

Drills are still manually placed and setup, and autonomous mobility and positioning would be the next development.

Explosive Placement

The loading of drilled holes with explosives, detonators, and primers is still an active area of robotics research [49.20]. Current practices see miners assembling detonators and primers and explosives are either pumped or placed manually into holes (with the aid of hydraulic machinery). Detonators and wiring are installed and linked back to an *exploder box* to initiate the blast (sometimes from a central location). This job is hazardous, not because of the handling of explosives, but because of the confined nature of the operation and the proximity of the miners to the hydraulic equipment (booms) and the solid tunnel walls. There are a number of robotics challenges associated with this task including locating the drill holes, assembling the primers and detonators, and inserting the hose into the drill hole. The positioning problem is hard for the same reason as for drill control: a large mass to be positioned using a nonrigid manipulator. End-effector-mounted sensors can be used to map the holes and provide the fine control to guide the explosive charging tube into the hole. Explosives and associated detonators can then be pumped into the holes as required.

Secondary Rock Breaking

One of the aims of underground hard rock mining to break the rock (most commonly with explosives) to a size that can be easily handled by the haulage vehicles, conveyors, and lifts. The spacing of blasting holes, their length, and the quantity of explosives used are optimized to achieve the ideal fragmentation size of the rock. However, sometimes a boulder is created that is too large to be handled. These rocks are typically broken with additional explosives *in situ*. Particularly problematic are large rocks that jam the flow of ore in the draw point of a block cave mine. Drilling and blasting these rocks is very hazardous and would be a strong candidate for robotics.

There is a class of smaller boulders that can often be moved by an LHD or haul truck but that is too large to be fed into a rock crusher before lifting to the surface. The chute to a rock crusher is guarded by a grill called a *grizzly*. The size of the grill openings is made so that only rocks small enough to be crushed may pass through. Larger rocks do not fit and must therefore be broken

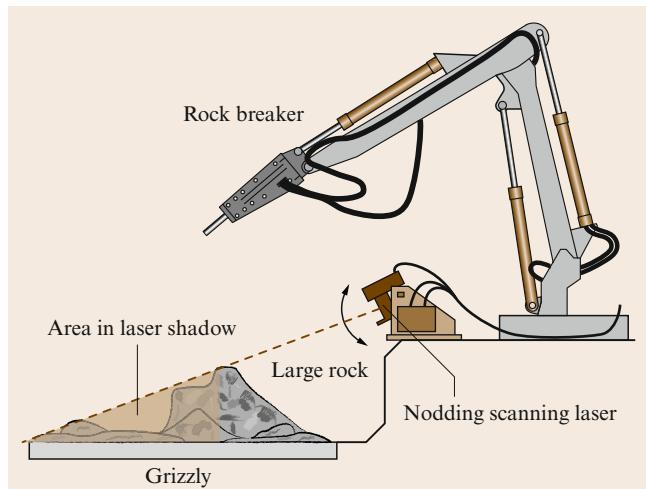

Fig. 49.11 Mechanical rock breaker

on the grizzly in order to pass through it. This job is carried out using a mechanical rock breaker, as shown schematically in Fig. 49.11. Rock breakers consist of a hydraulic or pneumatic jackhammer with a pick tool on the end mounted on a hydraulic multijointed arm driven by a human operator. The task of rock breaking is a logical one to be automated as, due to its infrequent nature, it is hard to justify a full-time operator when oversized rocks may occur a few times a day. The key research issues are sensing and perception, detecting when a rock needs to be broken, or simply needs nudging through the grizzly and then determining where on the rock to place the jackhammer pick in order to break the rock [49.21].

Metalliferous Roadway Development

Underground metalliferous mines use tunnels or roadways to access ore and facilities. These tunnels may sometimes be called declines, inclines, drifts, cross-cuts, drives, and development headings depending on the function and region.

Traditional roadway development involves the steps shown in Fig. 49.12. Each cycle will extend the tunnel 3–6 m. The first step in the cycle is to survey and map the shape, location, and geology including grade and geological features. Note that the nature of the terrain has only been interpolated from drill core extracted at sparsely spaced locations. This work is done by surveyors and geologists before the ground has been supported. This is a hazardous zone which may not have settled since the previous blast. Research for robotic survey using photogrammetry, scanning lasers, and multispectral

Fig. 49.10 Tamrock drill jumbo for developing tunnels in metalliferous mines

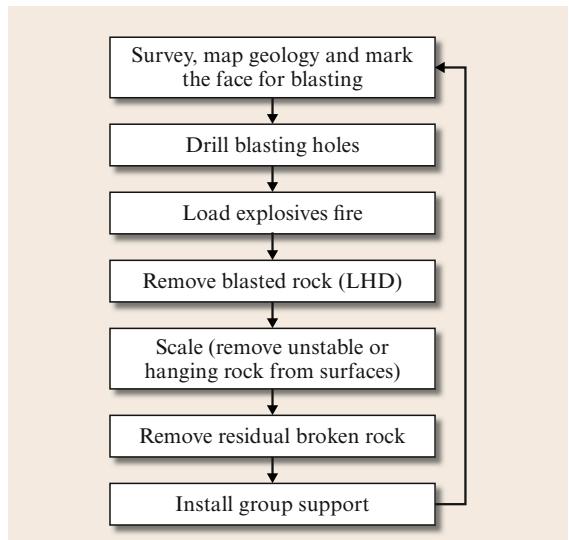

Fig. 49.12 Sequence of operations for tunnelling in metalliferous mines

analysis is in the early stages of development to acquire the necessary data without human entry.

Blast holes are drilled into the end of the drive in the direction of advance, typically using a drill jumbo (Fig. 49.10). Once blasted the rock is removed using an LHD to provide access for scaling. Scaling removes loose rock from the freshly blasted surface and this

is done either by hand, or using a drill jumbo. More recently successful trials have been undertaken using high-pressure water-jet scaling. Scaling is a hazardous task that is worthy of robotic control.

Ground support may be any combination of one or more of: rock bolts, steel mesh (typically 2×4 m sheets), sprayed reinforced concrete (shotcrete) sprayed plastic resin. It serves to increase the stability of the tunnel walls and roof, making the area safe for humans to work in. Methods of installation range from manual to mechanized using purpose-built machines. No automated methods are known at the time of writing, but development projects are underway. Ground support installation is particularly suited to robotics since the working environment is dangerous.

In some roadways where the rock is relatively soft or long straight sections are required, tunneling machines similar to those used in civil tunneling can be used, but this is uncommon. Tunneling machines use rock cutters which make slow progress in hard rock. However, rock cutting has some significant advantages and with the development of improved cutting technology this may become a common method of roadway development in the future. Rock cutting can produce smooth surfaces that are shaped for maximum stress tolerance and do not require the same level of preparation such as scaling or the installation of ground support.

Geology-Based Guidance Systems

As people are removed from the active mining zones, they can no longer use their senses to assess local conditions. Hence the introduction of specialized instrumentation is necessary to provide feedback. The use of scanning lasers and inertial navigation instruments is now accepted and is used for geometrical navigation and condition sensing. A further step change in guidance technology can be realized through the development and application of sensors that are sensitive to geological features including marker bands and mineralization. The use of such sensors is being trialled in coal mining, as mentioned in Sect. 49.3. In metalliferous mining, there are no current applications but significant opportunity exists, for example, hyperspectral imaging adapted from satellite imaging can be used to identify and map the mineralization of a face to help guide a mining machine. *Fraser et al.* [49.22] have shown that hyperspectral radiation is sensitive to minerals of interest and this could be developed to allow a metalliferous mining machine to follow ore seams.

49.2.3 Case Study: Nonconventional Robotic Miner

A proposed new mining method being developed [49.8] will deliver a safer and more economic way to mine a range of ore body types. It is a radical departure from conventional mining, exemplifying a new mining method which can only be achieved with robotic technology. Known as ROES™ it has been developed to solve many of the current mining occupational health and safety hazards, reduce mining costs, and reduce the time to bring ore into production. These benefits will also allow some existing subeconomic resources to be mined economically, thereby increasing the stocks of available ore (*reserves*).

The system involves vertical or inclined access to ore bodies rather than traditional horizontal access and will use robotic equipment for all activities associated with drilling, blasting and survey. This reduces the amount and size of tunneling required (*development*) compared with traditional methods. The level of control and real-time feedback to mine operators will also deliver greater mining coordination and flexibility. Figure 49.13 shows a comparison between the geometries of the ROES™ and sublevel open stoping mining methods.

ROES™ involves three main robotic activities: drilling, explosive placement, and survey. All of the

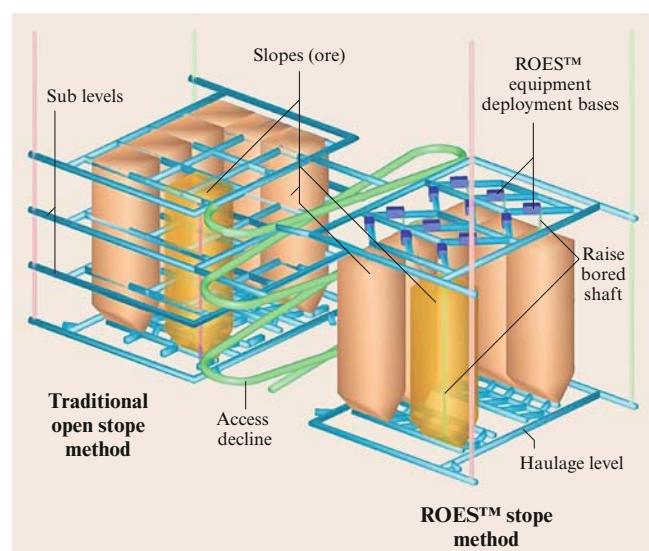

Fig. 49.13 Reduction in tunnelling required by ROES™ compared to traditional sub-level open stoping

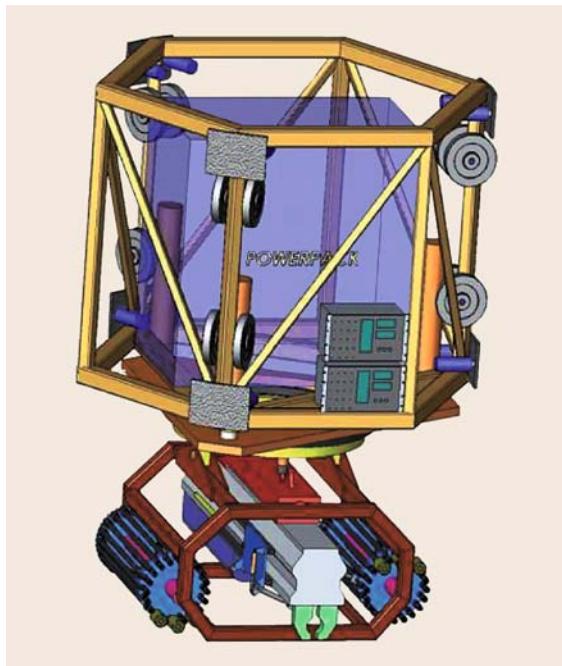

Fig. 49.14 Conceptual drilling module

equipment will be suspended from wire rope and deployed from the top of the vertical shaft to access the ore. The platforms will include onboard computers, PLCs, video cameras, machine encoders, and communications technology. Communication with the top of the shaft is possible via radio or infrastructure mounted into the

support and power cables. Such methods exist and are in use in the mining industry.

The drilling machine (Fig. 49.14) will be relatively small and stiff, which improves the drilling accuracy which is very important, so the pose and location of the drilling machine must be known in relation to the ore body and other structures. During travel to the drilling zone, one or a combination of several methods can be used to track the pose and location: odometry from the winder, high-level onboard inertial sensor, and laser distance measurement from the top of the shaft. The use of reference laser, beacons or novel methods that observe and track the movement of the machine against the wall of the shaft are also possible.

The rock drill is mounted separately from the main platform to provide control over its bearing, vertical position, and pitch. Once in the approximate drilling location, the main support platform can be wedged tightly in place against the shaft walls using hydraulic rams. The fine position of the drill can be controlled by a combination of electric and/or hydraulic actuators. Drill rods and spare drill bits are mounted on conventional carousels mounted either side of the drill and a robotic arm is used to transfer them to and from the drill.

The explosive placement platform will be similar in concept to the drilling platform. A survey platform will also be used to determine the condition of the shaft, drilled holes, stope void and size distribution of the blasted rock in the void below using sensors such as: millimeter-wave radar, photogrammetry and scanning lasers.

49.3 Underground Coal Mining

While many aspects of the coal extraction process, either by continuous miner or longwall-based methods are now highly automated, there has been a generally low rate of adoption of robotics in the underground coal mining industry worldwide. Conventional automated industrial process control systems are universally applied to fixed infrastructure coal conveying and processing elements of the mining chain, but there has been little commercial adoption of techniques to autonomously or tele-remotely control the operation of the basic mobile and semimobile coal extraction equipment. Commercial systems are currently limited to simple line-of-sight radio remote control of continuous miners and longwall shearers. In this section we will explain why the adoption of robotics has been slow in this environment.

The immediate underground coal mining environment is a hazardous area due to the presence of potentially explosive atmospheres. Accordingly, regulating authorities impose strict rules to govern the design and implementation of electrical equipment. This in turn translates to the necessity for high investment to develop robotics technology for a relatively limited market.

The coal face area is a dynamic environment with a high level of both expected and unexpected changes in geological conditions. This requires continuous observation of the current mining conditions and rapid and appropriate response to these occurrences to sustain the mining process. This function is carried out by experienced human operators. It is a challenging task to develop appropriate sensing methods both for local-

ization of the equipment and replacement of the human sensing ability to determine whether the equipment is mining coal or rock.

Despite these barriers, significant work has been done in developing robotics technology for this domain, particularly in navigation and sensing techniques and this section will explore significant issues, advances, and implementations.

49.3.1 Coal Mining Process

The nature of coal mining has led to the development of different styles of extraction equipment and potential robotics approaches. The longwall mining method, which accounts for the majority of underground worldwide production, is based on large equipment installations where motion of the individual components is highly repetitive and relatively constrained, whereas room (or bord) and pillar mining is more flexible, based on smaller mobile equipment.

Longwall Underground Coal Mining

In the longwall mining method ([49.23], Chap. 7) the primary extraction mechanism is a longwall shearer which has two ranging arms at the ends of which are rotating drums containing picks that remove the coal from the face. With reference to Fig. 49.15, the shearer travels along the face on a structure also housing an armored (or articulated) face conveyor (AFC) that carries the coal to one end of the face. The coal is then removed via other conveying systems to the surface. The roof is supported over this operation by a number of adjacent powered

roof supports (also known as shields or chocks) which are each connected to the AFC. After the shearer passes, the chocks release from the roof, advance under hydraulic power into the cavity created by the removal of the coal, reposition the AFC and resupport the roof. The cycle then continues. Longwall face lengths range from 100 to 400 m and extraction rates can be of the order of 3000–4000 t/h. The advantages of the longwall method are the high sustained production rate and the ability to extract up to 80% of the coal seam.

Automation has been applied to various elements of the longwall mining process, particularly face alignment and cutting horizon control. Significant work has been done in the development of sensors to detect the interface between coal and rock in order to automatically keep the extraction process within the coal seam [49.24–27]. Face equipment manufacturers have produced automation systems that currently allow remote control of both face alignment and cutting horizon of longwall operations. The motion of powered roof supports can be initiated by the passage of the shearer. The sequence of support motion and the distance each hydraulic actuator moves are also programmable. Consequently a desired profile of the longwall face in plan view can be generated and input to the supports.

Room and Pillar Coal Mining

The alternative common underground coal mining method is room (or bord) and pillar ([49.23], Chap. 6) where the extraction system is based on the so-called continuous miner (Fig. 49.16). This is a much more mobile item of equipment than the longwall and can utilize many aspects of vehicle robotics technology. The boom raises and lowers the cutting drum and the unit is driven and steered through the track drives. The tail of the continuous miner then delivers cut coal to a flexible

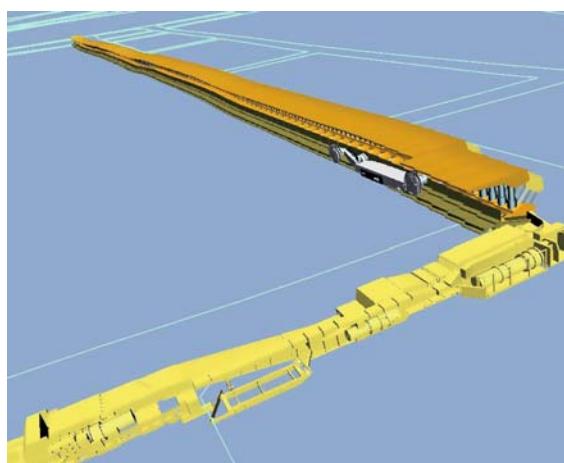

Fig. 49.15 Schematic of a longwall mining equipment installation

Fig. 49.16 Continuous miner

conveying system or to shuttle cars ([49.28], Chap. 9) that in turn link to fixed conveyor belt infrastructure. The method requires less investment to establish than longwall and can operate in a wider range of geological conditions but has a lower production rate and does not extract as high a percentage of the available coal. All mainstream continuous miners are now operated via radio remote control so in a logical extension, robotics applications to this method include teleoperation, navigation, and control of roof and floor extraction horizons.

Operational Constraints

The underground coal mining environment presents unusual impediments to the implementation of robotics technology. Perhaps the most significant of these is the existence of explosive risk zones due to the presence of methane and coal dust in the atmosphere where mining equipment operates. There are various protocols for the implementation of equipment that could trigger an explosion. At one extreme, equipment can be designed so that energy levels are low enough to make the equipment unable to release sufficient energy to ignite explosive gases and thus be intrinsically safe. This greatly restricts the functionality of such equipment and the development costs are very high.

The other major implementation method is to house commercial equipment in purpose-built protective *flameproof* enclosures which can prevent an explosion inside the enclosure from propagating into hazardous external atmospheres. While this enables flexibility in the equipment that can be used, there are rules governing the design and testing of the enclosures, so development processes are slow and costly. There are problems implementing sensing systems requiring provision of transparent or at least dielectric windows in the enclosures for visible light, infrared, laser or radar-based sensors, and even computer screens for user interfaces. The dimensions of such windows are restricted in order to be explosion resistant. Moreover, such enclosures must not be opened during operation so live testing of operational hardware is virtually impossible. On the upside, the necessity to provide such robust housing for electrical and electronic equipment has a benefit in that protection is also afforded against the usual problems of water and dust.

Highwall Coal Mining

The above underground mining scenarios are currently largely manned operations. Highwall mining is a derivative of room and pillar mining and can only be

Fig. 49.17 A highwall mining operation

implemented by remote control. A series of parallel entries is made into the coal seam left exposed under the final highwall of a strip-mined open cut pit using a remotely controlled continuous miner. The coal is then conveyed to the surface by a continuous haulage method. In Fig. 49.17 continuous haulage is achieved using a series of interconnected conveyor cars. A *launch vehicle* is used to insert and remove cars, redirect the coal flow to a stockpile and as a location for an operator station. Supporting pillars of 1–3 m in width remain between adjacent entries, each of which can be up to 500 m long. If the entry spacing and pillar widths are not maintained then loss of equipment through roof falls and, in the extreme, catastrophic failure of a number of supporting pillars can result.

The rationale behind this method is that it is a low-cost way of extracting coal when overburden depths mean that open cut extraction methods are uneconomic. The method can extract about 60–70% of the available resource and then makes inaccessible deeper coal from other mining methods. Consequently the method is now falling from favor, being replaced by longwall operations with access roadways being driven directly into the seam from the highwall.

49.3.2 Scope for Robotics

Localization

Several of the methods described above require precise knowledge of the position of the cutting tool, and the underground environment is particularly challenging for accurate localization. To address this problem in the longwall context a shearer position measurement system (SPMS) based on inertial navigation has been developed [49.29] to accu-

rately measure the three-dimensional position of the shearer.

Inertial navigation (INS) technology is a logical method to measure machine position in the mining environment. State-of-the-art ring laser or-fibre optic sensors are robust, often being designed for military applications. They require little or no connection to external sensors and thus can be located within the machine envelope in protected locations. The United States Bureau of Mines conducted tests using the Honeywell modular azimuth positioning system (MAPS) and subsequently the Honeywell ore recovery and tunneling aid (HORTA) units in the late 1980s for continuous miner guidance applications [49.30]. This work resulted in field trials in 1997 [49.31]. Further developments by CSIRO in Australia, resulted in the development of the first full-survey highwall mining guidance system in the mid-1990s [49.32, 33]. This system is now a critical requirement for highwall mining in Australia and is receiving increasing international acceptance.

The INS sensor is also applicable to longwall mining. If the real-time position and orientation of the shearer are continuously measured, the fact that the shearer passes over all the supports in a fixed geometrical relationship can be used to calculate the real-time positions of all the supports and thus the longwall face as a whole. This development, when added to existing manufacturers' capability, has facilitated reliable longwall face automation.

Planning and Control

Given better information about the position of the cutter and the position of the coal seam from geological models and online measurements it is possible to apply robotic path-planning techniques. However, true closed-loop control of face alignment has not been possible because there has been no reliable method to measure the true plan position of all the powered supports to provide accurate feedback to the control system. This process lends itself to the application of robotics in controlling the motion of the supports to manage face alignment and also the motion of the ranging arms on the shearer to position the extraction roof and floor horizons optimally in the seam.

Shuttle Cars

Currently the shuttle car operator docks the machine to the discharge conveyor of the continuous miner, controls the filling process, drives the shuttle car to a discharge point at a fixed conveyor, controls the emptying process, and returns to the miner to repeat the cycle. Often two

shuttle cars are used in parallel to increase throughput so there are scheduling issues when one unit is required to wait for the other to unload or load. The entire operation could be automated using navigation developments already applied to LHD vehicles in metalliferous mining as described in Sect. 49.2.2. However no prototype or commercial shuttle car automation systems have yet been reported.

49.3.3 Rapid Roadway Development

Often longwall mining operations are delayed because the necessary gate roads have not been completed. Ground support in these roadways is often provided by roof and rib (wall) bolting. This is a relatively involved process in which firstly a hole is drilled into the strata using a portable or machine-mounted drill rig. The drill steel is then withdrawn and bladders of epoxy are manually inserted into the hole. Finally the bolt is inserted into the hole, again using the drill rig. The bolt is spun to break the bladders which mixes the epoxy and hardener to bond the bolt to the strata. Often the bolt is then tensioned to compress the strata to form structural support of the roof and rib.

Placement of bolts has been identified as a limiting factor in the speed of roadway development so there has been considerable industry attention given to improvement of the speed of bolting. Unfortunately the conventional bolting procedure poses several automation challenges shared also with other underground drilling applications discussed in this chapter. Automatic relocation of the hole in order to insert different devices to inject the epoxy grout and then to place the bolt is difficult to achieve in the operating environment. The development of a self-drilling bolt has eliminated several of the automation issues because it is now possible to drill a hole with the bolt itself and then leave the

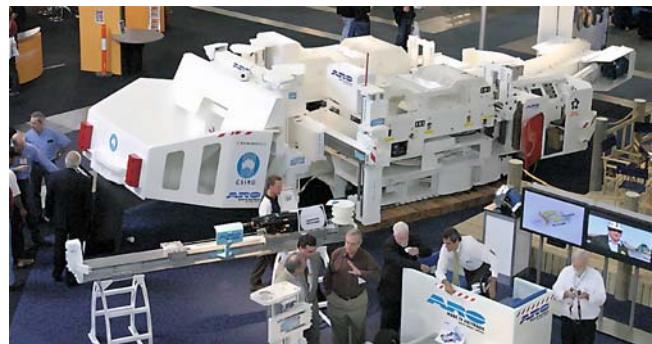

Fig. 49.18 Prototype machine for roof and rib bolting

bolt in place while the epoxy is introduced, mixed, and cured.

A system has been developed to implement automatic roof and rib bolting using a self-drilling bolt

concept [49.34]. The major elements of this system, shown in Fig. 49.18, are removable cassette storage of bolts, an automated bolt delivery system, and automatic drilling/bolting rigs

49.4 Surface Coal Mining

Many different minerals are extracted in surface mining operations, for example coal (Fig. 49.3), oil shales, bauxite, iron ore, and phosphate. We can consider two different excavation requirements: removing the overburden which often covers the commodity of interest, and the commodity itself. The remainder of this section will discuss the general principles of excavation and material haulage using open-pit coal mining as an example. Most aspects of the process, and the types of equipment required, are common to many other open-pit mineral extraction operations.

A consequence of many years of commodity extraction is that all the remaining commodity is buried deeper than what has been removed to date. Miners refer to a stripping ratio, which is the ratio of the overburden volume that must be removed to access one tonne of mineral. Over the last 20 years, in the Australian coal industry for example, this ratio has climbed from 2–5:1 to 8–15:1 today. More material must be moved to reach the mineral, requiring a massive improvement in the productivity of overburden removal and a reduction in cost in order to maintain profitability – this is the challenge that automation and robotics can contribute to.

Various types of machine are commonly used for excavation. In approximately increasing size order: front-end (or wheel) loaders, back hoes, bulldozers, rope shovels, hydraulic excavators, draglines, and bucket wheel excavators. Front-end loaders, back hoes, and bulldozers are mobile plant that can be rapidly deployed as required. Their disadvantage is a relatively low productivity in dirt movement. Draglines and bucket wheel excavators have high capital costs, but operating cost per volume moved is very low.

From a robotic perspective, there has been important prior work in automating excavation machinery. *Singh* [49.28] provides a good treatment of much of this work using a number of implemented systems to illustrate the state of the art. Work at Carnegie Mellon University by *Singh*, *Cannon*, *Rowe*, *Stenz* and others in the 1990s, culminated in a comprehensive study and experimental evaluation of an autonomous 25 t hydraulic backhoe-type excavator [49.35]. This work in-

cluded the development of techniques to estimate soil hardness and dig forces which were integrated into an autonomous digging control law, as well as methods for planning dig locations and clean-up operations. Other work in this area can be found in [49.36–40]. The smaller machines are typically hydraulically actuated and the control issues associated with such machines has been investigated by *Tafazoli* et al. [49.41] and *Bonchis* et al. [49.42,43]. Rope-shovels and hydraulic excavators are discussed in Sect. 49.4.2.

The remainder of this section will discuss the two main approaches to overburden removal for coal mining: the dragline excavator, and the truck-shovel operation in which a rope shovel or hydraulic excavator loads material into a truck.

49.4.1 Dragline Excavator

The dragline (Fig. 49.19) is the tool of choice for overburden stripping. Invented in 1904 for use digging the Chicago canal, the fundamental principles have changed little since, but they have evolved into truly massive electrically powered machines; see Fig. 49.3. Modern machines typically have boom lengths of over 100 m, weigh up to 5000 t, with bucket capacities of the order of 100 t.

They comprise a rotating assembly that includes the *house* (drive motors, controls, and operator cabin), tri-structure or mast, and boom. The house rotates on a bearing surface on top of the *tub* which sits on the ground. A large-diameter ring gear is fixed to the tub and the house is rotated by a number of pinions driven by motors in the house. While earlier and smaller draglines used a tracked base, the modern walking dragline drags its tub along the ground by means of large eccentrically driven *walking shoes* at the side of the machine. The dragline has three driven mechanical degrees of freedom: the house and boom rotate with respect to the tub; the bucket can be hoisted by a cable passing over sheaves at the tip of the boom; and the bucket can be dragged toward the house by a cable passing over sheaves at the base of the boom (Fig. 49.19). During digging, the

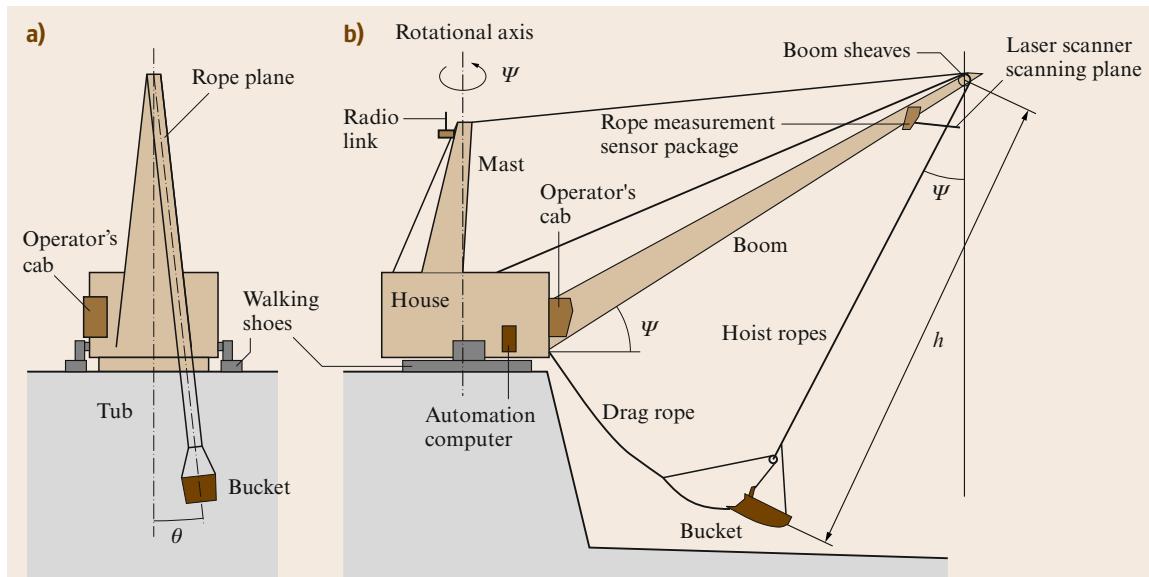

Fig. 49.19 Schematic of dragline

bucket motion is controlled using only the drag and hoist ropes. When the bucket is filled it is hoisted clear of the ground and swung to the dump position by slewing the house and boom. The drag and hoist drives now control the position of the bucket within a vertical plane that contains the centreline of the boom however the bucket is free to swing normal to that plane. Interestingly the bucket has three degrees of freedom within the boom plane but only two control inputs, making control of bucket orientation a complex function of position, speed, and rope tension [49.44].

Capital cost of these machines is of the order \$US 40–80 M and the operating cost is approximately \$US 5 M per year (labor, power, and maintenance) working 24/7. A dragline can only excavate to 50 m and with pit depths now well over 100 m the overburden must be removed in two dragline passes, or by using shovels and trucks (Sect. 49.4.2) to prestrip. The threshold depth at which underground mining methods would be employed continues to increase.

The issues facing owners of these machines are: maximizing productivity (m^3/shift) in the presence of operator variability and maintenance costs (around 30% of operating cost). It has been estimated that a 1% improvement in machine productivity is valued at around \$US 1 M per machine per year. Operation is cyclic, and each cycle moves up to 100 t of overburden, and typically takes 60 s of which 80% of the time is swinging the bucket through free space. The work is repetitive,

yet requires considerable skill. Performance can vary by up to 20% across the operator population, and for an individual will vary over a shift (up to 12 h).

The solutions currently pursued include: operator performance monitoring, improved training, and routine overloading of the machine which exploits the generous design safety margins and trades off productivity and maintenance costs.

Robotics offers the possibility of control that minimizes cycle time while bounding the stresses that cause machine damage. The challenges are to replace the human function of visually sensing the state of the bucket, its rigging and the local terrain and actuate the drag, hoist (joystick) and slew (pedal) controls in a coordinated fashion, controlling and exploiting the bucket's natural tendency to swing, while working within the significant voltage, current, and power constraints of the motors.

Early attempts at dragline automation [49.45] simply replayed the operator's control inputs but this failed because the control inputs are based on the instantaneous machine state which is a history of the initial condition and subsequent inputs, as well as the initial and goal states which vary from dig to dig. A key challenge is sensing the machine and bucket state which would include encoders on the motors and a noncontact sensor of bucket angles since the bucket is treated very roughly, being pulled through several meters of broken rock. Noncontact solutions involving computer vision [49.46]

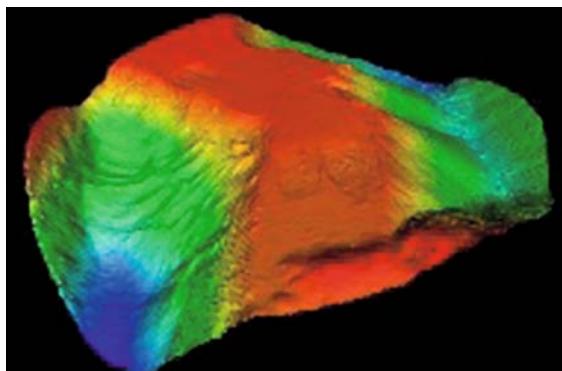

Fig. 49.20 Terrain mapping from the tip of a dragline boom

and laser range finders [49.47] have been proposed. Once equipped with sensors a dragline can be considered as a three-DOF (degree of freedom) robot (drag rope, hoist rope, slew angle) with a flexible, or unactuated, final link [49.48]. There are two control problems. Firstly the tool-tip (bucket) motion along a defined trajectory in free space [49.49] which is similar to that of controlling cable suspended loads for cranes [49.50], and consumes 80% of the cycle time. In a major production trial [49.51] a dragline automation system performing this free-space motion moved over 250 000 t of overburden in 3042 cycles over a 2 week period. Performance was equivalent to a human operator but the automation system had to lift the bucket higher in order to compensate for uncertainty in the environment. Mapping the surrounding terrain [49.52], as shown in Fig. 49.20, would allow the automation system to plan time-optimal collision-free paths.

The second control problem is moving the bucket through the ground in order to fill it, and determining when it is full. Some initial work in this area is reported in [49.53].

Another important consideration is a human interface that allows fast and seamless transfer between automatic and human-controlled operation [49.49].

49.4.2 Truck–Shovel Operation

As implied by the name the truck–shovel operation has two different machine types: a rope shovel (Fig. 49.21) or hydraulic excavator (Fig. 49.22) to excavate material and load it into the truck which hauls it away. While draglines have the lowest cost per unit volume removed (at least ten times more cost effective than a truck and shovel operation) they are very significant capital assets and difficult to move quickly around the mine. By

Fig. 49.21 A rope shovel dumping into a haul truck. A truck typically holds between one and three dipper loads of material (©CSIRO)

Fig. 49.22 A hydraulic excavator (©Automated Positioning System, Brisbane)

contrast trucks and shovels can form more *flexible* operations since smaller individual units can be added or subtracted or readily deployed around the mine site.

Truck–shovel combinations can be used for overburden removal, either totally or in a prestripping mode in preparation for a dragline. Trucks and shovels are very commonly used to excavate the exposed coal seam.

The modern shovel (Fig. 49.21) is descended from the 19th century steam shovel and employs large electric drives and a cable transmission. Hydraulic excavators have a dipper mounted on the end of a rigid five-DOF hydraulic arm, typically on a tracked base. These machines are kinematically much closer to industrial robots, but on a massive scale, with dipper sizes over 20 m³ available.

From an automation perspective [49.53] many of the issues are the same as for draglines: filling the bucket with broken rock, planning a time-optimal collision-

free trajectory, and human interface. The rigidity of these machines simplifies the estimation of bucket tooth position.

Typically these machines swing and dump material into a haul truck, see Fig. 49.21. A perception system could be used to detect the truck and dump the material into a free area of the tray. Planning the motion of the trucks and the shovel becomes a problem in multirobot scheduling and path planning.

Blasting

The overburden is typically a soft sandstone, and the coal seam itself, after millions of years of compression, also resembles rock. In order to excavate it must first be blasted to fracture the material into pieces that can be excavated. A matrix of blast holes is drilled in the overburden layer and fired prior to overburden removal. The process is repeated with the exposed coal seam.

This process is amenable to automation, though it has not yet been demonstrated. The drill rig is a large-wheeled machine which needs to be positioned on the bench, and the drilling process itself needs to be automated. The drill string is assembled from short components as the drilling progresses. Online feedback from the drill head, speed, and torque, can provide geological data about the strata being drilled through. Accurate knowledge of the drill head is also required, since it can be deflected by geological conditions causing the blast to deviate from the design. Once the holes are all drilled there is scope for automating the explosive loading process: currently large tankers of explosive that visit each hole, insert a hose into the hole along with primers and detonators, and pump the explosive.

49.4.3 Surface Haulage

In surface mines, material (commodity or overburden) must be moved from where it is broken to where it will be processed or stockpiled. Haul trucks are the preferred means of moving material around a surface mine, typically diesel-electric vehicles with payloads of up to 400 t. The automation of these haul trucks has been an ongoing research and development activity for the truck manufacturers for over 10 years. Both Caterpillar and Komatsu (the two largest manufacturers of haul trucks) have had very active automation research programs. The key robotics challenges to the automation problem are

localization and obstacle detection. GPS is an obvious choice as a primary localization sensor. However, GPS is not reliable close to the highwalls of a typical open pit (due to a lack of observable satellites and due to multipath issues). The ramps out of pits typically hug the walls, which makes the use of GPS as a localization sensor difficult. This problem can be solved using pseudo-lites to cover the GPS dead spots or other sensors such as laser scanner, radar, inertial guidance, and odometry in these areas. Both Caterpillar and Komatsu demonstrated autonomous driving of haul trucks in the late 1990s [49.54].

It is the area of obstacle detection that is far more challenging. Autonomous haul trucks must be capable of detecting rocks on the road in front that have fallen from other trucks. They may be required to detect other vehicles (if the haul road is open to other mine traffic) and they may be required to detect mine personnel. The development of robust obstacle detection systems for these vehicles is difficult because of the relatively harsh conditions encountered in mining environments. The operating environment could include rain, dust, mud, high humidity, diesel fumes (small particles), extremes of temperature, severe vibration, extreme vehicle pitching and rolling, and bright light sources (e.g., the sun). [49.55] shows how a 2-D scanning laser can be used to map the terrain ahead of a mining vehicle and hence be used to detect obstacles. Scanning lasers have been widely used for obstacle detection in the DARPA Grand Challenge [49.56] where nearly all competitors used such sensors as the primary means of detecting obstacles.

The technology for autonomous trucks has now been established but there are still very few examples of mines using autonomous haul trucks in regular production. It seems that the technology is ahead of the culture in this case and the mining industry is not quite ready for this big leap in autonomous operation. Instead examples of semiautomation or driver assists are starting to be tried. An example of this is the work in [49.57] where a collision warning system for haul truck drivers has been developed. This system uses many of the sensing systems of an autonomous truck but instead of directly controlling the truck the driver is alerted when he/she are starting to head off the road (maybe due to tiredness or inattention), or when another truck is on a potential collision course.

49.5 Conclusions and Further Reading

Today, mining remains hard and hazardous work with a wide scope for the application of robotics. The main drivers are the need for greater productivity and improved health and safety for mine personnel. Mining robots differ considerably from traditional factory robots in that the mining environment is ever changing, that is, the purpose of mining, and the machines are typically hydraulically actuated, and are often diesel powered. These challenges have meant that robotics has not been rapidly adopted by the mining industry to date, but it is clear that the mining industry will have to adopt more automation, and with it robotics, to further significantly improve productivity and safety as traditional methods such as staff training, improved work practices, and larger and improved machine design are providing diminishing returns.

Further reading on the state-of-the-art robotic mining machines in operating mines as at 2006 can be obtained from [49.1] and examples of current robotic miners include

- automated mobile haulage trucks in underground metal mines
- automated drilling machines [49.58, 59]

Areas of development, currently being researched, include

- a large and early challenge will be safe operation of mixed fleets, where robotic and manned vehicles operate in the same workspace,
- teleoperation, with immersive environments, is likely to grow in usage, but with the operators located thousands of kilometers away instead of actually at the mine site as is normal today. These telemining technologies will be essential when it comes to mining the rich but difficult to access mineral resources deep under the ocean [49.60] and on planets and asteroids,
- in situ processing of mineral ore by leaching to extract the metal, or in situ gasification of underground coal, remove the need to excavate and transport the material, much of which is waste. These methods will all require underground operations that are suited to robotics [49.61],
- microtunneling machines [49.62], or moles, will follow arbitrary paths through the ground, releasing gas from coal seams, or following narrow bands of commodity. Research in propulsion, localization, and communications will be required to make this a reality,
- automated explosive placement [49.20] and stoping methods [49.8],
- automated tunneling including installation of ground support [49.34],
- robotic rock cutting machines [49.63].

Search and Rescue Robotics

Robin R. Murphy, Satoshi Tadokoro, Daniele Nardi, Adam Jacoff, Paolo Fiorini, Howie Choset, Aydan M. Erkmen

In order to summarize the status of rescue robotics, this chapter will cover the basic characteristics of disasters and their impact on robotic design, describe the robots actually used in disasters to date, promising robot designs (e.g., snakes, legged locomotion) and concepts (e.g., robot teams or swarms, sensor networks), methods of evaluation in benchmarks for rescue robotics, and conclude with a discussion of the fundamental problems and open issues facing rescue robotics, and their evolution from an interesting idea to widespread adoption. The Chapter will concentrate on the rescue phase, not recovery, with the understanding that capabilities for rescue can be applied to, and extended for, the recovery phase. The use of robots in the prevention and preparedness phases of disaster management are outside the scope of this chapter.

Rescue robots serve as extensions of responders into a disaster, providing real-time video and other sensory data about the situation. They are an emerging technology, and have not yet been adopted by the international emergency response community. As of 2006, they have been used in only four disasters in the United

States (World Trade Center, and hurricanes Katrina, Rita, and Wilma), where they were still viewed as a novelty. However, rescue robots are seeing some use in local incidents. For example, several fire rescue departments in Japan and the United States routinely use small underwater robots for water-based search and

recovery, a ground robot has been used for a mine explosion in the United States, and interest in the use of aerial vehicles for wilderness search and rescue is growing. The general lack of adoption is to be expected since the technology is new, and the concept of operations of novel technologies as well as the refinement of the hardware and software coevolution will

take time. Rescue robot applications are often similar enough to military operations that the same platforms can be adapted; however, some rescue tasks are significantly different than their military counterpart, some tasks are unique to rescue, and the human–robot interaction for civilian response diverges from military patterns of use.

50.1 Overview

Disaster response is always a race against time, to move as fast as possible to reach all potential survivors and yet move slowly enough to avoid creating additional collapses, damage, or risk to rescuers and victims. The primary motivation is to save lives; robots can assist in meeting this goal either by interacting directly with victims or structures or automating support activities.

50.1.1 Motivation

Historically, the push for rescue robotics started in 1995 as outcomes of the tragic loss of life in the Hanshin–Awaji earthquake in Kobe, Japan, and the bombing of the Murrah federal building in Oklahoma City, United States [50.1]. The advances in robotics and artificial intelligence in the early 1990s supported the moral imperative for roboticists to reach out and help. As a result, research efforts began in individual laboratories. Two mobile robot competitions (the AAAI mobile robot competition in the United States, and the RoboCup rescue league internationally) were started shortly thereafter to engage the scientific community in rescue research.

The 2005 World Disasters report [50.2] suggests just how many lives have been, and will be, impacted by urban disasters. Over 900 000 people were reported killed from 1995 to 2004, with the total amount of disaster-related damage estimated at 738 billion US dollars. Of the victims in urban disasters, only a small fraction may actually survive. Consider from [50.3, 4] that the majority of survivors (80%) of urban disasters are surface victims, that is, the people lying on the surface of the rubble or readily visible. However, only 20% of survivors of urban disasters come from the interior of the rubble, yet the interior is often where the majority of victims are located, providing motivation for robots that can explore deep within collapses. The mortality rate increases and peaks after 48 h, meaning that survivors who are not extricated in the first 48 h after the event are unlikely to survive beyond a few weeks in the hospital.

50.1.2 Rescue Robot Tasks

While the overall motivation for rescue robotics is to save lives, the motivation for specific robot designs and capabilities depends on their potential tasks. The types of tasks that have been proposed for rescue robots are described below.

Search is a concentrated activity in the interior of a structure, in caves or tunnels, or wilderness and aims to find a victim or potential hazards. The motivation for the search task is speed and completeness without increasing risk to victims or rescuers.

Reconnaissance and mapping is broader than search. It provides responders with general situation awareness and creates a reference of the destroyed environment. The goal is speedy coverage of a large area of interest at the appropriate resolution.

Rubble removal can be expedited by robotic machinery or exoskeletons. The motivation is to move heavier rubble faster than could be done manually, but with a smaller footprint than that of a traditional construction crane.

Structural inspection may be either conducted on the interior (e.g., to help rescuers understand the nature of the rubble in order prevent secondary collapses that may further injure survivors) or on the exterior (e.g., to determine whether a structure is safe to enter). Robots provide a means of getting structural sensor payloads closer and in far more favorable viewing angles.

In situ medical assessment and intervention are needed to permit doctors and paramedics to interact verbally with victims, visually inspect the victim or apply diagnostic sensors, or to provide life support by transporting fluids and medication through narrow tubing during the four to ten hours that it usually takes to extricate a victim. The lack of medical intervention was a major problem at the Oklahoma City bombing [50.5].

Medically sensitive extrication and evacuation of casualties may be needed to help provide medical as-

sistance while victims are still in the disaster area, also known as the hot zone. In the case of a chemical, biological, or radiological event, the number of victims is expected to exceed the number that can be carried out by human rescuers in their highly restrictive protective gear; this makes robot carriers attractive. Since medical doctors may not be permitted inside the hot zone, which can extend for kilometers, robot carriers that support telemedicine may be of huge benefit.

Acting as a mobile beacon or repeater to extend wireless communication ranges, enable localization of personnel based on radio signal transmissions by providing more receivers, and to serve as landmarks to allow rescuers to localize themselves.

Serving as a surrogate for a team member, such as a safety officer or a logistics person. In this task, the robot works side-by-side with rescuers, for example, a group breaching rubble deep within the interior of a disaster may have difficulty using a radio to request additional resources because of noise. However, a team member outside of the rubble can see and hear through the robot the state of progress and anticipate needs. The objective is to use robots to speed up and reduce the demands of tasks, even if they are done by humans.

Adaptively shoring unstable rubble to expedite the extrication process. Rubble removal is often hindered by the need to adopt a conservative pace in order to prevent a secondary collapse that might further injure a trapped survivor.

Providing logistics support by automating the transportation of equipment and supplies from storage areas to teams or distribution points within the hot zone.

Some of the above tasks are similar to tasks for military robots, especially search and reconnaissance and mapping, but many are unique or have a different flavor. For example, structural inspection, rubble removal, and adaptively shoring rubble are rescue specific. Tasks such as casualty extraction appear to be similar but are significantly different. Consider that a wounded soldier is unlikely to have a spinal-cord injury and is likely to be in a space large enough for a human to work in, so a robot entering the area and dragging the soldier to safety is appropriate. However, a crushed victim of a building collapse is physically trapped or pinned in a small space, requiring rubble removal, and the victim's spinal

cord must be immobilized before extraction; clearly victim extraction in the search-and-rescue domain is more challenging.

50.1.3 Types of Rescue Robots

Rescue robots are needed to help quickly locate, assess, stabilize, and extricate victims who cannot be easily reached. They typically do this by extending the rescuers' ability to see and act. On the ground, small unmanned ground vehicles (**UGVs**) can enable rescuers to find and interact with trapped victims in voids that are too small or too dangerous for human or canine entry. Large **UGVs** can accomplish tasks such as removing large rubble faster than humans. In the air, unmanned aerial vehicles (**UAVs**) robots extend the senses of the responders by providing a bird's eye view of the situation. In the water, unmanned underwater vehicles (**UUVs**) and surface vehicles (**USVs**) robots can similarly extend and enhance the rescuers' senses.

Rescue robots can be broadly categorized into types based on *modality* and *size* [50.6], though other taxonomies that mix modality, size, and task have been proposed [50.7]. There are four modalities of robots: *ground*, *aerial*, *underwater*, and *water surface*. The modality impacts on the basic design and capabilities of the robot. Within each modality, rescue robots can be further described as one of three sizes: *man-packable*, *man-portable*, and *maxi*. The size of the robot impacts both on the tasks for which it is suited and how soon after a disaster it might be used. In order to be man-packable, the entire robot system, including the control unit, batteries, and tools, must fit into one or two backpacks. Man-packable robots are more likely to be used immediately after a disaster since they can be carried by responders over debris and up and down ladders into the core of the disaster, while larger equipment must wait for paths to be carved out. The next larger size is man-portable; these are robots that can be carried a short distance by two people or on a small all-terrain vehicle. Man-portable robots can be used as accessibility within the hot zone improves or outside the hot zone for logistics support. Maxi-sized robots require trailers or other special transportation logistics. This inhibits their insertion into the hot zone, unless they are being used on the exterior of the rubble.

50.2 Disaster Characteristics and Impact on Robots

The type of disaster influences the choice of robot platforms and payloads. *Natural disasters* generally span

large geographic areas, making a bird's eye view from a **UAV** invaluable in establishing situation awareness and

determining areas or individuals which need immediate evacuation or assistance [50.8]. *Manmade disasters* are geographically concentrated with the most vital aspects of the disaster invisible beneath the rubble. Small ground robots that can enter deep into the interior of the rubble, and large robots, which can help remove rubble, appear to hold the most promise for manmade disasters. Note the focus on the search for victims and on general information gathering. This focus implies that communications plays a major role in the design of search-and-rescue robot systems and the impact of the environment on wireless communications is an important consideration.

Independently of the type of disaster, search and rescue is very demanding both in terms of robotic capabilities and working conditions for the operator [50.9]. The robot is, by definition, operating in a harsh, mobility-challenging environment. The presence of abrasive dust and water, the corrosive effects of wet cement, and the wide range of obstacles in the environment serve to accelerate the wear and tear on a robot [50.6, 10]; therefore, the adage *simple is better* is especially true in rescue robotics. The disaster also places demands on the robot operator that will likely impact performance. Certainly, the operator will be stressed by the time criticality and life-saving urgency of the mission. Other sources of stress include: the operator will not be able to keep the robot in line of sight (which is a more favorable operating regime), perception to the robot is computer-mediated and therefore cognitively fatiguing, and the operator is likely to be sleep-deprived and may be at some personal risk.

50.2.1 Categories and Phases of Disasters

An incident may be *local* or it may be a true *disaster*; a disaster exceeds local resources or expertise and requires specially trained teams from outside the immediate agency to be involved. Disaster operations consist of four phases: *preparedness, prevention, rescue, and recovery*. Preparedness and prevention are *pre-incident activities*, whereas rescue and recovery are *post-incident tasks*. Rescue is also distinct from the recovery phase of a disaster operation; recovery seeks to mitigate longer-term threats to life and damage to property and to extract the dead.

Rescue is the broad term applied to activities immediately following a critical incident that directly deal with immediate threats to the survivability of those impacted by the event. This includes locating, assessing the medical condition, stabilization, and extrication of

survivors. *Rescue* is often used interchangeably with the term *search and rescue*, which actually refers to the teams and activities that work in the field, whereas *rescue* is frequently used by the public to connote the larger disaster management activities needed to support the teams and victims. *Search* refers to activities related to finding survivors; while *rescue* refers to the activities related to extricating survivors. In general, the typical process of search and rescue takes two tracks: *strategic* and *tactical*. Strategic operations focus on mission planning and coordination for the entire enterprise, which may involve robots as mobile sensor, communication networks, or logistics support.

Within search and rescue, there are numerous specialties and these specialities may impact on the design or use of a robot. Of these, *urban search and rescue* (abbreviated as *US&R* or *USAR*) has been the subject of the majority of work in rescue robotics. Urban search and rescue takes its name from its focus on the aftermath of urban structures collapsing around people. These structures may collapse for natural reasons such as earthquakes, hurricanes, and flooding or they may stem from manmade causes such as structural failures or terrorism. However, there are other types of search and rescue, though these are generally associated with local incidents. *Wilderness search and rescue* tracks people in the outdoors, such as lost hikers or people buried by avalanches. *Water-based search and rescue* deals with situations such as saving victims of floods or high currents (also known as *swift water rescue*) or in the aftermath of traffic accidents where victims are trapped in cars that have plunged into a river or bay.

In order to understand how to apply robotics to disaster response, it is helpful to understand the general pattern of activity, which can be summarized as [50.11, 12]:

1. Responders become aware of the existence of victims. This awareness may be generated by information from family, neighbors, and colleagues, an understanding of demographic patterns (e.g., at night, apartment buildings will be heavily occupied, while during a work day, office buildings will be occupied), or by a systematic search.
2. The response command staff attempt to understand the disaster site. They investigate the site for conditions such as hazardous materials, the risk posed to the rescuers themselves, any pending threats to trapped victims, and resource restrictions such as barriers to transporting resources to the site, nearby

- usable equipment and materials that can be exploited, and any other barriers to a timely rescue.
3. The command staff plans the operations.
 4. Search and reconnaissance teams are sent to map the situation and assess environmental conditions. Accurate estimates of the need for emergency medical intervention are highly desirable in order to optimize allocation of medication personnel in the field and to prepare ambulances and hospitals. (In the case of the Kobe earthquake, this stage took the longest time [50.11].)
 5. Excavation of rubble to extract victims begins. Note that removal of rubble in search and rescue differs from construction removal of rubble, because the safety of the victims is the top priority.
 6. Responders gain access to victims and apply emergency medicine *in situ*.
 7. Victims are transferred to hospitals.
 8. Field teams report activities periodically, usually at the end of the shift, and the command staff modifies or replans accordingly.

Robots are particularly needed for *tactical search and rescue*, which covers how the field teams actually find, support, and extract survivors. Tactical search and rescue typically begins independently of strategic planning [50.13]. As discussed in [50.12], the first responders on the scene, policemen and firemen, as well as civilians immediately assist with extracting survivors. Regional search-and-rescue teams are deployed and arrive within a few hours, while strategic operations are only beginning to be set up. Based on the condition of the structure and the size of voids, rescuers may enter the rubble, typically using a right-wall-following algorithm. In order to locate inaccessible victims not visible on the surface of rubble, rescuers working in teams of two typically bring in canine teams to smell for the presence of survivors, or use pole-mounted search cameras. Search cameras and boroscopes can usually extend visibility into the rubble by several meters, depending on the irregularity and turns in the voids. If a team has any indication of a survivor, another team is called over to verify the finding. If the finding is verified, and the victim is presumed to be alive, extrication begins. Rescue teams work systematically through a structure and mark each void as to when it was searched and what the findings were.

50.2.2 Natural Disasters

Natural disasters, such as earthquakes, tsunamis, hurricanes and typhoons, volcanoes, avalanches, landslides,

and floods, present many challenges for rescue robots. Natural disasters are usually geographically distributed, perhaps affecting a 200 km or more radius around the epicenter of the event. The sheer size of the affected area presents many challenges to the emergency response. The primary impact of natural disasters is on residences, light commercial buildings, sea walls and canals, and transportation and communications infrastructure. This means rescuers have thousands of structures to check quickly for survivors, but those structures will be fairly small and amenable to manual and canine search. Besides the sheer volume of structures to check, communication disruptions prevent rescuers from getting timely information as to the state of transportation access and the general needs of an area. However, designing robots to meet these challenges is important because natural disasters provide the most hope of a large number of survivors. Uninjured survivors may simply be stranded and can survive for up to 72 h.

As described in [50.8], responders are often left with no choice but to break up into small teams and begin searching in the largest centers of population with rescue on a *first-come first-served* basis. Because of the lack of pervasive communications, these teams and squads must work independently and typically with no real-time access to information being gathered by governmental agencies. Survivors may have hidden themselves in closets or in the attic, and therefore be difficult to detect. The risks to rescuers include live or suddenly re-energized electric lines, gas leaks, contamination from sewage, and victims who may try to protect themselves from perceived looters.

50.2.3 Suitable Robot Technologies for Natural Disasters

Natural disasters present unique opportunities and problems for robots. The major missions are to provide situational awareness of the distribution and degree of need of survivors (e.g., who needs immediate evacuation, who can remain in place longer), identification of routes of entry for responders, and assessment of conditions that may present a further immediate threat to life [50.8, 14]. These missions generally require coverage of large areas with information ideally provided immediately to the team of responders. As such, these types of missions favor the use of UAVs, particularly man-portable and man-packable models that can be launched as needed from small clearings and provide real-time video directly to the responders. Rotary-wing UAVs are useful even in densely forested rural areas to

enable the assessment of rural areas and road damage. Both types of vehicles may be flown at night, but this would be subject to local airspace regulations.

It is important to remember that disasters often have a water-related component. Most of the world's population lives near a bay or river and relies on bridges and sea walls. **USVs** are expected to be of more benefit than **UUVs** in inspecting this infrastructure for several reasons [50.15]. They can be launched from a distance, and because they provide a view above and below the water line of bridges, sea walls, docks, etc. **UUVs** are difficult to control in swift water and may become easily trapped by debris in the aftermath of flooding or a cyclonic event.

As a whole, ground robots may not be as immediately useful as **UAVs** and **USVs** for natural disasters [50.8, 16]. Ground robots are handicapped by the number of dwellings and light commercial buildings that must be explored at least as rapidly as a human team, compounded by the need to often break down a door or window in order to insert the robot. It is unlikely that ground robots will be able to compete with canines and their ability to smell the presence of survivors without having to break and enter intact dwellings.

50.2.4 Manmade Disasters

In comparison to natural disasters, manmade disasters (such as a terrorist bombing or serious accident) occur in a small area. The challenge is often not how to see the entire external extent of the damage, but rather to see what is not visible: the interior of the rubble, the location and condition of survivors, and the state of potentially dangerous utilities (e.g., electricity, gas lines) [50.6, 17]. The communications and power infrastructure usually exist within a 10 km range and cell

phones generally work outside of the collapsed area. Voids in the rubble may be irregular in shape and vertical in orientation. Wireless communications in the interior of the rubble is unpredictable, and generally nonexistent due to the large amount of steel within commercial structures, but the combination of irregular voids and sharp rubble do not favor the use of fiber optic cables. Visibility is difficult as there is no lighting and everything may be covered with layers of gray dust, further hampering recognition of victims, potential hazards, or accurate mapping. The interiors may be wet or contain standing water due to water lines, sewers, and sprinkler systems. Survivors are more likely to be in dire need of medical attention.

50.2.5 Suitable Robot Technologies for Manmade Disasters

The attractiveness of robots for manmade disasters stems from their potential to extend the senses of the responders into the interior of the rubble or through hazardous materials. **UGVs** are expected to be essential for building collapses, attacks such as the 1995 sarin release in the Tokyo subway, and responses to radiological disasters such as Chernobyl and Three Mile Island, while **UAVs** are key for mapping external plumes and spills of toxic chemicals. **UGVs** are expected to be the dominant modality for victim rescue in a building collapse, though other modalities might help with long-term recovery. This strongly suggests that **UGVs** should be waterproof or at least highly water resistant, since the interior of the rubble is likely to have some water present from the sprinkler and sewage systems. The small size and irregular shape of voids in the rubble also suggests that **UAVs**, no matter how small, will be unlikely to have enough space to fly in and navigate the interior.

50.3 Robots Actually Used at Disasters

While many types of robots have been proposed for search and rescue, only a few have actually participated in a rescue or been allowed to operate on site after a disaster for testing purposes; all of these have been teleoperated. Six of the seven disasters that have employed robots have occurred in the United States, with one in Japan (Table 50.1). The majority of deployments have fortunately been by scientists at the Center for Robot-Assisted Search and Rescue (United States) or the International Rescue System Institute (Japan), providing

crucial information about robot design, concepts of operation, and human–robot interaction. In terms of ground robots, small tracked platforms dominate but there have been promising results with a snake robot fielded at the Niigata Chuetsu earthquake, as described below. Man-portable and man-packable fixed- and rotary-wing aerial platforms also have been useful at disasters. Many state National Guards in the United States own the Predator **UAV**. Unmanned surface vehicles have been used once with good results. Small **UUVs** such as the VideoRay

Table 50.1 Tables showing the modalities and sizes of robots deployed to actual disasters or used for experimentation at the disaster site

| Disaster Deployment | | UAV | UGV | USV |
|-------------------------------|----------------------------------------|-----------------------------------------------------|------------------------------|------|
| 2001 | World Trade Center, New York, USF | | Man-packable Man-portable | |
| 2005 | La Conchita, California mudslides, USF | | Man-packable | |

| 2005 | Hurricane Katrina, USA | Man-packable rotary-wing | | |

are commonly used internationally to help find bodies after a car accident or drowning. Only three agencies are known to own ground rescue robots, the Tokyo Fire Department in Japan, the New Jersey Task Force 1 State Urban Search and Rescue team in the United States, and the United States Mine Safety and Health Administration. There is no known disaster where a robot actually found a survivor, though robots have generally received high marks for completing their search missions and finding remains.

50.3.1 2001 World Trade Center, United States

Unmanned ground vehicles were used at the World Trade Center 9/11 disaster in New York City, United States [50.10]. The disaster occurred on 11 September 2001 with terrorists crashing planes into the twin towers, which subsequently collapsed. Another building in the complex was sheared in half, and a fourth building burned down. Close to 3000 people and firefighters were killed immediately. A massive search-and-rescue response was conducted in the hope of finding trapped survivors in stairwells and basements covered under the pancaked debris of 110 storeys of collapsed steel structure.

Three species of small UGVs (Inuktun micro-VGTV, Inuktun micro-Tracks, and Foster-Miller Solem) were used initially to actively explore the rubble of the twin towers, Tower One and Tower Two, plus the partially demolished Tower Four. Later the Foster-Miller Talon was also used to inspect the building founda-

tions. The UGVs were all affiliated with the DARPA Tactical Mobile Robots program, and were fielded under the direction of the Center for Robot-Assisted Search and Rescue (CRASAR) in conjunction with the state of New York State Emergency Management department and the New York Department of Design and Construction. Seventeen species of robots were available, but only the most portable, ruggedized, and user-friendly were actually selected for use by the responders.

The first robots arrived on scene by 16:00 on 11 September 2001 and tethered robots were put into service around midnight. Robots were used through to 2 October 2001, when the last robot broke. The robots and operators were deployed with several Federal Emergency Management Agency teams, especially Indiana Task Force One, through until 21 September 2001. The robots were used to explore voids with less than 1 m diameter that a person or dog could not enter or voids less than 2 m diameter that were still on fire. The robots found approximately 10 sets of remains in rubble 7–20 m below the surface but no survivors. Only one robot was lost, a Solem, which lost wireless communications, stopped in place, and the safety rope broke during retrieval; note that the density of the rubble significantly interfered with wireless networks. Later in September, as rescue became improbable, larger man-portable Foster-Miller Talon robots began to be used to explore the stability of the basement, especially the slurry wall. The slurry wall was a foundation shared by many other buildings in that part of New York and damage could create further structural difficulties. The

New York (City) Department of Design of Construction actually breached holes in likely locations of the perimeter of the basement in order to insert the larger robots.

The lessons learned fall into two categories: *design of robots* and *human–robot interaction*. These are summarized below, following [50.10]. Robot platforms will be operating in narrow, vertical spaces that pose communications interference. Each robot will need a safety rope and, if wireless, the wireless system should be replaced with a communications (fiber-optic) tether sturdy enough to act as a safety rope. Robots should be invertible, since the confined spaces often do not permit sufficient room for self-righting, and with sufficient waterproofing to permit decontamination and to operate in water, rain, and snow. The minimum payload is a color camera and two-way audio, while an operator control unit should contain record and playback video capabilities. Thermal imaging was not of use at the World Trade Center due to the overall heat in the voids, but is generally desirable.

50.3.2 2005 La Conchita Mudslide, United States

Ground robots were used unsuccessfully at the La Conchita mudslide [50.18]. On 10 January 2005, at the small town of La Conchita outside of Los Angeles, a sudden mudslide destroyed 18 houses, killed ten people and left searchers looking for six people missing for several days (the missing persons were out of the state on vacation). While this was not a mass disaster, it did extend beyond a local incident and engaged regional and national response teams.

CRASAR responded with an American Standard Robotics VGTv Extreme, a waterproof upgrade of the polymorphic Inuktun micro-VGTv used extensively at the World Trade Center. The robots were used twice and failed within two minutes and four minutes, respectively. The obvious reason for the failure in both cases was poor mobility. The robot was initially directed to search a crushed house where a canine team had indicated the possibility of a victim. The robot entered the house via a narrow gap between the foundation and flooring, but immediately failed when a root in the wet soil became lodged in the left track and it came off. In the second run, the robot was inserted into the intact second story of a house damaged on the lower floor to test a vertical entry. The robot detracked once again, this time due to the compliance of the thick shag

carpeting. Though a poor track design (originally intended for movement on smooth ventilation ductwork) was the ultimate cause of failures, the severity of the design flaw was undetected by both the manufacturer and CRASAR due to the lack of adequate testing under realistic conditions.

The lessons learned for robotics from this disaster were that ground mobility remains a major challenge and that adequate testing is important. Open track designs appear to be unsuitable for rescue; they are too susceptible to detracking and vulnerable to debris becoming wedged in the tracks. Testing in diverse soil and interior terrain conditions is important, adding emphasis to the need for adequate standards.

50.3.3 2005 Hurricanes Katrina, Rita and Wilma, United States

State and military unmanned aerial vehicles were used in the aftermath of several hurricanes in the United States, along with a ground robot. In 2005, the southern Gulf Coast of the United States was battered by a series of hurricanes from June through November. Hurricane Katrina was the worst hurricane in the history of the United States. It made its primary landfall near New Orleans on 29 August 2005, devastating the states of Louisiana and Mississippi and portions of Alabama, impacting an area of 200 km², costing nearly 2000 lives, and leaving behind 80 billion US dollars in damage. Hurricanes Rita and Wilma were less extensive and damaged parts of Texas, Louisiana, and Florida.

The 2005 hurricane season saw the first use of UAVs for a large-scale disaster [50.16]. During the hurricane Katrina response, two UAVs were used by CRASAR in Mississippi as part of the Florida State Emergency Response Team to search rural regions cut off by flooding and downed trees. The UAVs are shown in Fig. 50.1: a battery-powered fixed-wing and a battery-powered rotary-wing (a Like90 T-Rex miniature helicopter modified for stability in high winds) UAVs. An internal-combustion Silver Fox was used later in the week over New Orleans by the Department of Defense to help identify which areas were still in need of assistance. All systems were under 2 m in their characteristic dimension, easily dismantled and transportable, and flew below regulated airspace, with procedures spontaneously developed to ensure safety and avoid collisions with manned aircraft. The UAVs were tasked for surveying, providing information directly to the responders rather than waiting for the data from unmanned helicopter flights to be processed and then manually transported to the responders in the field. In hurricanes Rita and Wilma, the Texas and Florida state National Guards flew much larger Predator UAVs in regulated airspace to provide timely information to strategic decision makers. The Predator class of UAVs are physically larger, require more people to operate, and a large take-off and landing zone, and must be co-ordinated with airspace operators since they operate at the same altitudes as manned aircraft.

An American Standard Robotics VGTv Extreme robot, the same model that failed at La Conchita, was used by Florida Task Force 3 State Urban Search and Rescue Team to successfully investigate the first floor of an apartment building in Biloxi, Mississippi, which was unsafe for human entry. The team did not have a canine

and was unsure if a trapped victim would be able to shout in reply to an audio challenge, so the decision was made to deploy the robot. Unlike La Conchita, the area of operation was favorable and the interior was smooth linoleum. The robot showed that no one was trapped inside.

The lessons learned during the 2005 USA hurricane season were primarily related to how large, geographically distributed disasters influence the choice of robot modality and how they can be used. The disasters highlighted the need for miniature aerial vehicles which could provide tactical teams with viewpoints of 1–10 km on demand or viewpoints that had not been possible before (e.g., from a miniature helicopter) [50.19]. Autonomous waypoint navigation of fixed-wing platforms was available but was not used; instead responders were much more interested in actively directing the UAVs. This suggests that the ultimate control regime will not be full autonomy but rather enabling a responder to use the robot as if it were an extension of their person.

50.3.4 2006 Sago Mine Disaster, United States

A maxi-class ground robot was used at the Sago Mine disaster in the United States. On 2 January 2006, a mine explosion in Sago, West Virginia killed 12 miners and severely injured another. It took two days to reach the victims, who were approximately 3 km from the surface; the primary obstacle was not physical debris but the need to operate in an environment saturated with carbon monoxide and methane. The Sago Mine disaster is considered a disaster, despite the relatively small number of people trapped in a confined area, because rescue teams and equipment had to be deployed from other states and from the Mine Safety and Health Administration (MSHA).

A large Remotec ANDROS Wolverine robot was deployed by the Mine Safety and Health Administration. The Wolverine class of robot is primarily designed for bomb-squad applications, where its slow speed and heavy weight (over 500 kg) is not a disadvantage. The robot had been previously modified with an enclosure rendering it intrinsically inert in the presence of explosive gases and a fiber-optic communications tether added to improve communications. Even with its slow speed and limited agility, the robot has the advantage of being able to enter a mine faster than a person in a contained suit and also being less likely to create an explosion. Unfortunately, the robot, nicknamed V2, was only able to

Fig. 50.2 The V2 robot used at the 2006 Sago Mine Disaster (courtesy of the US Mine Health and Safety Administration)

penetrate about 700 m into the mine before getting stuck on rails.

The lessons learned from the use of a [UGV](#) at the Sago Mine disaster highlighted again the need for better mobility, communications, and navigational autonomy. It illustrated the need for robots to enter areas that are unsafe for humans, but also that simply *wrapping* a robot with an explosion proof enclosure is a stopgap measure; a new class of robots for operating in explosive environments is necessary. Communications remains difficult, and the fiber-optic tether is a vulnerable component. While the fiber-optic tether was not severed during the disaster deployment, it had been damaged in prior tests and reopenings of mines. The ability to maintain reliable wireless communications with more agile robots remains a top priority in underground rescue. Navigation via teleoperation is a known challenge and often distracts the operator from larger search and assessment issues.

50.3.5 Post-Disaster Experimentation

In many cases, the real hope of rescue has passed before robotics equipment can be requested and deployed. Fortunately, forward-thinking response personnel may allow roboticists to work in the disaster zone (hot zone) during the later stages of the rescue or the recovery. In these deployments, the robots were not actually used for rescue operations but rather for experimentation, allowing the response community to evaluate and comment on rescue robot progress as well as rescuers to collect valuable data. Operations in post-disaster conditions are much more realistic than the best test beds.

At the 2001 World Trade Center disaster, CRASAR teleoperated an iRobot Packbot and a SPAWAR Urbot in a collaterally damaged building and parking garage near the main disaster site [50.10]. While the robots worked largely as expected, one surprise was the negative impact of water and dust on stair climbing and general mobility. The water from the sprinkler systems and the dust made surfaces very slippery.

In 2004, the International Rescue System Institute (IRS) inserted a serpentine robot into a house damaged during the Niigata Chuetsu earthquake (Fig. 50.3). This was the first snake robot used at a disaster site and showed the promise of biomimetic alternatives to tracked platforms. The first quake occurred on 23 October 2004, and was the largest to have hit Japan since the Hanshin Awaji earthquake in 1995. Thirty-nine people were reported to have died and massive damage was done to the transportation infrastructure. The robot, a variant of the Soryu III robot developed in collaboration between the Tokyo Institute of Technology and IRS, is 1.2 m long and weighs 10 kg, with a turning radius of 0.41 m, and a maximum speed of 0.37 m/s. The IRS Soryu carried a charge-coupled device (CCD) camera, an infrared camera (FLIR), and two-way audio as well as proprioceptive sensors. The robot was controlled through a tether that also served as a safety rope. In addition, the Soryu can support a CO₂ sensor that can detect human breathing, navigation sensors such as a laser range finder, and localization sensors, though it does not appear that this was tested. The testing in the debris concentrated on mobility.

Three days after hurricane Wilma in 2005, CRASAR deployed both a modified Like90 T-Rex and a man-portable, experimental unmanned surface vehicle ([USV](#)) to inspect seawall and bridge damage at Marco Island,

Fig. 50.3 IRS Soryu robot searching a house destroyed by the Niigata Chuetsu earthquake (courtesy IRS)

Fig. 50.4 Unmanned surface vehicle exploring the bridge to Marco Island, Florida (courtesy of CRASAR)

Florida [50.15]. The **USV**, shown in Fig. 50.4, carried a DIDSON acoustic camera, capable of penetrating through turbid waters and mud, as well as a camera above the surface. The **UAV** was used independently to investigate damage topside, but was very helpful to the **USV** crew in establishing where the **USV** was in relationship to piers and pilings; this strongly indicates the need for **UAV-USV** teams. The use of the **USV** near and underneath large structures hampered wireless communications and Global Positioning System (**GPS**) signals, posing additional demands.

Three months after hurricane Katrina in 2005, CRASAR used a small rotary-wing **UAV**, an iSENYS IP3, to document the structural damage to multistory commercial buildings along the Gulf Coast impacted by hurricane Katrina [50.16, 19]. The eight days of intense flying, which duplicated emergency response missions, showed that three people are needed to operate a **UAV** safely close to urban structures: a pilot, a mission specialist to run the payload and take pictures, and a flight director to serve as safety officer and maintain overall situation awareness. The post-hurricane-Katrina effort confirmed the concept of operations from hurricane Wilma, where a mission consists of a short flight (five to eight minutes) on each face

Fig. 50.5 A small **UUUV** used for underwater inspection (courtesy of CRASAR)

of the building, allowing the pilot and flight director to keep the vehicle in line of sight. This concept of operations fosters safety and reduces cognitive fatigue for the pilot. Although it is likely that teleoperated line-of-sight in the United States will be mandated, the close proximity to the building (1–3 m) indicates the need for semiautonomy, especially guarded notion, to assist the pilot and prevent collisions.

50.3.6 Search and Recovery

While ground and aerial rescue robots are new, very small underwater robot cameras such as that shown in Fig. 50.5 have been routinely used by law enforcement and fire rescue teams for over a decade to find submerged cars that have gone into the water. These operations are generally considered search and recovery, rather than rescue, because the victims have drowned and are beyond revival by the time the specialized equipment can arrive. The **UUUVs** are miniature torpedo-like devices with cameras teleoperated by a person on the surface. The problems facing **UUUVs** are sensing through the turbidity of the water and control of devices in strong currents that prevent them from being used in swift water.

50.4 Promising Robots and Concepts

Search and rescue is a demanding application and it is reasonable to expect that new types of robots will evolve to meet the challenge. Numerous speculative designs for unmanned ground and aerial vehicles

have been proposed, and representatives that have been tested are described below. While approaches to search and rescue have mainly been presented in terms of single-robot activities, teams of robots proffer inter-

esting future scenarios where teams of robots swarm and cooperate to accomplish their mission. Robots need not look like robots in order to be useful for search and rescue; unattended ground sensors, blimps, kites, and smart shores using the principles of robotics and artificial intelligence are poised to make a difference in the near future. In addition, basic research in legged robots (Chap. 16), wheeled robots (Chap. 17), micro/nanorobots (Chap. 18), multiple-robot systems (Chap. 41), networked robots (Chap. 42), general under-water robots (Chap. 44), and aerial vehicles (Chap. 45) are expected to yield more concepts for rescue robotics.

50.4.1 Alternative Ground Rescue Robot Designs

Polymorphic tracked vehicles represent the state of the practice of ground rescue robots. These tracked vehicles have been primarily used for navigation and sensing missions, ignoring missions that require manipulation. Wheeled platforms are severely limited by the roughness of the terrain and the need to overcome obstacles, steps, ramps, but combination wheeled and tracked vehicles are commercially available. Small tracked robots with manipulators have been developed for bomb-squad activities and appear well suited for transfer to rescue applications. In addition, many alternatives to tracks have been proposed. Of these, serpentine (or *snake*) robots and legged vehicles appear the most promising. Jumping or rolling robots have been proposed to cope with rough terrains, but their effectiveness still needs to be demonstrated.

Robots with manipulators (such as that seen in Fig. 50.6) extend the capabilities of ground vehicles by allowing the robot to sample the environment, interact with survivors, move light obscurations (manipulators typically cannot lift heavy objects), and add unique camera viewpoints. Operators of the Foster–Miller Talon robot at the World Trade Center disaster used the camera mounted on the robot arm to peer over railings and inspect the basement substructure below. Manipulator arms are often used as camera masts, allowing the operator to see more of the environment, examine the surfaces of desks, tables and counters, and to see if a robot is stuck or disabled. However, adding a manipulator comes at a cost. The manipulator extends the volume of the robot, impacting on navigation; the arm is often at risk of being damaged in confined spaces by being hit on overhanging rubble. Manipulators also add to the control and mechanical complexity of the robot.

Fig. 50.6a,b Examples of tracked robots with manipulator arms that have been used for disasters or rescue competitions. (a) View from Foster–Miller Talon at the WTC of its arm (courtesy of CRASAR) and (b) telemAX by Telerob at the Rescue Robotics Camp (courtesy of R. Sheh)

Free serpentine robots such as the Soryu III used at the rubble at the Niigata–Chuetsu earthquake provide a fundamentally different style of mobility, while *fixed-based* snakes can be used in tandem with a more traditional platform as a highly flexible sensor manipulator [50.20]. Examples of both types of snake robots are shown in Fig. 50.3 and Fig. 50.7. Serpentine robots are more correctly known as hyperredundant mechanisms [50.21]. Free snakes propel themselves either by direct propulsion, making direct contact with the ground, or undulation, wriggling the internal degrees of freedom of the robot. Snake robots present some of the most demanding challenges for roboticists [50.22]. In order to be truly deployable, much work is needed in design and actuation, as well as control. Autonomous gaits need to

Fig. 50.7 A CMU fixed-base snake being tested at a facility in California (courtesy H. Choset)

be developed in conjunction with a sensor skin that will let a snake move in confined spaces out of the line of sight of an operator.

In order to overcome the difficulties posed by unknown terrain, legged robots and crawler robots have been proposed. In addition, some types of crawler robots can climb walls and reach locations that would otherwise be very hard to reach. Legs are interesting because they exploit biomimetic principles. The RHex hexapod robot [50.23], proposed for search and rescue among other potential applications, is shown in Fig. 50.8 climbing random step fields. The legs on RHex are curved and rotate, yet duplicate the spring-like capabilities of insect legs. They illustrate how biologically inspired forms of locomotion do not have to look like animal legs to achieve the same effect. RHex has favorable mobility properties but the slapping motion of the legs may stir up large amounts of dust in interior building collapses and interfere with sensing. Crawler robots such as the Terminatorbot [50.24] use their arms or legs to pull themselves through the rubble. The Terminatorbot is designed to withdraw itself into a cylinder that can be inserted through one of the small boreholes commonly drilled by responders to get through walls, then open up and begin moving. Other types of crawlers include lizard- or gecko-like robots that adhere to walls; these types are promising but have not been tested for the dusty, wet, and irregular conditions found in disasters.

50.4.2 Aerial Rescue Robots

Aerial rescue robots represent the most advanced robotics technology in use, and new concepts continue to emerge. Aerial vehicles can be further subdivided into *fixed wing* (a.k.a. plane-like), *rotary wing* (helicopters),

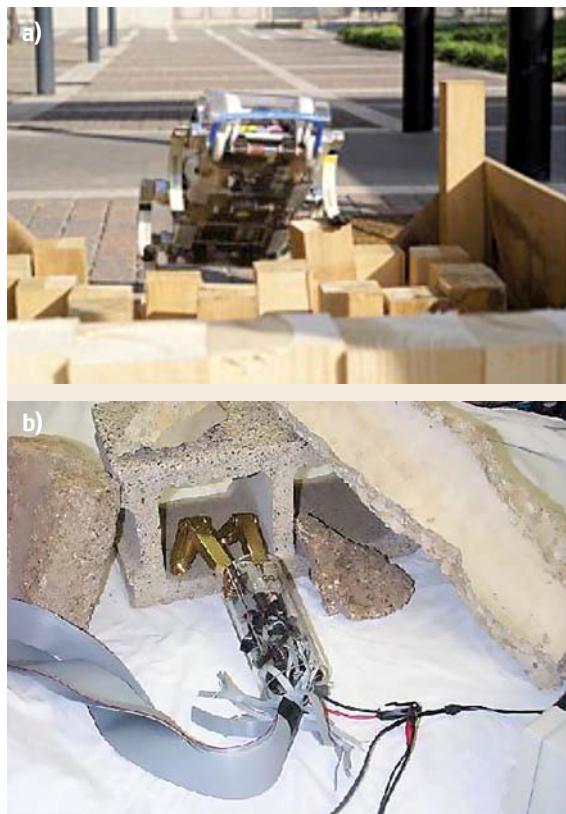

Fig. 50.8a,b Examples of legged and crawler robots. (a) Hexapod (legged) robot from the RHex project traversing a portion of the NIST test bed (courtesy of R. Sheh) and (b) Terminatorbot being tested in rescue test bed (courtesy of R. Voyles)

lighter-than-air (blimp), and *tethered* (kite) platforms. Fixed-wing UAVs typically travel long distances and can circle points of interest, while rotary-wing platforms can hover and require a small area to launch and land. Lighter-than-air vehicles may be tethered, similar to a kite. Underwater vehicles may also be subdivided into tethered and untethered platforms.

Large unmanned helicopters, such as the Yamaha R-Max, continue to be adapted for commercial rescue-and-recovery missions, including carrying heavy payloads capable of estimating the amount of rubble and debris generated by a disaster. Small fixed-wing platforms for tactical military use may have great benefit to the response community. Novel ideas include a plane the size of a person's hand that can fly indoors and planes with foldable wings, making it easier for responders to carry them. Novel rotary-wing designs are

also being proposed. Quadrotor helicopters appear far more stable and easier to pilot; a design that balanced the larger size of a quadrotor with an appropriate payload could make UAVs more assessable to non-pilots. Another exciting direction is hybrid platforms that can change from fixed-wing operations, covering large distances, to rotary-wing operations, flying near or inside buildings [50.25]. However, UAVs are drawing the attention of agencies that control airspace and may become heavily regulated in the future.

50.4.3 Unique Concepts of Operations

Current rescue robot scenarios have typically complemented or enhanced human capabilities, but within a fairly conventional, single-robot framework. New concepts of operations for exploiting rescue robots are being continuously identified. At this time, the major themes are *multi-robot teams* or *swarms*, robots forming or extending *communications and sensor networks*, *smart tools*, and *roboticized animals*. Past experience has shown that current ground robots are not appropriate for multi-robot team operations; relatively few voids occur that current robots could explore and these may be in different sectors assigned to different teams, so the idea of an operator managing 10 or more robots each actively investigating the rubble is speculative for now.

Teams of robots that cooperate with each other or work on the same objective have already been demonstrated for rescue activities. Homogeneous teams have been entered at the RoboCup rescue competition [50.26]. After hurricane Wilma, a UAV and USV team accomplished together what a single USV could not [50.15]. The small Inuktun robots used at the World Trade Center were actually intended to be the daughters (or joeys) of a marsupial (kangaroo) team, where a larger ground robot would deposit the smaller robots into voids [50.27]. (In reality, responders carried and inserted the robots.) Aerial vehicles that drop intelligent sensors and motes is another type of heterogeneous team. One of the most intriguing types of teams is swarms. Researchers such as [50.28] have discussed the possibility of using cost-effective, insect-sized robots to penetrate deep within a pancake building collapse and then signal the presence of a victim. Such teams can make use of collective intelligent behaviors from simple animal models that are far more complex than the behavior exhibited by the individuals. Consequently, robot teams can be composed of a large number of simple devices, thus yielding greater robustness to failure and distributed information gathering. One of the key features of swarm

approaches is that they can scale up easily. The insect swarm scenario leaves hard problems like control, sensing payloads, localization of the victim, and communications to the imagination, but is certainly a worthy concept. However, some of the search algorithms used by insects may be adapted to single robots, for example win-shift win-stay sampling exhibited by bees may be useful for search [50.29].

Robots, stationary and mobile, can facilitate the establishment of communications and sensor networks. As repeaters for mobile ad hoc networks, robots on the land, sea, and air can extend the range and throughput of wireless networks [50.30]. Aerial vehicles are particularly attractive as they can provide larger relay ranges while providing a bird's eye view of the disaster. However, a UAV does not always have to move: a tethered blimp or kite can support a sophisticated payload with no maintenance or support for days [50.31, 32].

Another concept is that of *smart tools*, particularly lifts that can help stabilize collapsed structures during extrication [50.33, 34]. Extrication is one of the most time-consuming activities in rescue. Rescuers must proceed cautiously when removing rubble in order to prevent secondary collapses or slides that would further injure the survivors. Experiments suggest that roboticized lifts or shoring mechanisms would be able to sense and respond fast enough to small movements in the rubble to adaptively maintain stability. [50.34]

The trend towards miniaturization of sensors and wireless communications has led some researchers to propose having search dogs carry roboticized cameras (dog-cams) or wiring rats with controllers. Attaching cameras to search dogs has been explored for several years and such a system was used at the World Trade Center. The concept does not compete with robots, as robots are used to enter places canines cannot. The canine team handlers have generally objected to dog-cams because the cameras and communications gear interfere with the dog's mobility, pose the hazard of snagging, and the dog cannot be readily commanded to stop at points of interest beyond the line-of-sight of the handler (dogs use visual cues as commands, more than audio). However, there is less objection to placing nodes in a rat's brain to stimulate and drive the rat into a void while carrying a camera or other sensors [50.35]. The motivation for a robot rat stems in part from the rat's mobility and relative low value. While the technical feasibility of a robot rat may be within reason, assuming advances in wireless communications, the response community has been lukewarm towards the idea [50.36]. Unlike rates, robots can be kept in storage for years and can pene-

trate through pockets of fire or areas with no oxygen. A robot rat has all of the limitations of dog, including the problem of a handler becoming too emotionally attached, and is likely to scare a trapped survivor just as much as the other rats that swarm a disaster. The con-

ventional wisdom is that, if the sensors, wireless, and power systems can be miniaturized and operate reliably enough to control a rat deep within rubble, those systems will enable responders and robots to work without the rats.

50.5 Evaluation and Benchmarks

There are a variety of methods for evaluating a rescue robot or the larger mixed human–robot system. *Simulations*, either through computer simulations or physical test beds duplicate some key component of a disaster or a disaster on a smaller scale, are common. Simulations provide availability and repeatability. *Demonstrations* at physical test beds, such as training sites for responders or through the RoboCup rescue competition, have been the primary source of feedback about rescue robots. Demonstrations can provide feedback on the performance of a robot under known conditions and to a lesser extent about the mixed-team performance. Demonstrations are often not repeatable but do offer a higher degree of physical fidelity with expected disaster settings than can be achieved through computer simulation. Simulations can be used for statistically significant experimentation, however, the need to control the number of variables in an experiment often leads to a form of reductionism, where a hypothesis is tested but under such artificial conditions as to undermine the value of the experiments. *Technology insertions* into actual disasters provide valuable information, though that information is not repeatable, and the ground truth is often unknown and generally relies on the skill of the observers.

In order to evaluate a rescue robot or mixed human–robot team, there must be metrics and measurement methods. Unfortunately, rescue robotics is such a new field of endeavor that metrics and methods are still currently under development. The scope of the evaluation influences the choice of metrics and methods. Rescue robots can be evaluated within at least four different categories:

1. the physical attributes of the robot, which can be further broken down by subsystem
2. the human operator performance
3. the performance of the humans and robots together as a mixed team
4. the impact of the robot team on the survivors or non-team members

At this early stage in the development of rescue robots, metrics and methods are being proposed for physical, operator, and team performance [50.37].

Metrics and methods are used by technologists to measure progress towards a useful product while standards represent that product's minimum capabilities and attributes and enables consumers (in this case, the response community) to purchase worthwhile systems. Standards rely on metrics and methods for measuring compliance, though these may sometimes be different from those used by researchers and developers. The US government National Institute of Standards and Technology (NIST) is leading the effort to standardize rescue robots for adoption by US responders. This effort is being conducted through ASTM and thus, even though it is largely driven by the US, will likely result in an international standard that may be adopted by other countries. NIST has considerable experience in testing rescue robotics, beginning with the creation in the late 1990s of a portable standard test bed for search and rescue for use by the RoboCup rescue and AAAI mobile robot competitions.

50.5.1 Computer Simulations for Rescue Robotics

Computer simulations provide a low-cost mechanism to explore the larger behavior of a robot or system. Generally, computer simulations provide high fidelity for testing software execution, but their physical fidelity depends on the physics engine. Simulating sensors and the complex environments produced by a disaster is difficult and is rarely accurate enough to test perceptual algorithms. At the time of writing, two readily available computer simulations exist for exploring the strategic and tactical applications of rescue robots within the RoboCup rescue framework [50.38], the *RoboCup rescue simulation project* [50.39] and *USARSim* [50.40]. These simulations are well understood, accepted, open-source, and free; as such, they should be useful for most

researchers or practitioners interested in ground-based rescue robotics.

The RoboCup rescue simulation project is used in the RoboCup rescue simulation league to study agent-based approaches to strategic planning for the disaster response. The simulator assumes a strong centralized response capability that is not necessarily the case for all countries or regions; the United States, for example, relies on a highly distributed organization that obviates many centralized coordination schemes. Although the simulation is focused on strategic decision making, particularly dynamic resource allocation, it does support the examination of how robot resources might be allocated during a disaster and how data from a robot might be propagated through a system. It permits the simulation of monitoring of disaster damage from reports by humans, distributed sensors, and robots and can simulate complex interactions such as telemedicine.

USARSim is a computer simulation developed by the University of Pittsburgh for physical robot simulation in disaster situations [50.40]. The simulation replicates the NIST standard test bed for search and rescue and permits efficient prototyping and testing of robot design and most aspects of control software. It uses Unreal game engine for handling physics and graphics, and virtual robots have capability of sensing (image, laser range finder, etc.) and actuation (wheel, motor, etc.) with data processing (image recognition, SLAM, etc.) in artificial environments. In 2006, the RoboCup rescue competition created a simulation league using this environment.

50.5.2 Physical Test Beds

Physical test beds provide a more realistic venue than a computer simulation for evaluating rescue robots, but may not be available to researchers, too expensive to use or to travel to, or not adequately capture some key aspect of a disaster. Physical test beds generally fall into two categories: *test beds developed for the fire rescue community* or the *NIST standard test bed for search and rescue*.

Fire rescue training test beds occur throughout the world and are used to train human firefighters and rescue specialists. Some facilities are also used to train canine teams. These test beds are constructed from construction and sewer debris, can introduce smoke and some simulants, and pose challenging mobility conditions, but vary in terms of fidelity. In many test beds, the density of the debris does not contain the actual amount of metals in a real collapse. This can lead to optimistic reports of

success of sensors and wireless communication devices. The test beds, being designed for human training, do not replicate the conditions under which a ground robot would be used. The terrain is generally on the exterior of the rubble and does not exercise the robot in confined

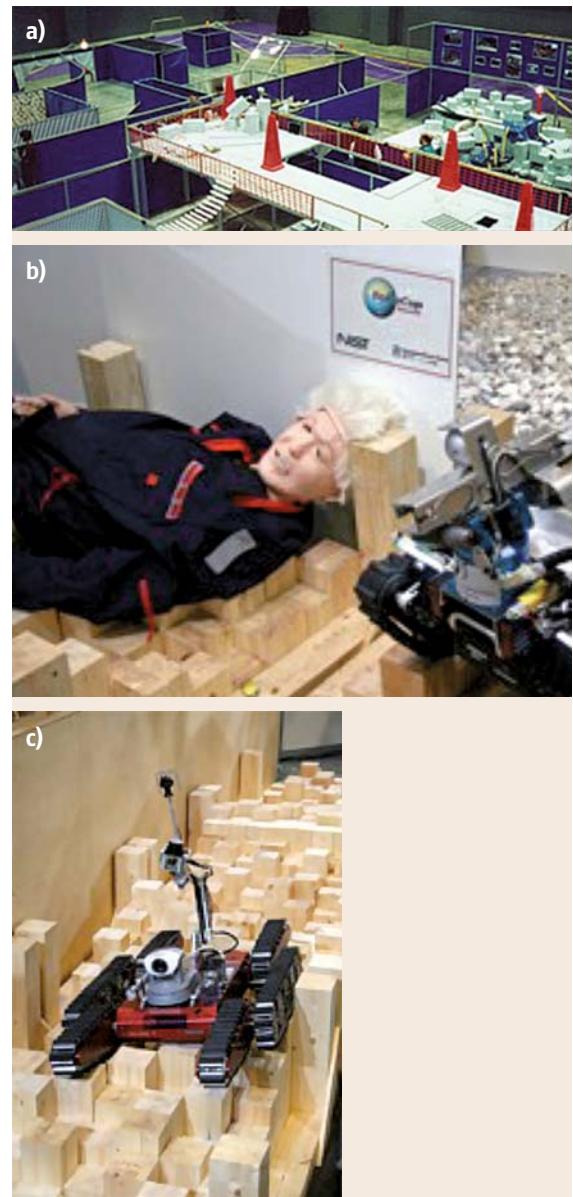

Fig. 50.9a–c View of the NIST standard test bed for search and rescue used by RoboCup Rescue. (a) View of overall test bed, (b) dummy representing a victim, and (c) a step challenging robot mobility (courtesy NIST)

or vertical spaces. Depending on the size of the facility, the test bed may or may not be suitable for evaluating UAVs. An example of a fire training test bed appeared earlier in Fig. 50.7b.

Perhaps the most influential physical simulation for researchers is the RoboCup rescue physical league which uses the NIST standard test bed for search and rescue, shown in Fig. 50.9. This competition started in 2001 [50.41] and has more than 40 team entries every year from all over the world. The RoboCup rescue physical league scores robot performance in terms of mobility, mapping, situation awareness, sensing, shared autonomy, etc. A robot or robot team competes in one of three arenas which simulate disaster situations at the annual RoboCup world competition. The mission of the robot teams is to collect victim information (existence, state, and location) by sensor fusion of vital signals (heat, shape, color, motion, sound, CO₂, etc.) and report a map of victims in disaster space so that responders can efficiently arrive at the victim for rescue. In addition to the arenas, the competition and test bed contain individual skill test stations, for example, in order to test mobility, robots must traverse a random step field made of wood. The test bed was designed to be portable and reasonably inexpensive and several locations around the world have set up duplicates. As a result of the constraints of cost and portability, the test bed is not fully

representative of actual disaster physical conditions and does not test the operating conditions for the human teams.

50.5.3 Standards Activity

Standards for rescue robots and systems are being generated at the time of writing. The E54.08 subcommittee on operational equipment within the E54 Homeland Security application committee of ASTM International started developing an urban search and rescue (USAR) robot performance standard with the National Institute of Standards and Technology (NIST) as a US Department of Homeland Security (DHS) program from 2005 to 2010. It plans to cover sensing, mobility, navigation, planning, integration, and operator control in order to ensure that the robots can meet operational requirements under the extreme conditions of rescue. The standards will consist of performance measures that encompass basic functionality, adequacy and appropriateness for the task, interoperability, efficiency, and sustainability. The components of the robot systems include platforms, sensors, operator interfaces, software, computational models and analyses, communication, and information. Development of requirements, guidelines, performance metrics, test methods, certification, reassessment, and training procedures is planned.

50.6 Fundamental Problems and Open Issues

Rescue robotics is clearly a challenging field with many open issues. This section discusses the challenges by subsystem (mobility, communications, control, sensors, power), then the general human–robot interaction (HRI) challenges, and finally the remaining problems in evaluation. In addition to these specific areas discussed below, there are three cross-cutting challenges that should be mentioned: how to reduce mission times; how to localize, map, and integrate data from the robots into the larger geographic information systems used by strategic decision makers; and how to improve the overall reliability of rescue robots.

One of the most pressing challenges that cut across all subsystems is how to make rescue robot operations more efficient in order to find more survivors or provide more timely information to responders. Since rescue robots typically perform missions that humans cannot do, it is hard to compare performance directly. However, it may be useful to consider how robot operations can

be made more efficient in terms of pre-mission preparation (e.g., how long does it take to set up the robot system), mission execution, and post-mission activities (e.g., how long does it take to change batteries, decontaminate, inspect for wear, or perform minor repairs, etc.). Efficient mission execution remains the subject of much research, particularly investigations into how to speed up navigation through rubble or damaged areas with faster robots or autonomy. Studies have consistently shown that ground robots operating in the interior of collapsed buildings are physically moving only 51% of the time and that only 44% of the operator's activities are directly related to navigation [50.42]. Therefore speeding up mission activities such as building situation awareness and recognition may be as important to any type of rescue mission as speeding up navigation.

Rescue robots are tasked with missions where geographical information would help responders. For example, for ground robots, finding the presence of

a survivor in rubble is helpful, but knowing the location of the survivor is better, and knowing the path of the robot and the condition or type of rubble along the path even more helpful to extrication. Unfortunately, ground and surface vehicles are generally tasked in areas where structures prevent reliable [GPS](#) reception and underwater vehicles cannot receive [GPS](#) signals. Fixed-wing aerial vehicles, such as those used after hurricane Katrina, Rita, and Wilma, generally come with software that permits path mapping in [GPS](#) coordinates that can be displayed on maps, as well as determining the [GPS](#) location of any object in the camera view. Improvements to ground and surface vehicle mapping are expected to be a function of sensor miniaturization. As seen in Chap. 38, significant progress has been made in three-dimensional (3-D) simultaneous localization and mapping using range sensors larger than fieldable rescue robots.

Reliability of rescue robotics is obviously important, as robots which frequently break or need copious amounts of maintenance will be discarded. Failures may stem from physical failure, due to manufacture or unanticipated demands of the environment, or human error, including design failures or operator errors. As of 2004, ground rescue robots exhibited a mean time between physical failures ([MTBF](#)) of only 20 h, meaning that robots break every other shift, well below the desired 96 h proposed by the [US](#) military as the minimum for ground robots for urban operations [50.43]. In practice, a field ground or aerial robot system consists of two or three robots to provide complete redundancy, plus tools and spare parts.

50.6.1 Mobility

Mobility remains a major problem for all modalities of rescue robots, but especially for ground vehicles being used for urban search and rescue. The challenges for ground robots stem from the complexity of the environment, which is an unpredictable combination of vertical and horizontal elements with unknown surface characteristics and obstacles. The field is currently lacking any useful characterizations of rubble to facilitate better design. However, even without a complete understanding of rubble environments, it is clear that more work is needed in actuation and mechanical design as well as in algorithms that would enable the robot to adapt its mobility style to the current terrain (also known as *task shaping* [50.44]). Aerial vehicles, particularly helicopters, are vulnerable to wind conditions near (or in) structures and obstacles such as power lines, trees, and

overhanging debris. Surface and underwater vehicles have to contend with swift currents and floating or submerged debris, placing significant demands on agility and control.

50.6.2 Communications

Robots rely on real-time communications for teleoperation and for enabling responders to see what the robot is seeing immediately. Ground robots communicate either through a tether or via wireless radio. Aerial and surface robots are wireless, while underwater rescue robots are controlled via a tether. The communication bandwidth demands of all modalities are generally high due to the use of video imagery, and the tolerance to communications latency is low due to the control needs. In addition to communications between the tactical rescuers and their robots, it is difficult to report or transfer critical information provided by rescue robots to the strategic enterprise. Disasters typically destroy the communication infrastructure, both telephones and cellular phones, and alternatives such as satellite phones become saturated by response agencies.

Wireless communications with robots remain problematic. Operations below ground or near structures interfere with the physical propagation of radio signals. As shown in high-fidelity [US&R](#) response exercises, ad hoc wireless networks established by responders are likely to become quickly saturated, with no way of establishing priority over information. At the World Trade Center, data from the Solem robot deployed in the interior of building WTC4 returned totally black frames for 1 min 40 sec of the 7 min run before wireless communications were totally lost and the robot was abandoned [50.10]. In addition, many wireless robots use lossy compression algorithms to manage bandwidth, which interfere with computer vision techniques, and/or connect through insecure links, raising the possibility that news media might intercept and broadcast sensitive video of trapped victims.

Rescue robots working underground, either for [US&R](#) or mine rescue, have two alternatives to wireless communications: either operate with a tether or deploy repeaters to maintain wireless communications. Many wireless robots now can be purchased with a fiber-optic tether; however, these tethers are fragile and may break or tangle. The fiber-optic tether may also tangle with the safety rope used to support the robot during vertical drops. Data for the World Trade Center deployments indicated that a dedicated person was required to manage the tether but that 54% of tether management operations

were to allow the robot to reach a more favorable position or to recover the robot after its mission [50.10]. Hybrid communications, in which a robot is primarily on a tether then operates for short distances over a local wireless link before reconnecting to the tether, appear to be attractive.

50.6.3 Control

Robot control can be subdivided into *platform control*, which is usually considered by control theory, and *activity control*, which generally falls under the purview of artificial intelligence. Rescue robots are challenging both for traditional control and for artificial intelligence. The high degree of mechanical complexity of all modalities and the demands of the environment present major challenges for control theory. The robot's activity is usually handled by teleoperation; a human is needed to direct the robot and to perform mission sensing. The well-documented problems of manual teleoperation (see Chap. 32 Telerobotics) argue for increasing autonomy [50.45].

50.6.4 Sensors

Sensors, and sensing, pose the greatest mission challenge; without adequate sensing, a robot may be in an area of interest but be unable to navigate or to execute the larger mission. The physical attributes of a sensor (size, weight, and power demands) impact on whether it can be used with a particular robot platform. Currently sensors are not interchangeable between platforms; standards are needed for footprint sizes, mounting, connections, and display space.

The functionality of a sensor depends on the modality and mission [50.17]. The primary sensor missing from all robot modalities operating outside of water is a miniature range sensor. With a miniature range sensor, the success in localization and mapping seen with larger robots would be transferable to rescue robots. The sensor payloads for other missions depend on those applications; however, two sensor needs for US&R are particularly noteworthy. One is a detector that can perceive victims obscured by rubble; current radars have not been reliable in mixed rubble. Another needed sensor is one that can tell if a victim is unconscious but alive without touching the victim. A robot may be able to see a victim, yet not be able to crawl to the victim and make contact or scrape away enough dirt or clothing to take a pulse. Stand-off detectors such as millimeter-wave

radars and gas detectors appear promising but have not been validated at this time.

Smaller, better sensors are not sufficient; improvements in sensing algorithms are also needed. At this time, humans are expected to interpret all sensing data manually in real time. This is a daunting task for many reasons. Human performance is handicapped by physiological factors introduced by sensing through a computer display (also known as computer mediation), the location of sensors at viewpoints low to the ground, generally restricted fields of view, and fatigue. The modality output itself may also be nonintuitive, such as ground-penetrating radar. However, autonomous detection and general scene interpretation is considered well beyond the capabilities of computer vision. This presents a case where neither the human nor the computer can accomplish the perceptual task reliably and argues for investigation into human-computer cooperative techniques for perception. Algorithms that enhance the image for human inspection, supplement depth perception, or cue interesting areas are within the reach of computer vision.

50.6.5 Power

The robot modality and mission poses distinct challenges for power. In general, battery power is preferred over internal combustion because of the logistics difficulties in transporting flammable liquids. While the requirements of each rescue robot application is largely unknown, a partial understanding is emerging of the power profile. For example, the operation tempo of a ground vehicle operating underground is on the order of 3–4 runs, each around 20 min in duration, over a 12–14 h shift, with the robot kept on hot standby for the majority of the shift. Rotary-wing aerial vehicles for tactical reconnaissance and structural inspection show an operations tempo of 5–8 min per face of a building, while fixed-wing vehicles are airborne for less than 20 min. Other rescue missions, such as wilderness search and rescue, will have different requirements but the need for batteries over internal combustion and for determining the power profile is the same.

The size and weight of the power source is important. It may be the single driver in the overall size of the platform and influence key design attributes such as the placement of the payload. A word of warning is warranted: a common design flaw in rescue robots is to locate the batteries so as to maximize stability but with the unintended consequence of making it very time-

consuming to reach and replace them in the field without special tools.

50.6.6 Human–Robot Interaction

Human–robot interaction (HRI) has emerged as a major challenge in rescue robotics and has been declared to be an exemplar domain within HRI [50.12]. Robots are part of a humancentric system; even if robots were fully autonomous, responders want the information in real time and the option to modify the robot’s tasks. There are at least four key problems to be resolved in HRI. First, there is the issue of *human-to-robot ratio* for operations. Currently a single robot requires between two and three humans, depending on modality, for safe reliable operation. Second, these *operators have to be extensively trained*, which may be out of the question for many response teams. Third, user interfaces for operations do not provide sufficient situation awareness and need improving, which may in turn reduce training demands. Fourth, humans will interact with the robot outside of the operator role and this leads to a need for *affective robotics*. For example, a survivor will have a relationship with the *front* of a robot [50.46] as well as a rescuer working alongside a robot [50.47].

Reducing the human-to-robot ratio is probably the best known challenge for HRI. Unmanned aerial and water-based vehicles for defense and research applications have a long tradition of at least two operators per vehicle, one as a pilot, the other as a payload specialist. The number may increase due to payload or mission complexity or safety (e.g., the requirement for a safety officer). Unmanned ground vehicles have presumed that a single operator is sufficient to drive and look, though studies with ground rescue robots dispute this and show a ninefold increase in performance when two operators work cooperatively [50.42]. Since rescue workers work in teams of two or more, a single-operator single-robot control regime is not essential [50.12]. The need for multiple humans impacts on the viability of alternative scenarios, such as swarms or teams of multiple robots; these may require too many operators unless higher degrees of autonomy and situation awareness are possible.

Training is a related issue in human–robot interaction [50.48]. Rescue workers have limited time compared with military operations to learn about robots and few opportunities to practice. While a bomb squad or special weapons and tactics team for law enforcement may be called out several times each month, a rescue team may be called out only a few times each year. For

the near future, rescue workers may not have had prior training or experience with a robot prior to the disaster and be expected to use prototypes with only *hasty* training.

Situation awareness is defined by Endsley in [50.49] as “the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future.” Drury et al. [50.50] have defined types of situation awareness within search and rescue based on an analysis of RoboCup rescue tasks, while Casper and Murphy [50.51] and Burke et al. [50.42] have examined operator situation awareness in technology insertions. User interfaces are a key component in facilitating situation awareness. In rescue robotics, user interfaces are generally primitive and work through the operator’s visual channel to provide robot, task, and situation awareness of the state of the robot, task progress, and the general operational environment. To highlight the importance of user interfaces, one robot at the World Trade Center was rejected because of the complexity of its interface [50.10]. While the user interface for fieldable rescue robots primarily display the video output from the robot, experiences from RoboCup rescue suggests that a good interface will both facilitate commanding the robot (inputs) and will provide three types of information (outputs):

- the robot’s perspective: camera view(s) from the robot’s current position, plus any environmental perceptions that enhance the general impression of telepresence
- sensor and status information: critical information about the robots internal state and its external sensors
- if possible, a map: a bird’s eye view of the robot situated in the local environment

There has been a move towards videogame-like interfaces for ground vehicles; this is consistent with the 10 min *rule* of human–computer interaction that states that if a user cannot figure out how to use the main function of a computer within 10 min, the interface is flawed. However, the videogame interface may facilitate rapid, superficial control of the robot at the cost of limiting the transition to expert control which might not be best handled by a handheld controller. In general, all assessments of rescue robot interfaces agree that the operator’s visual channel is overloaded: the operator is expected to see too much and is likely to miss important information or become quickly fatigued. The use of other modalities such as sound, spoken language, and tactile feedback is warranted, though care must be taken

to consider whether such modalities will work in the noisy environs of a rubble pile or will interfere with personal protection equipment.

The focus of human–robot interaction on the operator and human–robot ratio has led to the issues associated with humans *in front* or *beside* the robot to be ignored. Ideally, rescue robots will interact with trapped survivors and facilitate their care and comfort. Likewise, a robot may be inserted into a confined space to act as the surrogate for a team member, such as a team leader or safety officer. Studies show that people view these robots socially, that is, they may ascribe traits of being scary or unhelpful based on the way the robot looks and moves [50.46]. Therefore, affective robotics applies to rescue robots as well as entertainment robots.

50.6.7 Evaluation

Evaluation of rescue robots is difficult not only because of the diversity of platforms and missions but also because each disaster is truly different. In addition, robots are part of a humancentric system: they are operated by humans in order to provide information to humans. Evaluation of the performance of a rescue robot system at an actual disaster is currently ad hoc. No computer

or physical simulation for predicting the performance of robots and humans in a disaster has been validated; indeed, there is little argument that simulations are far easier than a real response. The difficulties of simulation are exacerbated by the differences between disasters. For example, the World Trade Center was unique in terms of the large amount of steel and the density of the collapsed material, while earthquakes and hurricanes are different from terrorist events.

Metrics for measuring performance remain a worthwhile quest. Quantitative metrics, such as the number of survivors or remains found, do not capture the value of a robot in establishing that there are no survivors in a particular area. Performance metrics from psychology and industrial engineering are only now beginning to be applied. These methods require enhanced computer and full-scale simulations in order to collect data. Data collection on human and overall system performance during a disaster has been done through ethnographic observations and are now moving to direct observations of situation awareness during demonstrations [50.42, 52]. Direct data collection during a disaster may not be possible as methods may interfere with performance (and therefore be unreasonable, if not unethical) and arouse fears by operators of *Big Brother* and being held liable for any errors in operation.

50.7 Conclusions and Further Reading

Rescue robots are making the transition from an interesting idea to an integral part of emergency response. Aerial and ground robots have captured most of the attention, especially for disaster response, but water-based vehicles (both surface and underwater) are proving useful as well. Rescue robots present challenges in all major subsystems (mobility, communications, control, sensors, and power) as well as in human–robot interaction. Man-portable and man-packable systems are the most popular because of their reduced logistics burden, but the size of the platforms exacerbates the need

for miniaturized sensors and processors. Wireless communications remains a major problem. While recent deployments have relied on polymorphic tracked vehicles, researchers are investigating miniature planes and helicopters, new robot designs, especially biomimetic, and alternative concepts of operations. Standards are currently under development and this will help accelerate the adoption of rescue robots. The annual IEEE Workshop on Safety, Security and Rescue Robotics is currently the primary conference and clearinghouse for research in rescue robotics.

Intelligent Vehicles

Alberto Broggi, Alexander Zelinsky, Michel Parent, Charles E. Thorpe

Part F | 51

This chapter describes the emerging robotics application field of intelligent vehicles – motor vehicles that have autonomous functions and capabilities. The chapter is organized as follows. Section 51.1 provides a motivation of why the development of intelligent vehicles is important, a brief history of the field, and the potential benefits of the technology. Section 51.2 describes the enabling technologies for intelligent vehicles to sense vehicle, environment and driver state, work with digital maps and satellite navigation, and communicate with intelligent transportation infrastructure. Section 51.3 describes the challenges and solutions associated with road scene understanding – a key capability for all intelligent vehicles. Section 51.4 describes advanced driver assistance systems, which use robotics and sensing technologies described earlier to create new safety and convenience systems for motor vehicles, such as collision avoidance, lane keeping, and parking assistance. Section 51.5 describes driver monitoring technologies that are being developed to mitigate driver fatigue, inattention, and impairment. Section 51.6 describes fully autonomous intelligent vehicles systems that have been developed and deployed. The Chapter is concluded in Sect. 51.7 with a discussion of future prospects, while Sect. 51.8 provides references to further reading and additional resources.

51.1 Why Intelligent Vehicles?

An important field of application of robotics has emerged in the last 20–25 years which is centered on

the automobile, named *intelligent vehicles*. The automobile has been one of the most important products of

the 20th century. It has generated an enormous industry and has given individuals a freedom of movement that has completely changed our ways of living. Indeed, the automobile has been a key factor in the large change in the way our urban societies are structured. Today, there are more than 800 million vehicles on the planet and this number is expected to double in the next ten years. This challenge has led to the development of an active research domain with the ultimate goal of automating the typical tasks that humans perform while driving. An intelligent vehicle is defined as a vehicle enhanced with perception, reasoning, and actuating devices that enable the automation of driving tasks such as safe lane following, obstacle avoidance, overtaking slower traffic, following the vehicle ahead, assessing and avoiding dangerous situations, and determining the route. The overall motivation of building intelligent vehicles has been to make motoring safer, and more convenient and efficient.

51.1.1 Brief History

The history of intelligent vehicles has developed over the last two decades. Although the first ideas were born in the 1960s, the level of maturity of the technology at that time did not allow pursuit of the original goal of implementing fully autonomous all-terrain all-weather vehicles. The first documented prototypes of automated vehicles were fielded by a few groups in the military arena in the mid 1980s [51.1–3]. The initial stimulus that triggered these innovative ideas was provided by the military sector, which was eager to provide complete automation to its fleet of ground vehicles.

It was not before the 1980s that this interest was transferred to the civil sector: governments worldwide launched the first projects, which supported a large number of researchers in these topics. The interest of the automotive industry in developing real products was only triggered after feasibility studies were successfully completed and the first prototypes were demonstrated. Testing of autonomous vehicles on real roads in a real environment was one of the most important milestones in the history of intelligent vehicles. This happened in the mid to late 1990s. Figure 51.1 shows the first motor vehicles that pioneered the development of intelligent vehicles. In the summer of 1995, the Carnegie Mellon Navlab group ran their *No Hands Across America* experiment [51.4]. They demonstrated automated steering, based solely on computer vision, over 98% of the time on a 2800 mile trip across the United States. Later in 1995 the Bundeswehr Universität Munich (UBM), Germany fielded a vehicle that was demonstrated with a 1758 km

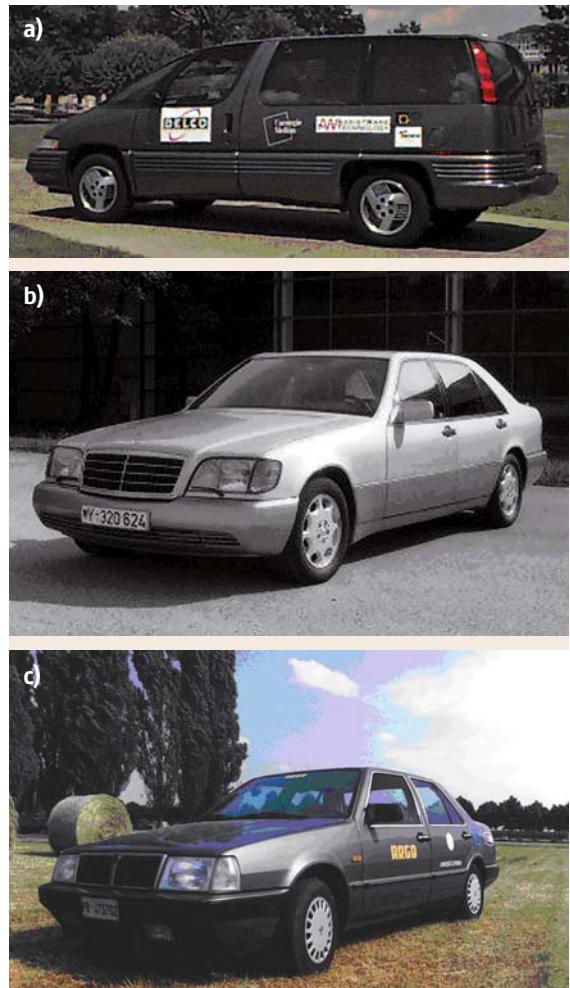

Fig. 51.1a–c Pictures of pioneering autonomous vehicles, from top to bottom: (a) NAVLAB, (b) UBM, and (c) Argo vehicles

trip from Munich to Copenhagen in Denmark and back. The vehicle was able to drive autonomously for 95% of the trip. The car suggested and executed maneuvers to pass other cars. Unlike later robot cars, this car located itself on the current road and followed it until instructed otherwise. It did not localize itself in global coordinates and could drive without Global Positioning System ([GPS](#)) and road maps as found in a modern automotive navigation systems. The car's trunk was full of transputers and ad hoc hardware. A different approach was followed by VisLab at the University of Parma within the Argo project: the passenger car that was designed and developed was based on a low-cost approach. An

off-the-shelf Pentium 200 MHz personal computer (**PC**) was used to process stereo images obtained from low-cost cameras installed in the driving cabin. The vehicle was able to follow the lane, locate obstacles, and – when instructed – change lane and overtake slower vehicles. The main milestone of this project was the successful test of the Argo vehicle in a tour of Italy of more than 2000 km called ‘Millemiglia in Automatico’ in which the vehicle drove itself for 94% of the total distance.

Current research initiatives are oriented towards the development of intelligent vehicles in realistic scenarios. However, due mainly to legal issues, full autonomy has not yet been set as the ultimate goal: the automotive industry has set as its primary goal the need to equip vehicles with supervised systems and – more generally – advanced driving assistance systems (**ADAS**) instead of automatic pilots. In other words, the driver is still in charge of running the vehicle, but the drive is monitored by an electronic system that detects possibly dangerous situations and reacts by either warning the driver in due time, or taking control of the vehicle in order to mitigate the consequences of the driver’s inattention. Given the aforementioned legal issues, the ultimate goal has shifted towards driving assistance systems since com-

plete vehicle automation was not felt to be a primary strategic area of investment for automotive industries. Concurrently, Departments of Transportation worldwide have been primarily interested in social, economic, or environmental objectives aimed at enhancing fuel efficiency, road network usage, and improving quality of life in terms of mobility [51.5].

The good results obtained by **ADAS** in the automotive arena in recent years has induced the military sector to give a new vigorous push to the original ideas of automating its fleet of ground vehicles. The Defense Advanced Research Projects Agency (**DARPA**) launched the Grand Challenge in 2003, a race for autonomous vehicles that had to travel for more than 200 km in unstructured environments. This unprecedented challenge attracted a large number of top-level research institutes, who worked with the million-dollar prize in mind and helped the scientific community take a considerable step forward.

In 2005 the **DARPA** Grand Challenge required autonomous driving in a rough terrain desert scenario with no traffic, obstacle types known in advance, and few if any road markers on a course predefined by 2935 **GPS** points. Five cars (maximum speed 40 km/h) completed the 211 km desert course:

1. Volkswagen of Stanford (Stanley 6 h 54 min)
2. Hummer of CMU (Sandstorm 2.5% slower)
3. CMU’s second Hummer (Highlander 5% slower)
4. Gray team (Kat 5 8% slower)
5. Terramax truck (44% slower)

Figure 51.2a–e shows photographs of the five finishing vehicles. Refer to [51.6] for the technical details of the **DARPA** Grand Challenge.

Fig. 51.2a–e Grand Challenge Vehicles (a) Stanley (1st) (b) Sandstorm (2nd), (c) Highlander (3rd), (d) Kat-5 (4th) and (e) Terramax (5th)

Having intelligent vehicles running on our road network would bring a number of social, environmental, and economical benefits. An intelligent vehicle able to assess the driving scenario and react in case of danger would allow up to 90% of traffic accidents that are caused by human errors to be eliminated, saving human lives. According to the World Health Organization an estimated 1.2 million people worldwide are killed each year, and about forty times this number injured, due to traffic accidents.

At the same time, vehicles able to drive at high speeds and very close to each other would decrease fuel consumption and polluting emissions; furthermore they would also increase road network capacity. Vehicles communicating with a ground station could share their

routes and be instructed to reroute in order to maintain a smooth traffic flow. Vehicles that can sense and obey speed limits or traffic rules would reduce the possibility of misinterpretation and antisocial driving behavior.

Fully automatic vehicles would also offer a higher degree and quality of mobility to a larger population, including young, old, or infirm individuals, reducing the need even for a driving licence. Finally, the availability of vehicles that could drive themselves would increase the quality of mobility for everyone, turning personal vehicles into taxis able to pick up people and take them to their final destination in total safety and comfort, dedicating the driving time to their preferred activities.

However, this full application of intelligent vehicles is far from being complete, since unmanned vehicles technology is still under development for many other applications. The automation of road vehicles is perhaps the most common everyday task that attracts the

greatest interest from the industry. However, other domains such as agricultural, mining, construction, search and rescue, and other dangerous applications in general, are looking to autonomous vehicles as a possible solution to the issue of the ever-increasing cost of personnel. If a vehicle could move autonomously on a field to seed, or enter a mined field, or even perform dangerous missions, the number of individuals put at risk would drastically decrease and at the same time the efficiency of the vehicle itself would be increased thanks to a 24/7 operational schedule. The key challenge for intelligent vehicles is safety; accidents must not occur due to automation errors and there is zero tolerance to human injury and death.

This chapter focuses on road and traffic applications of intelligent vehicles, which are catalyzing the interest of the automotive industry, car makers, and providers of automotive technologies.

51.2 Enabling Technologies

The basic sensing and actuation technologies for intelligent vehicles are readily available on the market. The key challenge to integrating new technologies is heavily dependent on the control strategies associated with the sensor data processing and reasoning. Automated systems must consider all subsystems in a vehicle, including the interaction of the technology with the driver. Key drivers for the new technologies in an intelligent vehicle are the desired applications. Solutions are developed on the premise that the system must satisfy the requirements of the application with the minimum level of technology.

Intelligent vehicle applications require the following:

- The position, and kinematic and dynamic state of the vehicle
- The state of the environment surrounding the vehicle
- The state of the driver and occupants
- Communication with roadside infrastructure or other vehicles
- Access to digital maps and satellite data

Position localization is a key technology for intelligent vehicles. The position of the vehicle must be known if the vehicle is to be controlled along a particular trajectory. To control an intelligent vehicle to perform applications such as collision avoidance or automatic lane changing requires knowledge of the kinematic and

dynamic states of the vehicle. Standard robotics techniques for position, kinematics, and dynamics are used in intelligent vehicle applications (see Chap. 34). Encoders are mounted on the steering column and the tail shaft. Vehicle heading, speed, and acceleration can be computed from the encoders using standard techniques (see Chap. 20).

To execute the trajectories in an intelligent vehicle a number of techniques are used. In many current applications of fully automated vehicles, the trajectories are fixed with limited choices at intersections. To execute the trajectories, the vehicles simply follow markers such as an antenna (a wire carrying an alternating current), magnets or passive transponders such as radio frequency identification ([RFID](#)) tags that are imbedded in the road or simple painted lines. In more advanced navigation systems, the vehicle generates trajectories in a map stored in its memory and localizes itself with respect to this map in order to execute them. This localization can be done using absolute positioning through a combination of global navigation satellite systems ([GNSS](#)), vehicular kinematic state, and inertial navigation. Alternatively, position localization can be done by relative localization using local markers such visual landmarks. (For specific reference to earlier mobile robot landmark navigation see Chap. 36.)

In order for the vehicle to execute trajectories, it needs to control the speed and the steering of the

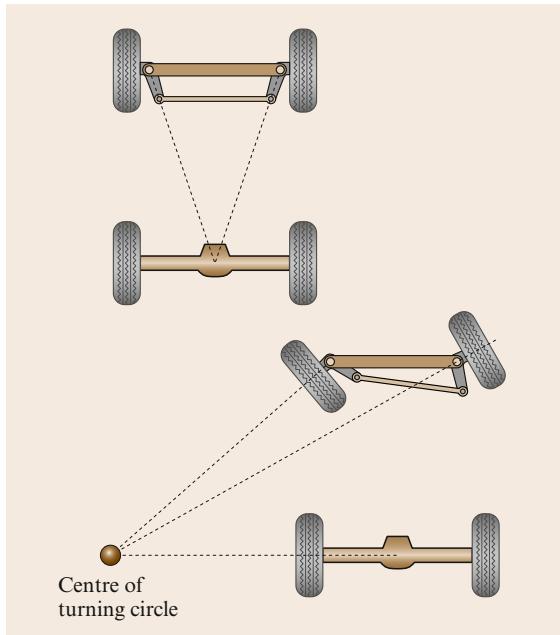

Fig. 51.3 Ackerman steering model

vehicle. Modern vehicles now incorporate electronic control units to control the acceleration (motor torque and possibly gearbox and clutch), the braking (electric or electrohydraulic brake control) and the steering angle (electric power assistance), and it is therefore quite easy

to implement trajectory control of the vehicles [51.7]. The safety of these critical functions remains a challenge, and is usually solved through redundancies in the sensors, actuators, and control units.

51.2.1 Environment State

Sensing the state of the environment surrounding the vehicle is a critical aspect of intelligent vehicle applications. The most difficult function for intelligent vehicles is road scene understanding. This includes locating key landmarks: the road, other vehicles, pedestrians, traffic signals, road signs, and other unstructured obstacles. A more difficult challenge is speed control following the detection of event in the road scene. The common sensors are infrared [51.8], ultrasound [51.9], radar [51.10], laser range finders [51.11], and computer vision [51.12], which continually scan the environment as shown in Fig. 51.4. Radar is generally used for obstacle detection at a distance, while infrared and ultrasound are used for close proximity obstacle detection. Laser ranging and image processing are used to more robustly recognize the road scene under various weather conditions. Certain road scene conditions such as road signs and traffic lights can only be understood using vision sensing. Sensor fusion is commonly used in intelligent vehicle applications, particularly between monocular vision and radar/laser sensors. This work is principally being done by the tier 1 automotive suppliers (Bosch, Denso, Del-

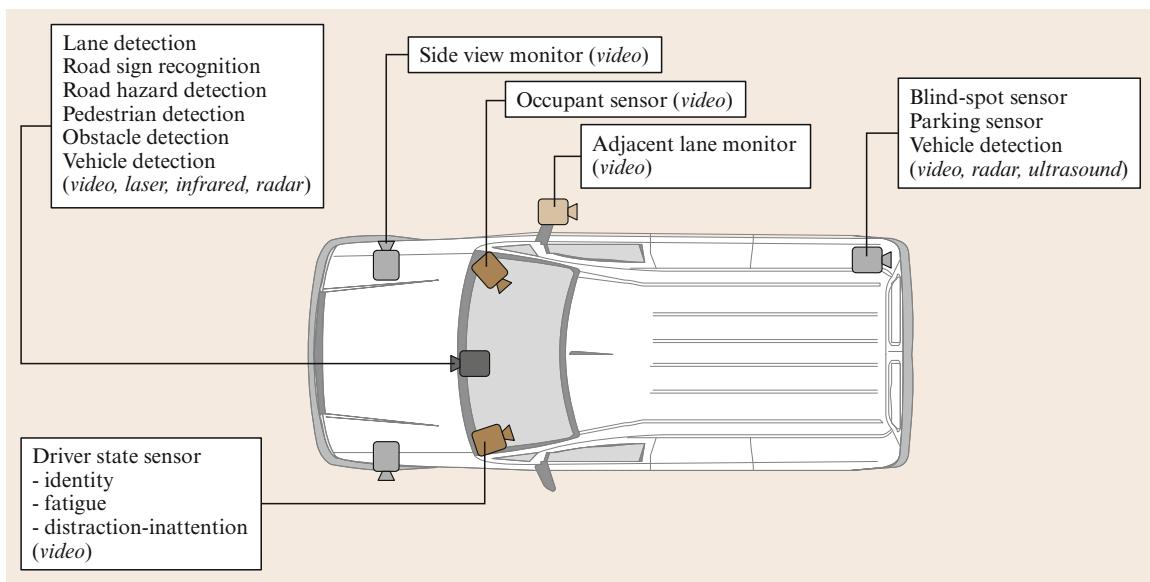

Fig. 51.4 Environment state sensing

phi, Visteon, Siemens, NEC) in cooperation with the major automotive manufacturers.

Using such sensors it is possible to map the environment surrounding the vehicle and then, using techniques such as simultaneous localization and mapping (**SLAM**) (Chap. 37), generate the complex manoeuvres needed for parking or for obstacle avoidance.

51.2.2 Driver State

Additionally an intelligent vehicle needs to understand the driver state, if it is to give appropriate warnings or need to take action. Vision sensors [51.13] can monitor a driver's attentiveness and fatigue by observing the direction of the driver's gaze and eyelid behavior. In an emergency knowing the position of the driver's head can assist in the safe deployment of airbags. Also, after an accident, observing the state of the driver and other occupants could be useful for the dispatch of emergency services to the accident scene.

51.2.3 Communication

Communication technologies enable interesting intelligent vehicles applications. Allowing vehicles to communicate with each other and with the highway offers the possibility to create vast improvements in the safety and efficiency of the road system. Applications include intersection collision avoidance, emergency braking, and sharing of road and traffic condition information.

The basic communication modes are distinguished as

- vehicle to/from roadside infrastructure
- vehicle to vehicle

Dedicated short-range communications (**DSRC**) have been set up to from the vehicle to infrastructure communications to support traveler information, commercial applications (toll/parking fee collection, in-vehicle advertising), and safety applications (intersection collision avoidance, approaching emergency vehicle warning, rollover warning) [51.14].

DSRC is a wireless protocol specifically designed for intelligent transportation systems. It is a subset of **RFID** technology, working in the 5.9 GHz band (**US**) or 5.8 GHz band (Japan and Europe). It is generally implemented with a dedicated protocol, uses short messages, and works in direct line of sight over short ranges (200–300 m).

For vehicle-to-infrastructure communications, a communication protocol architecture is currently being specified by the **ISO** [51.15], in the technical committee 204 working group 16 [51.16]. This protocol architecture is known as continuous air interface long and medium range (**CALM**) [51.17] and is being implemented in Europe under the cooperative vehicle infrastructure systems (**CVIS**) integrated project [51.18]. **CALM** is based on IPv6 protocols developed by the Internet engineering task force (**IETF**) [51.19], particularly the network mobility (**NEMO**) protocol, which allows sessions to be maintained between an in-vehicle Internet protocol (**IP**) network and the Internet backbone using any type of available media (3G, general packet radio service (**GPRS**), Wi-Fi, WiMax, M5, **DSRC**, satellite, etc.). For vehicle-to-vehicle applications, systems that support ad hoc networking are still in early stages. A vehicular ad hoc network (**VANET**) is a form of mobile ad hoc network (**MANET**) to provide communications among nearby vehicles and between vehicles and nearby fixed infrastructure equipment using direct and multi-hop intervehicular communication. Most of the research issues of concern to **MANETs** are of interest in **VANETs**, but the details differ. Rather than moving at random, vehicles tend to move in an organized fashion. The interactions with roadside equipment can likewise be characterized fairly accurately, and most vehicles are restricted in their range of motion, for example, by being constrained to follow a highway. The major work in this area is being supported by a series of workshops organized by Association of Computing Machinery (**ACM**) Special Interest Group on Management of Data (**SIGMOD**) [51.20].

Interaction between **NEMO** and the **MANET** or **VANET** is also under investigation but is not yet officially dealt with by any standardization body.

51.2.4 Digital Maps and Satellite Data

Combining **GPS** with stored digital maps creates a wide variety of intelligent vehicle applications [51.21]. Map data can greatly assist in the problem of road scene interpretation, map data can improve lane detection quality, help deal with the problems when sensors such as cameras do not work, e.g., in sunlight at dusk or dawn. Digital maps are widely used in commercial navigation systems for route guidance [51.22]. Such systems will be improved if real-time updating of the map occurred from traffic information [51.23]. Additional functionalities to be added include curve approach warnings [51.24], curve speed control [51.25], traffic sign information, and speed limit information [51.26].

51.3 Road Scene Understanding

Perception plays a key role in any robotic application. In the case of intelligent vehicles, the perception task is referred to as road scene understanding. It involves using different sensors (described in Sect. 51.2.1) combined with automatic reasoning, in order to create a synthetic representation of the environment around the vehicle. The knowledge base accumulated by this task is then used either to issue warnings to the driver in the case of advanced driving assistance systems (ADAS) or to control vehicle actuators in the case of complete autonomous driving. A complete and precise description of the state of surrounding environment is the key factor that allows the reduction of the number of false and missed alarms and provides the basis for smooth automatic driving. Needless to say, the perception of an outdoor environment – even if partially structured – is a challenging problem not only due to the intrinsic complexity of the driving environment itself, but also due to the impossibility of controlling many environmental parameters. Figure 51.5 shows examples of day/night, sun/streetlight illumination, temperature, poor visibility, rain/snow, and

different meteorological conditions, which in general are impossible to control and have to be faced by sensing devices.

The research community is addressing the issue of providing vehicles with robust and precise perception of the state of the environment from two different perspectives. One approach is to provide vehicles with ever-increasing sensing capabilities and processing power aimed at the provision of powerful onboard intelligent systems; Daimler-Chrysler is a world leader in this area [51.27]. An alternative approach is to use road infrastructure as an active component capable of communicating with all vehicles and sharing information on road conditions in real time [51.28]. Indeed these two perspectives can also be merged to provide a mixed solution to safely control a vehicle and in dynamic environments [51.28].

The task of road scene understanding may be addressed differently, depending on the availability of an intelligent infrastructure and on other players exhibiting cooperative behavior. The task of understanding the state of the environment can be simplified through the availability of information coming from other sources, thereby limiting the need to perform a robust and complete sensing onboard each vehicle. Helpful information could come from the infrastructure itself (for example, road conditions and geometry, number of lanes, visibility, road signs, or even real-time information such as traffic-light status or traffic conditions) or other players (such as the presence of the vehicle with precise position, speed, and direction). The players may also carry real-time information gathered by and shared with other players.

Although research is currently focussed on both intelligent vehicles and intelligent infrastructures, the first generation of production intelligent vehicles will have to rely primarily on their own sensing capabilities since the availability of information coming from other sources such as the infrastructure and other vehicles will take a while to be deployed in real-world situations. In fact, in order to be of practical use, intelligent roads must cover a large proportion of a country, and simultaneously cooperative intelligent vehicles must also be sufficiently widespread. It is important to note that the investment in intelligent infrastructures and intelligent vehicles comes from different sources: mainly from governmental institutions for the former, and vehicles owners for the latter.

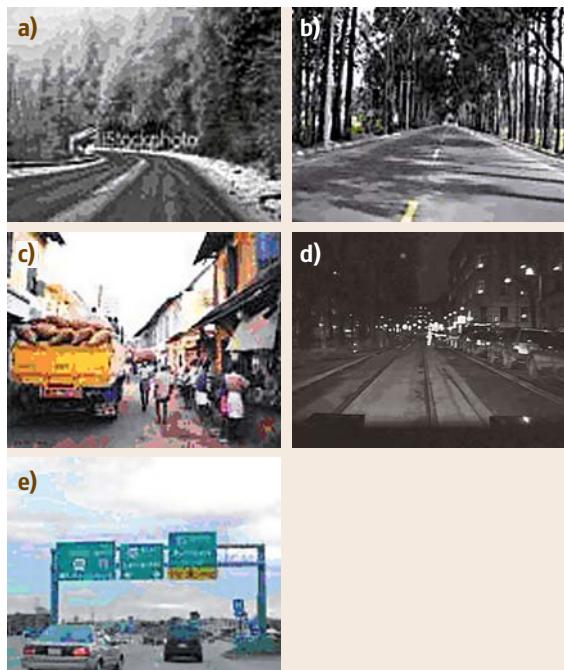

Fig. 51.5a–e Typical range of road scenes that intelligent vehicles must handle

The information that is owned by the infrastructure itself and that could be made available to the vehicles includes

- precise geometry of the lane/road
- road signs
- status of traffic lights

On the other hand, the infrastructure can also assess and deliver real-time data such as

- road conditions
- visibility
- traffic conditions

Another important piece of information that needs to be gathered by intelligent vehicles is the presence of other road players, such as

- vehicles
- vulnerable road users (pedestrians, motorcycles, bicycles)

Although it could be assumed that sometime in the future all vehicles will be equipped with active systems that allow them to be safely avoided by other vehicles, it is quite improbable that pedestrians and bicycles will have similar equipments: their presence will need to be detected using onboard sensors only. The same consideration also applies to obstacles that may unexpectedly be found on the road, or to temporary situations such as roadworks: if a vehicle needs to cope with the unexpected, then it needs to have the capability to assess the situation in real time with its own sensors.

This is why onboard sensing is of paramount importance for future transportation systems; vehicle-to-vehicle and vehicle-to-infrastructure communications may help and improve the sensing, but a complete sensor suite must also be installed on our future vehicles. The main challenges in road environment sensing are examined below.

51.3.1 Road/Lane Tracking

Many vehicles prototypes have been equipped with lane detection and tracking systems, starting from the very first implementations in the early 1980s [51.1–3]. Indeed in this case computer vision plays a basic role; although generally the road can also be detected with laser scanners [51.11], the only generic technology able to detect lane geometry and lane markings with high precision is computer vision. Most lane tracking approaches have focused on detecting lane markings and exploiting structure in the environment, such as the parallelism of

Fig. 51.6 Lane detection

the left and right lane markings, the invariance of road width, or the widely used flat-road assumption. These assumptions were mainly used to overcome the problem of having a single camera (a choice driven by cost). Some systems use stereo vision to detect lane markings and are able to work without such constraints. The problem of lane tracking in highway situations is basically a solved problem – with commercial systems being deployed in passenger and commercial vehicles [51.29]. An example of the typical output of a commercial lane tracker is shown in Fig. 51.6.

However, such systems cannot guarantee that lane detection systems will work with 100% reliability; these systems typically work with 95–99% reliability. Therefore, lane tracking systems are only being used in lane departure warning systems since no failures can be tolerated for autonomous driving. Efforts are underway to develop algorithms that will tolerate a variety of driving conditions, and push the 100% reliability boundary [51.30].

51.3.2 Road Sign Detection

Another fairly straightforward use of computer vision is road sign detection and understanding. Road signage is deliberately structured to aid human drivers. Road signs use a set of well-defined shapes, colors, and patterns. The signs are placed at consistent heights and positions in relation to the road. Therefore reading road signs is an achievable task for computer vision. Detection is done using a collection of shape and/or color detection schemes [51.31,32]. After the detection and localization phase, recognition takes place. Normally this task is performed by pattern-matching techniques such as image cross-correlation, neural networks, or support vector machines since the possible set of road signs is limited and well defined. Figure 51.7 illustrates the con-

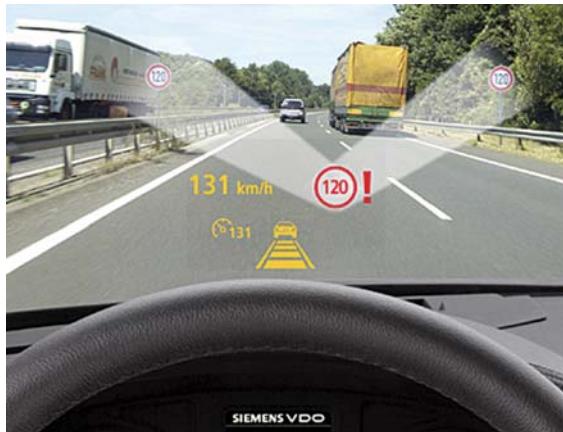

Fig. 51.7 Road sign detection for speed warning application

cept of a speeding warning system based on speed sign detection. The challenge for research work in this area lies in the robustness of detection and the reliability of classification of signs. Most automotive companies have systems under development, e.g., Siemens [51.33].

51.3.3 Traffic-Light Detection

Color and pattern matching are also the key techniques used for the detection of traffic lights [51.34]. Although the detection of traffic lights is not overly complex, this application hides one further aspect that makes vehicular applications difficult: besides the correct localization and recognition of a signal, special care has to be taken in checking the signal position and orientation on the road/lane since that signal may not be addressed to the current vehicle. This is particularly true in downtown intersections at which many traffic lights are visible at the same time; in this case the vehicle must have the capability to select the correct traffic signal that must be obeyed. Some experiments have been undertaken with active traffic signals, able to emit the status of the traffic light using radiofrequencies [51.35]. This involves additional infrastructure; at this stage vision seems to be the only simple viable solution.

51.3.4 Visibility Assessment

One of the key challenges is detection of fog. The meteorological visibility distance is defined by the International Commission on Illumination (CIE) as the distance beyond which a black object of an appropriate size is perceived with a contrast of less than 5%. Different techniques for measuring this parameter –

and thus detect foggy conditions – have been implemented [51.36]. Although many of the methods use vision, there are also efficient alternatives – generally used in fixed locations such as airports and traffic-monitoring stations – based on the use of multiple scattering lidars. The main challenge of using vision to estimate visibility is that a moving vehicle generally cannot rely on a specific reference point/object/signal at a specific distance.

51.3.5 Vehicle Detection

The detection of vehicles has been addressed using a large variety of sensor technologies, ranging from vision to lidars, from radars to sonars.

Despite being different in shape and color, vehicles share the same characteristics and feature a large size and reflective material. The position of vehicles is predictable once a rough indication of the road/lane position is available. Vehicles, in fact, can be successfully detected by many different sensors independently [51.37–39]. Figure 51.8 shows a vision-based vehicle detection system.

Nevertheless, although the solution to this problem seems straightforward, each sensor has its own domain of application and its own challenges. Vision is generally powerful, but may fail in low visibility and bad-illumination scenarios (night or tunnels) or in heavy traffic conditions when vehicles may occlude each other. Vision in the infrared domain (thermal imaging) is able to detect vehicles with a high confidence since vehicle tires and mufflers generally exhibit high temperatures and are therefore easily detected in the image. However, parked vehicles, trailers, and even vehicles which have just started to move are colder than running vehicles and therefore less visible. Lidars are generally robust, but have decreased sensitivity in adverse weather condi-

Fig. 51.8 Vehicle detection – lane and range position

tions. Radars, while cheap, can suffer from bias in lateral measurements due to the presence of other nearby reflecting objects. Finally sonars are applicable only for very short distances. The research challenge is to implement multisensor fusion robustly. A common approach is to fuse vision with radar [51.40].

51.3.6 Pedestrian Detection

The detection of vulnerable road users (pedestrians and bicycles) is one of the most difficult tasks for intelligent vehicles. The appearance of a pedestrian is challenging: a pedestrian shape can change greatly within a few tens of milliseconds, there are no clear invariants in color, texture, or size, and no assumptions can be made about posture, speed, or the visibility of parts of the human body such as the head. Machine learning methods have been successfully applied to this problem [51.11, 27, 31, 41]. Greater reliability and reduction

in false alarms have been achieved through the incorporation of stereo vision [51.42]. However, the detection of vulnerable road users is one of the most relevant research topics worldwide since a great number of benefits – including insurance reductions – may be achieved once a fully functional pedestrian detector is available on cars. Countermeasures may be activated to reduce the consequences of vehicle–pedestrian accidents, such as the firing of external airbags or the opening of the hood to lessen the impact of a head-on collision. Currently, with all possible technologies under evaluation, no solution seems to offer reliable detection in every scenario: radars are not able to detect pedestrians reliably in crowded scenarios, while vision has the many drawbacks listed above. Even thermal imaging, which – although still very expensive – is generally believed to be one of the most promising technologies, fails in some situations, such as hot summer days and, in general, in high-temperature environments.

51.4 Advanced Driver Assistance

Given the legal liabilities and technical challenges of achieving 100% reliability for autonomous intelligent vehicles, it appears likely that motor vehicles will have pieces of autonomous functionality added progressively and that cars will eventually evolve into autonomous robots. The perception techniques described earlier can be used in a variety of ways to make driving safer, more efficient, and less demanding. Individual perception techniques, or combinations of sensing modes, are being used to provide warnings to drivers of dangerous situations. These warnings are being used to prevent collisions in a variety of situations, such as when backing up, when leaving a roadway, into rear ends, on lane changing/merging, with pedestrians, and at intersections.

Developing a collision warning system requires many steps beyond building the perception system. For a typical example, roadway departure warning, the steps followed in a program initiated by the US National Highway Traffic Safety Administration include:

1. Statistical studies: In the United States, crashes involving a single vehicle leaving the roadway are relatively rare, but disproportionately dangerous; approximately 40% of the 40 000 fatal crashes per year in the US are single-vehicle crashes where the vehicle leaves the roadway. The first part of the study

looked at the prevalence of those crashes, and determined that this would be a good type of crash to prevent.

2. Causal factors: The second step was to determine the causes of those crashes. Most run-off-road crashes are due to driver factors such as excessive speed, inattention, or loss of control. This is an important observation, because it means that alerting the driver, or warning of difficult situations, could prevent those incidents. For the fraction of crashes caused by mechanical failure a warning system would not be useful; in this type of crash, mechanical failure is involved in less than 5% of the crashes.
3. Opportunities for intervention: This part of the study set out to determine whether a warning system could be effective, and, if so, how far in advance the warning would have to be given. Given typical road departure trajectories, typical widths of roads and shoulders, and the range of potential steering responses, this task generated requirements for how accurately the system would have to track vehicle trajectory in order to predict a roadway departure.
4. Human factors: Since the system being designed is a warning system, rather than an active control, it is crucial to understand what kinds of warning a driver (who may be distracted or sleepy) would respond to, and how quickly and accurately the response will

- be. Reaction times vary widely across individuals: using one second for reaction time is a fairly standard estimate.
5. Simulator studies: A driving simulator is like an aircraft flight simulator for cars or trucks, with a variety of simulated roads and conditions. Simulator studies were used to test driver response to warnings: directional or nondirectional audio warnings, steering wheel shakes, and combinations. A nondirectional audio cue worked best.
 6. System specification development: Based on the preceding steps, in order for a system to be useful, it needs to work at day and night, in almost all weather conditions, needs to measure vehicle speed, lateral position relative to the road, lateral heading, and roadway curvature, and predict future vehicle trajectories long enough in advance to trigger a warning alarm.
 7. Perception and system development: Given those specifications, there are several ways that a perception system could be built to sense the road and the vehicle's trajectory relative to the road. For this particular test, a lane keeping system – rapidly adapting lane position handler (RALPH) was developed and tuned [51.43].
 8. Limited tests: The entire system – sensors, processing, driver interface – was built and tested with a limited number of volunteers, and the system tuned and validated.
 9. Full-scale operational tests: The system was deployed in test fleets, including long-haul trucks and passenger cars.

51.4.1 Collision Avoidance and Mitigation

The complete cycle from the idea of using perception to prevent crashes, to full system development, took over 10 years in this case. The pure *robotics* part of the system is a crucial element, but is only one piece of the development needed to make a useful product. Some active control has already been assumed by today's vehicles. Antilock brakes have been on the market for many years. Traction control systems which control throttle to stop wheel spin are being introduced. Electronic stability control systems take this the next step further, controlling throttle and individual wheel brakes to help in cornering performance. So, gradually, people are willing to cede some control to very reliable automated systems. We can expect this trend to continue.

Each collision warning type has its own list of specific development challenges, as described below.

Backup Collisions

The sensing challenge is to see relatively small objects, such as fence posts or children's toys, while not picking up false alarms from pavement joints or leaves and debris. The sensors used in today's commercial vehicles are piezoelectric ultrasonic sensors, which are inexpensive [51.9]. However, ultrasonic sensors have well-known limitations. The challenge of developing low-cost, accurate, reliable sensors remains.

Rear-End Collisions

These are among the most difficult collisions to prevent, with the most challenging sensing conditions. Rear-end collisions often happen at high speeds, requiring long-distance sensing of other vehicles (up to 100 m at US highway speeds, much longer at the high speeds found on some European roads or for the longer braking distances needed for heavy trucks). That in itself is not too demanding a challenge: the sensed objects in this case are relatively large and have high metal components, so radar and lidar are both feasible sensing modes. The biggest range-sensing challenge is sorting out true targets (slow or stopped vehicles) from false targets (overhead signs or bridges, and side lobes from strong reflectors on the side of the road). It is also important to determine if the sensed vehicle is in the same lane as the smart car, or a different lane. Sensing lane markings at such a large distance is a very difficult challenge; merging lane sensing (often done by vision) with obstacle sensing (by a different sensor) and registering the two to within the resolution of a lane is a daunting task. This technology remains under development through industry and government programs [51.44].

Lane-Change/Merge Collisions

In the simplest case, the countermeasure to this kind of collision involves short-range sensing to cover the *blind spots* on the rear corners of a vehicle, where it is difficult to see with mirrors. For passenger cars, this area is quite small, and can be covered with a single sonar or radar. Often, the user interface is a warning light placed in the rear-view mirrors [51.45]; this reinforces good driver behavior of checking mirrors before changing lanes. The sensing challenge for heavy trucks or transit buses is the same as for cars, except that the area not visible in planar mirrors can be much larger. Figure 51.9 shows examples of blind-spot detection for cars and heavy vehicles.

The usual solution is a row of sensors along the side of the vehicle, although scanning lidars or panoramic vision are also used in some experimental applica-

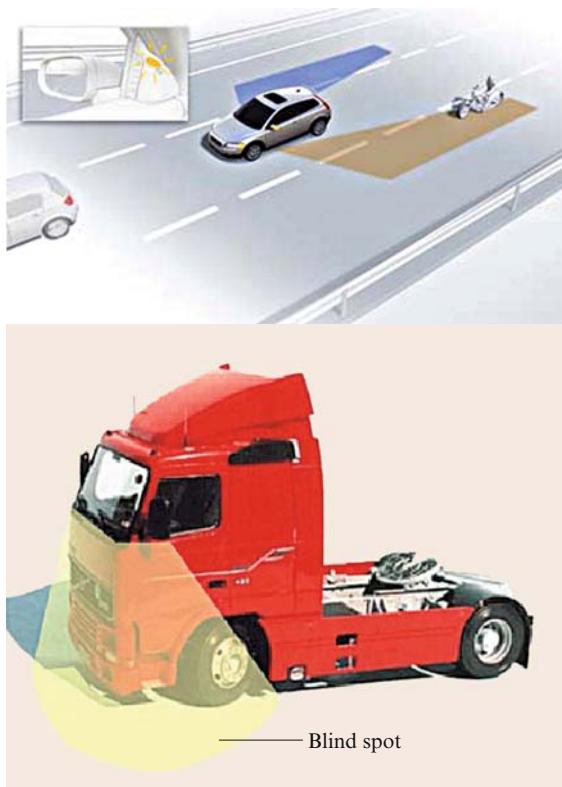

Fig. 51.9 Blind-spot detection

tions [51.46]. The further complication for lane-change warnings is in high-speed driving, where it is important to look not just adjacent to the vehicle but a long way to the rear, to find overtaking vehicles with high relative speeds. Recently a commercial product has been brought to market [51.47].

Pedestrian Collisions

Pedestrians are particularly important to detect, because pedestrians are much more vulnerable than people in vehicles; as discussed earlier they are also unfortunately relatively difficult to detect and very hard to predict. Just detecting a pedestrian is not sufficient. In transit operations, for instance, a bus operates close to pedestrians much of the time. To do meaningful collision warning, it is important to detect the pedestrian, detect their current path, look for cues such as crosswalks or curb edges that modify the probability of the pedestrian's trajectory, and match all of these factors with the predicted trajectory of the vehicle. It is crucial to tune the warning system to produce few false alarms while not missing real alarms. A particularly dangerous situation is pedes-

trians slipping and falling underneath a bus: these are very dangerous situations, but very difficult to detect in time to warn the driver. For these reasons, automotive manufacturers have worked on products such as night vision to enhance driver perception [51.48].

Intersection Collisions

Intersection collisions are particularly difficult to prevent because they often involve challenging sensing scenarios. Many of these collisions involve occluded vision, with lines of sight blocked either by large vehicles or by adjacent buildings. They also often involve high closing rates from oblique angles, making it necessary to see a long distance with a very wide field of view. The solution usually proposed is to add intelligence to the infrastructure, either in fixed sensing (such as radars looking down each approaching road) or in some kind of radio relay that takes data from approaching smart cars and passes it to other approaching vehicles. None of these solutions is particularly attractive: the large number of intersections makes it difficult to envision any universal solution.

Other Obstacle Collisions

Vehicles have collisions with many things other than other vehicles and pedestrians: animals (deer, dogs, cats), car parts (tire carcasses, rusted-out exhaust systems), cargo that falls off of trucks, construction debris, etc. Warning drivers about these kinds of objects on the roadway is a challenging task. A piece of construction timber on the roadway may be large enough to do significant damage to a car, but be small enough to be difficult to see, and be invisible to radar. Some interesting work has been done with high-resolution stereo vision [51.49], with polarimetric radar [51.50], and with high-resolution scanning laser range-finders [51.51]. However, in general this remains a difficult problem.

Other Actions

Besides warning the driver, there are other actions that an intelligent vehicle can take short of assuming control. If a collision is inevitable, particularly from the side of the vehicle where there is limited crush space, the system can brake and deploy airbags even before physical contact. Of course, such a system would have to be nearly 100% reliable. More simply, if the system senses an imminent front collision, it can preload the power brakes, saving fractions of a second in brake reaction time. The driver must still actuate the brakes, but the onset of hard braking can be much quicker. At 100 km/h, a 0.1 s saving in braking actuation saves approximately 3 m of

stopping distance, which can be the difference between a severe rear-end collision and a much lighter crash. Such systems are being introduced into the high-end market by all the major automotive manufacturers.

Collision Avoidance

The next step beyond emergency braking is an automated system. Such systems have several advantages over a human driver: much quicker reaction times, access to sensors such as individual wheel speeds and slips plus external sensors such as radars or lidars, access to individual brake controls and other controls, and so forth. So, if the system had ideal situational awareness, it could in many cases do a better job of avoiding a collision than a human could. This is still a very difficult area for implementation, however. First of all, the human has access to higher-level knowledge: the driver may be watching the behaviors of other cars, may make eye contact with pedestrians or drivers, may be watching a policeman directing traffic, etc. So it may be that a manoeuvre that, to the system, looks like the best way to prevent the collision, is actually the wrong action to take. Secondly, in most countries, as soon as the vehicle takes control there is a shift in the liability for any resulting crash from the driver to the manufacturer. So there is a great reluctance to take active control. An alternative approach recently developed is to observe the environment state with lidar, and monitor the dynamic vehicle state to determine whether the accident is unavoidable. If the driver can no longer take corrective action, that is, brake or turn away safely, then emergency braking occurs [51.11].

For now, however, active collision avoidance remains a research area, with significant questions of reliability, human factors, and liability.

Combining perception with control gives partial automation for specific tasks, such as adaptive cruise control, lane keeping, assisted parking, and slow driving in stop-and-go situations.

51.4.2 Adaptive Cruise Control

Adaptive cruise control (ACC) is the logical extension of standard cruise control to also include keeping a safe distance from the preceding vehicle. If there are no vehicles in front of the smart car, it follows a set speed, as with standard cruise control. If a slower-moving vehicle is in front, an ACC-equipped car will sense the vehicle using radar or lidar, and slow to maintain a safe distance (typically set to a 1.5–2 s following gap). Figure 51.10 shows an illustration of the ACC concept. The sensing

Fig. 51.10 Advanced cruise control (ACC)

challenge for ACC is much easier than the challenge of rear-end collision countermeasures, since ACC systems are only designed to deal with other moving vehicles.

The biggest sensing difficulty for rear-end collision countermeasures is separating stopped vehicles on the road from objects off the road; for ACC this difficulty is bypassed by ignoring all stopped objects. Moving objects are classified as in-lane or out-of-lane based on a number of heuristics. Often, the smart car's own steering radius is used as an estimate of the road curvature ahead, in order to determine whether vehicles ahead are in the same lane. Since the systems are explicitly sold as *convenience* instead of *safety* systems, they only need to deal with normal situations with relatively low differences in velocity, and they leave the more difficult situations up to the human driver. The human is still alert, controlling the steering, and watching the traffic. These systems are being introduced by all the major car manufacturers.

51.4.3 Stop and Go

Stop-and-Go driving assistance (also referred to as low-speed ACC) is at the opposite end of the speed spectrum, when vehicles are creeping along in dense traffic. At slow speeds, it is easy to track the vehicle ahead, and to move when it moves, steer when it steers, and stop when it stops. If the traffic accelerates to a modest speed, the stop-and-go system disengages, and the human must assume control of the throttle, brake, and steering. Since the speeds are very slow and the distances are short, many different sensing systems will work such as stereo vision, radar, and lidar [51.52, 53].

51.4.4 Parking Assist

Parking assistance is also a low-speed aid. In a typical scenario, the driver initiates the system by pushing

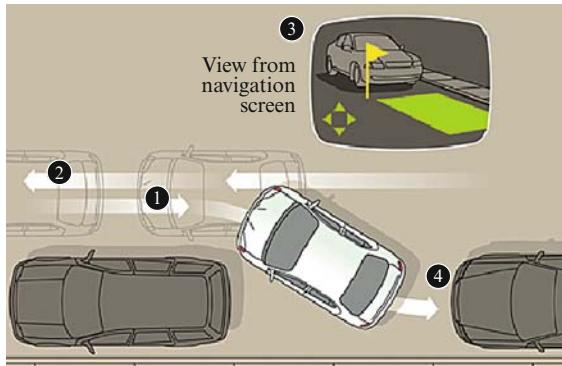

Fig. 51.11 Parking assistance

a button when driving past an empty parking space. The system measures the length of the space using odometry, measures the positions of the cars in front and in back using short-range sensors, and infers the position of the curb by assuming that the surrounding cars are standard-sized cars parked near the curb [51.54]. Figure 51.11 illustrates parking assistance.

Once the system is fully engaged, it takes over steering, planning and executing the ideal parallel park steering sequence. In some systems, the human is still responsible for throttle and brake, again insuring that the human is alert, watching for encroaching pedestrians or other obstacles. Such a system has been introduced by Toyota [51.55].

51.4.5 Lane Keeping

Lane keeping assistance is the natural extension to road departure warning systems. Given a lane tracking system, it is straightforward to add control of the steering wheel to keep the vehicle centered in its lane [51.1–3]. This has a number of uses. Some cities would like to run transit buses on narrow roadways, for instance the shoulder of highways or through narrow streets in old cities. Automated lane keeping systems using mechanical guideways are in use in several places [51.56]. It is easier and less expensive if such systems can be electronic rather than relying on specially installed mechanical guides. A specific subcategory is precision docking: for a transit bus to pick up a passenger in

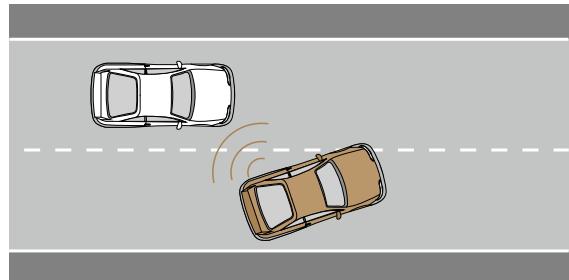

Fig. 51.12 Lane changing – side detection

a wheel chair, either the bus must deploy a special ramp (which is a slow process), or it must pull up to a level dock and leave a very small gap, so that the wheel chair can safely roll on or off. Short-range precision docking systems use either a downward-looking sensor, looking at painted lines or magnetic markers, or a sideways sensor looking at the curb or dock, in order to guide the bus to its parking spot. Finally lane-keeping assistance is a convenience for driving on highways, especially with gusty winds. Honda has released a vehicle equipped with both lane-keeping assistance and ACC [51.57]. The danger with such systems is that the driver no longer has an active moment-to-moment role, and may lose concentration or even fall asleep. These systems are not designed for full automation, and still require a driver to handle unusual circumstances. The next stage is to integrate driver state monitoring. If the driver is inattentive then all automatic systems are disengaged.

51.4.6 Lane Changing

Lane changing assistance is the next extension in partial autonomy. It combines lane keeping and ACC with blind-spot monitoring. If the car can safely overtake a vehicle, then a lane change is undertaken and speed is unchanged. Otherwise, the ACC slows the vehicle down. At its simplest such a driver assistance system can advise a driver whether a lane change can be safely undertaken [51.58]. In its most advanced form the lane change is undertaken completely automatically by the vehicle [51.1]. Such systems require an additional side-facing sensor, typically radar (shown in Fig. 51.12).

51.5 Driver Monitoring

There has been an evolution of thought regarding the role of the driver in intelligent vehicles. The grand goal

has been to replace the driver with a fully automated system. As discussed earlier, full automation of intel-

lignant vehicles is still some years away due to system reliability and legal liability reasons. The next step in the development of the motor vehicles is partial automation – where individual autonomous functions such as ACC, lane keeping, lane changing etc. are developed. Motor vehicle designers have realized that the driver cannot be removed from the vehicle, and must instead be supported by systems onboard a motor vehicle. Over 92% of motor vehicle accidents are caused by driver error [51.59]. It is likely that the next generation of intelligent vehicles will work in the following way.

1. The vehicle will monitor the road scene using advanced driver assistance system technologies discussed earlier to assess the state of the environment and warn the driver of dangerous situations, e.g., lane departure warnings.
2. The vehicle will also monitor the driver using vision sensors to assess the state of the driver. If a driver is fatigued, drowsy, inattentive, distracted or under the influence of drugs then accidents can occur. The vehicle warns the driver of dangerous circumstances, e.g., drowsiness warning.
3. For legal liability reasons intelligent vehicles will not take control, rather the driver will be alerted using visual, audio, or tactile warnings. The vehicle will not perform collision avoidance; rather collision mitigation will occur through emergency braking.
4. If an accident is unavoidable the vehicle can autonomously apply emergency braking. To maximize the safety of the occupants in the vehicle, seatbelt restraints are tightened and airbags are safely deployed.
5. After an accident has occurred knowing the state of the driver and the passengers is important. If an occupant has been injured a call to the emergency services can be dispatched automatically by the vehicle.

In all the steps described above monitoring the driver is critical. For future advanced driver assistance systems (ADAS) to work safely the driver should be put in the loop, for example, in a lane departure warning systems, it is not possible to determine whether a vehicle departing from a lane due to cause by driver intention or error. If the state of the driver is being monitored, and the system can detect that the driver's eyes are closed or the driver is looking away from the road, then it can be inferred that the lane departure was involuntary and that a lane departure warning should be given to the driver. For ADAS to be accepted by drivers the systems should not give false warnings. If the driver is looking directly at the road

then lane departure warnings should not be given (or a different subtle warning should be given). Similarly more sophisticated systems such as lane keeping should not be engaged unless the driver is fully attentive and has their hands firmly on the steering wheel. The key point is that drivers must be fully engaged with and in control of the driving task. This is a most important consideration in the design of ADAS for intelligent vehicles.

Combining perception with control gives partial automation for specific tasks, such as adaptive cruise control, lane keeping, assisted parking, and slow driving in stop-and-go situations.

51.5.1 Driver Fatigue, Inattention, and Impairment

By directly monitoring the driver using visual sensing opens up the possibility of developing a new class of ADAS applications. It is possible to monitor driver state through monitoring signals such as an electrocardiogram (ECG), temperature etc. However, market studies by automobile manufacturers have shown that people do not like any wires, or gadgets attached; driver monitoring must be noncontact and noninvasive. The only solution is to use vision as the sensing medium. The technical challenge to develop a computer vision system that can automatically detect a driver of any age, sex, race, with/without eye or sunglasses, and with/without facial hair is enormous. Recently significant progress has been made with systems being developed that can also detect where a person is looking (gaze direction) [51.13].

Once the driver's state (head position, eye gaze, eye blink rate) can be measured then ADAS applications

Fig. 51.13 Driver state detection

can be developed. Figure 51.13 shows the output of a commercial driver state detection system.

Driver Impairment

Safety authorities estimate that as many as 50% of all road accident fatalities are caused by driver impairment due to alcohol or drugs [51.60]. Recent research has shown that driver impairment can be detected by sensing abnormal scanning patterns of eye gaze. It promises to open up a new class of **ADAS**. There have been major education and legislative initiatives in many Organization for Economic Cooperation and Development (OECD) countries, resulting in a significant reduction in road fatalities. However, the difficult cases (fatigue, distraction, and inattention) have become more prominent. **ADAS** technologies could have a significant impact in further reducing the road toll.

Driver Fatigue

Safety authorities estimate that 25–30% of all road fatalities are caused by driver fatigue [51.61,62]. Research has shown that there are four visible factors that indicate the onset of fatigue – prolonged eye closure, uncontrolled head moments, drooping eyelids, and reduced eye-gaze scanning. Systems are under development that focus only on eye closure [51.63]; the challenge of fusing all four factors together into a robust algorithm that works for a wide range of drivers remains an open research problem.

Driver Inattention

Safety authorities estimate that up to 45% of all traffic accidents – from minor dents to serious incidents – are caused by driver inattention or distraction [51.64]. Research has shown that if the drivers consistently keep their eyes on the road then driving becomes a much safer experience [51.65]. All major automotive manufacturers are developing **ADAS** applications that warn the driver if they are distracted from the driving task. More sophisticated **ADAS** under development use the driver's gaze direction to check whether safe driving practices are being followed, for example, did the driver check the side mirror before a lane change was performed? If the driver fails to check the side mirror a warning would be issued.

Driver Workload

The increase in new electronic systems and gadgets that are being installed into today's motor vehicles

is also another source of distraction. Questions arise about when and under circumstances should a driver change a compact disc (CD) or answer a phone call. Research is underway into the development of workload systems. These systems take into account the vehicle state (speed, acceleration, braking, gear-change yaw rate etc.) to determine whether information management tasks such as answering a phone call, sending a short message service (SMS) message are allowed [51.65]. The next stage of research is to include sate information about the road scene and the driver. If the car is driving on a country road, and the driver is attentive then distractive tasks could be allowed and managed.

51.5.2 Driver and Passenger Protection

The automotive industry is moving towards the use of active safety systems such as airbags to complement passive systems such as seatbelts. **ADAS** will play a critical role in active safety systems. In emergency braking or impending rear-end collision situations, seatbelts can be pretensioned and airbags primed. Drivers and passengers could be further protected through the development of smart airbags [51.66]. Airbags, while considered to be an essential part of a modern car, can cause fatalities if the occupant is too close to the airbag, is a child, or is not wearing a seatbelt. Smart airbags deploy that are dependent on the position of the vehicle occupant's head. The driver state monitoring technologies discussed earlier are an essential component of smart airbags.

51.5.3 Emergency Assistance

The speed at which people are given treatment after a serious accident is critically related to the survival rate of victims. While it is expected that **ADAS** will lead to a reduction in road accidents, it will not eliminate accidents. Therefore it is important that automated systems for emergency situations are developed. Systems that use **GPS**, vehicle state information, and mobile communication systems have been developed that send the world coordinates of the vehicle to emergency authorities after an accident [51.67]. This information can be augmented by using driver monitoring technology to assess the condition of the occupants of the vehicle. Such types of system are currently being researched.

51.6 Automated Vehicles

Intelligent vehicles that are fully autonomous can be justified for safety, traffic congestion, and environmental considerations.

51.6.1 Operating Safely

The first problem is safety. As stated earlier, automobile accidents are one of the main causes of human fatalities – on a staggering scale. This is a catastrophe of larger magnitude than all armed conflicts since the beginning of mankind. The most economically advanced countries (the OECD) have been able to reduce the number of fatalities significantly through improved technology in vehicles – improved handling, braking and passive safety. Transport infrastructure has been greatly improved; modern freeways are ten times safer than regular roads [51.68]. However, these improvements appear to be reaching a limit in terms of the number of deaths per million passengers-kilometers, particularly in industrialized countries.

As discussed earlier, motor vehicles are inherently dangerous due to their reliance on human control. Slight errors at high speeds can have catastrophic results. As discussed earlier the most common cause is driver distraction, which leads to improper reaction times or driving actions. Human error also frequently occurs while handling emergency situations. A large percentage of drivers will take improper action in such situations and produce an accident that could have been avoided by a skilled and attentive driver [51.68]. The best solution to these problems is to remove the driver from the control loop. As discussed earlier the interim step is to assist the driver to warn him/her in case of potential danger (e.g., in the case of excessive speed before a dangerous bend or when a car is present in the blind spot while changing lane), or to take over control in emergency situations (e.g., emergency braking in the case of impending collision). For legal liability reasons, until it can be shown that autonomous systems have high integrity and reliability, people must be kept in the loop – in a supervisory capacity.

51.6.2 Traffic Congestion

The success of the automobile also leads to the saturation of the road infrastructure, particular in cities. Each car needs a certain amount of space in order to operate safely. The usual width of roads is 3.5 m in order to accommodate steering imprecision, while vehicles

are about 2 m in width. Spacing between vehicles also has to be kept at a safe minimum to prevent collisions during deceleration (this principally depends on driver reaction time). It is usually recommended that the spacing should correspond to a time gap of at least 1.5 s. This spacing leads to a maximum throughput of about 2200 cars per hour per lane, independent of traffic speed. This is not high if we consider that a suburban train can carry about 60 000 passengers per hour on an infrastructure of similar dimensions. Furthermore, high-density car traffic of greater than 2200 cars leads to a breakdown in traffic flow (stop-and-go traffic) and to increased likelihood of accidents, which can drastically decrease the overall capacity of system. The solution to this problem also lies in the removal of the driver from the control loop to improve lateral guidance (reduction of the width of lanes) and longitudinal control (with possible time gaps of around 0.3 s, independent of the speed) while maintaining traffic safety. Such techniques of automated driving could multiply the throughput of road infrastructure by a factor of five. This was demonstrated in particular by the work performed in the advanced highway systems (AHS) project in the United States, which led to the demonstration of seven-car platoons running at speeds up to 130 km/h on a dedicated freeway in San Diego with gaps of about 0.5 s [51.69].

Another congestion problem is associated with parking. Every individual vehicle is only used for a small percentage of its total usable life. Most of the time, motor vehicles occupy space very unproductively. Typically, a car requires about 10 m² of space. Usually, parking occurs at the curbside – a space that is very limited in large cities and cannot accommodate all the cars of residents and visitors. In parking lots, each car will need four times this amount in order to have access to each individual slot. If a transportation system based on fully automated cars could be developed, people would not need to own cars but could rely on a service such as the one offered by taxis with vehicles that would come on demand and offer a complement to mass transport. This is the concept of the cybercar, which is under development in Europe [51.70].

51.6.3 Environmental Factors

The ever-increasing deployment of passenger and commercial vehicles has led to critical environment problems of noise and of pollution in the local community. In addition greenhouse-gas emissions have an impact at the

global environment level. Recently automotive manufacturers have been able to reduce emissions of local pollutants drastically; noise in cities is now perceived as the major problem by the inhabitants. At the global level, the generation of CO₂ through the use of fossil fuels is also considered to be a major problem that will require drastic steps. In the short term, this may lead to limiting the use of vehicles that generate CO₂ above certain levels. In the longer term, this will lead the automotive industry to offer vehicles that run on various forms of energy and to new forms of transportation systems with much higher efficiency. Automated vehicles running in platoon formations on new infrastructures could form such a system.

51.6.4 The Automobile of the Future

All three challenges are now at the heart of new policies being developed in many countries. These policies concern safety and emissions features on the vehicles with a strong push towards advanced safety systems, as was recently seen in Europe with the *Intelligent Car Initiative* [51.71]. At the infrastructure level, there is also a strong push to implement regulation schemes to limit and control the use of road transport and promote alternative and more efficient transport means. In the future, this means that the use of a private automobile will be much more regulated and more integrated with other modes of transport.

The automotive industry might move from an industry of products to an industry of service where anyone can have access to mobility in the most cost efficient way. Both mass transportation and individual transportation would be offered by companies in the most cost-efficient way, respecting local regulations. Companies operating in this service industry could be transit operators, taxi

Fig. 51.15 Automated electric cars from Honda

companies, car rental companies, car-sharing companies or even new entrants into the transportation business such as mobile phone companies, which are already familiar with large customer bases and mobility services. Car-sharing operators such as those operating in Germany, Switzerland, Japan, and the USA are likely candidates [51.72]. Figure 51.14 shows a commercial car-sharing operation.

In this context, new types of vehicles such as electric ones and automated driving are being developed because of the decrease in cost of operation and improvements in safety.

Demonstration projects by Honda and by Toyota have already been put in place along these lines. However, this market is still searching for its operators and business model as well as the right products [51.70]. Figure 51.15 shows the Honda concept automated car.

There are two distinct trends in the future of automated vehicles. One is with advanced driving assistance, which has spread rapidly since the late 1990s with numerous techniques appearing recently in high-end passenger vehicles and commercial vehicles (buses and trucks). This trend has been described earlier in this chapter. The other trend is associated with the arrival of people-movers based on automated guided vehicles (small or large) in specific locations and on dedicated tracks (protected or not).

It is forecast that, in the next ten years, these two trends will merge, with individual vehicles having dual-mode capabilities: manual (with strong control and assistance) driving on regular roads and fully automatic driving on dedicated zones where no (or few) manual vehicles will be allowed, thereby ensuring smooth and safe operation of the automated vehicles [51.70]. This type of vehicle will be perfect for the implementation of mobility services with vehicles that can be called on

Fig. 51.14 Car sharing from Toyota

demand (perhaps through a mobile phone) when and where needed. With the development of such zones, new dedicated infrastructures will be built specifically for these vehicles to go automatically and at high speed from one automated zone to the next. This appears to be the most realistic path for *automated highways* to be realized, since it is now considered nearly impossible to have a smooth evolution from the actual infrastructure with its manual vehicles to one with a majority of fully automated ones. This is one of the reasons why the AHS project was cancelled in the USA despite a very successful demonstration in 1997.

51.6.5 Automated Vehicle Deployment

As discussed earlier some automated functions are being introduced in production vehicles. Honda and Toyota have introduced a combination of lateral control (lane keeping assistance using image processing) and longitudinal control (adaptive cruise control using laser and radar sensors) [51.57]. An intelligent parking assist sys-

Fig. 51.16 Toyota ABRT used in IMTS Phileas

Fig. 51.17 Cybercars at Schiphol airport, Amsterdam

tem has been introduced recently by Toyota, offering the ability for the car to be parked without the driver using the steering wheel. However, this system does not use sensors: the driver has to position his/her vehicle on the image of the rear camera [51.55]. However, most car manufacturers and some component manufacturers are actively working on the sensors to remove this task from the driver.

Fully automated vehicles without any human intervention or supervision are now appearing in the commercial domain. Automated bus rapid transit (ABRT) combines the service quality of rail transit with the flexibility and cost of buses (as shown in Fig. 51.16). Nonautomated bus rapid transit (BRT) is already recommended by the World Bank in developing countries as the most efficient mass transport system. By reserving a dedicated lane for bus operation and adding some light infrastructure to facilitate loading and unloading, capacities similar to those of a train (60 000 passengers/h/direction) can be obtained, as has been demonstrated in South America [51.73]. By adding

the driving automation on a **BRT**, the system can be made more efficient and safer, as is already the case with automated metros.

The intelligent multimode transit system (IMTS) consists of vehicles guided by magnetic markers imbedded in the middle of their dedicated roads. The platoon running function (three electronically linked vehicles running in file formation at uniform speeds) of the IMTS consists of precisely controlling the speed of all the vehicles in the platoon to be the same at all times [51.74]. In the city of Eindhoven in The Netherlands, multi-articulated buses with several steering axes are also running in automated mode on a dedicated track using magnetic markers [51.75]. These **ABRT** usually keep a driver on the vehicle since there is the possibility of reverting to the manual mode if need be (such as for an unexpected obstacle or in situations with many pedestrians); however, future plans are for full automation.

ABRT technology can also be found with smaller vehicles, now called cybercars, for on-demand door-to-door operation [51.70]. These vehicles have been put in operation for the first time at the Schiphol airport (Amsterdam) in December 1997 to move passengers from long-term parking lots to the airport terminal (Fig. 51.17). Since this time these cybercars have been

further developed, financed by the Information Society Technologies (**IST**) programme of the European Commission [51.70]. The long-term future of cybercars may lie with the development of dual-mode vehicles, with a particular emphasis on car-sharing operations [51.72]. Cybercars will have an automatic mode for operation in city centers (restricted to this type of vehicles) and a driver-operated (with assistance) mode for regular roads. The automobile industry is examining the viability of the development of such vehicles.

In order to match the performance of manually driven vehicles in urban environments, automated vehicles face major technical challenges. In particular, planning a trajectory for a car while avoiding moving and static obstacles remains as an important research challenge. In 2005, the **DARPA** Grand Challenge described at the beginning of this chapter brought together a large number of these researchers to demonstrate the feasibility of automated driving techniques. Five vehicles succeeded in completing the difficult course of 132 miles in the desert in totally autonomous mode. The next **DARPA** challenge in 2007 will see multiple vehicles operating simultaneously in an urban environment; this challenge will certainly bring products based on autonomous vehicle techniques closer to the market [51.76].

51.7 Future Trends and Prospects

Our cars, trucks, and buses are inevitably getting smarter. The future path is not completely known, and is likely to vary in different locations.

Several trends are clear, however. As sensor-equipped vehicles become more common, there will be increasing opportunities to build sensor-friendly technologies into roadways and into vehicles. It is straightforward to reduce the amount of radar clutter on roadsides by replacing large metal signs, which are excellent radar reflectors, with nonreflective signs made of plastic or composites. It will be desirable to make overpasses with lower radar reflectivities, either by using different materials, by coating steel structures with radar-absorbing material, or by proper geometry design. At the same time, it will be desirable to increase the radar cross-section of small vehicles, such as motorcycles, to make them easier for radar-equipped cars to detect. Radar-reflecting licence plates, for in-

stance, would make smaller vehicles stand out more clearly.

The next steps may be to deploy systems that support the active transmission information from infrastructure to vehicle and vehicle to vehicle. Dedicated short-range communications (**DSRC**) is already in wide use in smart toll collection. It is easy to imagine **DSRC**-equipped vehicles receiving alerts from roadside sensors of upcoming fog, or ice, or congestion. Intelligent vehicles that detect unusual roadway conditions (via radar or lidar, slip detectors, or driver actions such as hard braking) could broadcast that information to all nearby smart vehicles. As market penetration of equipped vehicles increases, the value of such ad hoc communications nets will go up dramatically.

Vehicle-to-vehicle communications need not be only via radio. Light-emitting diode (LED) brake lights can

be pulsed at kilohertz frequencies, well above the bandwidth at which human eyes can detect flicker, but easily received by following vehicles. This would be a straight-

forward way for a vehicle to tell other vehicles about the onset of hard braking, or other unusual roadway conditions.

51.8 Conclusions and Further Reading

The general public will become increasingly accustomed to intelligent systems – sensors and communications on vehicles. The only showstopper in the large-scale deployment of robotics technologies in the automobile field is the ability of the industry to deliver the technologies with total safety, which focus attention on the problems of failsafe systems and their certification. The rail and aerospace industries have solved these problems but in a very different environment. In these industries, the cost of safety for each vehicle can be much higher than in a car or a bus and the operational environment is also quite different, with professionals operating and maintaining the system. Manufacturers will slowly develop experience in reliability and cost engineering, and governments will gradually work out liability issues. For these reasons, systems that put the driver in the loop of new automation technologies will be the initial focus of development.

This technical progress still will not answer societal questions. Will smart vehicles make public transportation more efficient and desirable? Or will they make it easier for people to use their personal vehicles, since driving will be less stressful? The nature of transport, and its effect on urban areas, is not easily predictable. Intelligent transportation systems of the future will provide the tools to shape these discussions; society will have to choose its future from an increasingly rich set of alternatives.

Medical Robotics

and Computer-Integrated Surgery

Russell H. Taylor, Arianna Menciassi, Gabor Fichtinger, Paolo Dario

The growth of medical robotics since the mid-1980s has been striking. From a few initial efforts in stereotactic brain surgery, orthopaedics, endoscopic surgery, microsurgery, and other areas, the field has expanded to include commercially marketed, clinically deployed systems, and a robust and exponentially expanding research community. This chapter will discuss some major themes and illustrate them with examples from current and past research. Further reading providing a more comprehensive review of this rapidly expanding field is suggested in Sect. 52.4.

Medical robots may be classified in many ways: by manipulator design (e.g., kinematics, actuation); by level of autonomy (e.g., preprogrammed versus teleoperation versus constrained cooperative control), by targeted anatomy or technique (e.g., cardiac, intravascular, percutaneous, laparoscopic, microsurgical); or intended operating environment (e.g., in-scanner, conventional operating room). In this chapter, we have chosen to focus on the role of medical robots within the context of larger computer-integrated systems including presurgical planning, intraoperative execution, and postoperative assessment and follow-up.

First, we introduce basic concepts of computer-integrated surgery, discuss critical factors affecting the eventual deployment and acceptance of medical robots, and introduce the basic system paradigms of surgical computer-assisted planning, registration, execution, monitoring, and assessment (**CAD/CAM**) and surgical assistance. In subsequent sections, we provide an overview of the technology of medical robot systems and discuss examples of our basic system paradigms, with brief additional discussion topics of remote telesurgery and robotic surgical simulators. We conclude with some thoughts on future research directions and provide suggested further reading.

52.1 Core Concepts

52.1.1 Medical Robotics, Computer-Integrated Surgery, and Closed-Loop Interventions

A fundamental property of robotic systems is their ability to couple complex information to physical action in order to perform a useful task. This ability to replace, supplement, or transcend human performance has had a profound influence on many fields of our society, including industrial production, exploration, quality control, and laboratory processes. Although robots have often been first introduced to automate or improve discrete processes such as welding or test probe placement or to provide access to environments where humans cannot safely go, their greater long-term impact has often come indirectly as essential enablers of computer integration of entire production or service processes.

Medical robots have a similar potential to fundamentally change surgery and interventional medicine as part of a broader, information-intensive environment that exploits the complementary strengths of humans and computer-based technology. The robots may be thought of as information-driven surgical tools that enable human surgeons to treat individual patients with greater safety, improved efficacy, and reduced morbidity than would otherwise be possible. Further, the consistency and information infrastructure associated with medical robotic and computer-assisted surgery systems have the potential to make *computer-integrated surgery* as important to health care as computer-integrated manufacturing is to industrial production.

Figure 52.1 illustrates this view of computer-integrated surgery (CIS). The process starts with information about the patient, which can include medical images [computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), etc.], lab test results, and other information. This patient-specific information is combined with statistical information about human anatomy, physiology, and disease to produce a comprehensive computer representation of the patient, which can then be used to produce an optimized interventional plan. In the operating room, the preoperative patient model and plan must be *registered* to the actual patient. Typically, this is done by identifying corresponding landmarks or structures on the preoperative model and the patient, either by means of additional imaging (X-ray, ultrasound, video), by the use of a tracked pointing device, or by the robot itself. If the patient's anatomy has changed, then the model and plan are updated appropriately, and the planned procedure is carried out with assistance of the robot. As the intervention continues, additional imaging or other sensing is used to monitor the progress of the procedure, to update the patient model, and to verify that the planned procedure has been successfully executed. After the procedure is complete, further imaging, modeling, and computer-assisted assessment is performed for patient follow-up and to plan subsequent interventions, if any should be required. Further, all the patient-specific data generated during the planning, execution, and follow-up phases can be retained. These data can subsequently be analyzed statistically to improve the rules and methods used to plan future procedures.

52.1.2 Factors Affecting the Acceptance of Medical Robots

Medical robotics is ultimately an application-driven research field. Although the development of medical robotic systems requires significant innovation and can lead to very real, fundamental advances in technology, medical robots must provide measurable and significant advantages if they are to be widely accepted and deployed. The situation is complicated by the fact that these advantages are often difficult to measure, can take an extended period to assess, and may be of varying importance to different groups. Table 52.1 lists some of the more important factors that researchers contemplating the development of a new medical robot system should consider in assessing their proposed approach.

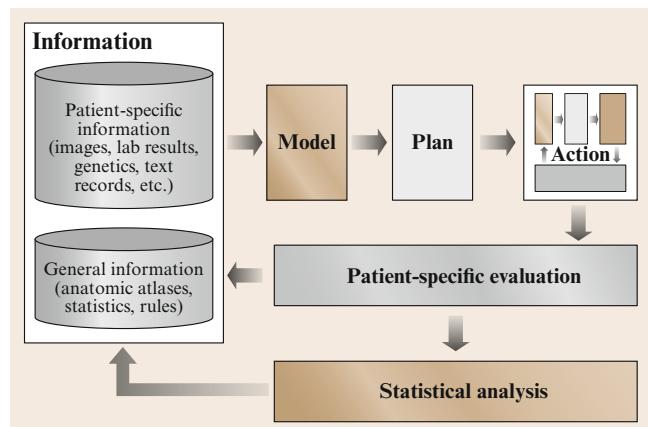

Fig. 52.1 Fundamental information flow in computer-integrated surgery

Table 52.1 Assessment factors for medical robots or computer-integrated surgery systems [52.1]

| Assessment factor | Important to whom | Assessment method | Summary of key leverage |
|--------------------------------------|--------------------------------|------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| New treatment options | Clinical researchers, patients | Clinical and trials preclinical | Transcend human sensory-motor limits (e.g., in microsurgery). Enable less invasive procedures with real-time image feedback (e.g., fluoroscopic or MRI-guided liver or prostate therapy). Speed up clinical research through greater consistency and data gathering |
| Quality | Surgeons, patients | Clinician judgment; revision rates | Significantly improve the quality of surgical technique (e.g., in microvascular anastomosis), thus improving results and reducing the need for revision surgery |
| Time and cost | Surgeons, hospitals, insurers | Hours, hospital charges | Speed operating room (OR) time for some interventions. Reduce costs from healing time and revision surgery. Provide effective intervention to treat patient condition |
| Less invasiveness | Surgeons, patients | Qualitative judgment; recovery times | Provide crucial information and feedback needed to reduce the invasiveness of surgical procedures, thus reducing infection risk, recovery times, and costs (e.g., percutaneous spine surgery) |
| Safety | Surgeons, patients | Complication and revision surgery rates | Reduce surgical complications and errors, again lowering costs, improving outcomes and shortening hospital stays (e.g., robotic total hip replacement (THR), steady-hand brain surgery) |
| Real-time feedback | Surgeons | Qualitative assessment, quantitative comparison of plan to observation, revision surgery rates | Integrate preoperative models and intraoperative images to give surgeon timely and accurate information about the patient and intervention (e.g., fluoroscopic X-rays without surgeon exposure, percutaneous therapy in conventional MRI scanners). Assure that the planned intervention has in fact been accomplished |
| Accuracy or precision | Surgeons | Quantitative comparison of plan to actual | Significantly improve the accuracy of therapy dose pattern delivery and tissue manipulation tasks (e.g., solid organ therapy, microsurgery, robotic bone machining) |
| Enhanced documentation and follow-up | Surgeons, clinical researchers | Databases, anatomical atlases, images, and clinical observations | Exploit CIS systems' ability to log more varied and detailed information about each surgical case than is practical in conventional manual surgery. Over time, this ability, coupled with CIS systems' consistency, has the potential to significantly improve surgical practice and shorten research trials |

Broadly, the advantages offered by medical robots may be grouped into three areas. The first is the potential of a medical robot to *significantly improve surgeons' technical capability* to perform procedures by exploiting the complementary strengths of humans and robots summarized in Table 52.2. Medical robots can be constructed to be more precise and geometrically accurate than an unaided human. They can operate in hostile radiological environments and can provide great dexterity for minimally invasive procedures inside the patient's body.

These capabilities can both enhance the ability of an *average* surgeon to perform procedures that only a few exceptionally gifted surgeons can perform unassisted and can also make it possible to perform interventions that would otherwise be completely infeasible.

A second, closely related capability is the potential of medical robots to *promote surgical safety* both by improving a surgeon's technical performance and by means of active assists such as *no-fly zones* or *virtual fixtures* (Sect. 52.3) to prevent surgical instruments

Table 52.2 Complementary strengths of human surgeons and robots [52.1]

| | Strengths | Limitations |
|---------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Humans | Excellent judgment Excellent hand–eye coordination Excellent dexterity (at natural <i>human</i> scale) Able to integrate and act on multiple information sources Easily trained Versatile and able to improvise | Prone to fatigue and inattention Limited fine motion control due to tremor Limited manipulation ability and dexterity outside natural scale Cannot see through tissue Bulky end-effectors (hands) Limited geometric accuracy Hard to keep sterile Affected by radiation, infection |
| Robots | Excellent geometric accuracy Untiring and stable Immune to ionizing radiation Can be designed to operate at many different scales of motion and payload Able to integrate multiple sources of numerical and sensor data | Poor judgment Hard to adapt to new situations Limited dexterity Limited hand–eye coordination Limited haptic sensing (today) Limited ability to integrate and interpret complex information |

from causing unintentional damage to delicate structures. Furthermore, the integration of medical robots within the information infrastructure of a larger CIS system can provide the surgeon with significantly improved monitoring and online decision supports, thus further improving safety.

A third advantage is the inherent ability of medical robots and CIS systems to *promote consistency* while *capturing detailed online information* for every procedure. Consistent execution (e.g., in spacing and tension-

ing of sutures or in placing of components in joint reconstructions) is itself an important quality factor. If saved and routinely analyzed, the *flight data recorder* information inherently available with a medical robot can be used both in *morbidity and mortality* assessments of serious surgical incidents and, potentially, in statistical analyses examining many cases to develop better surgical plans. Furthermore, such data can provide valuable input for surgical simulators, as well as a database for developing skill assessment and certification tools for surgeons.

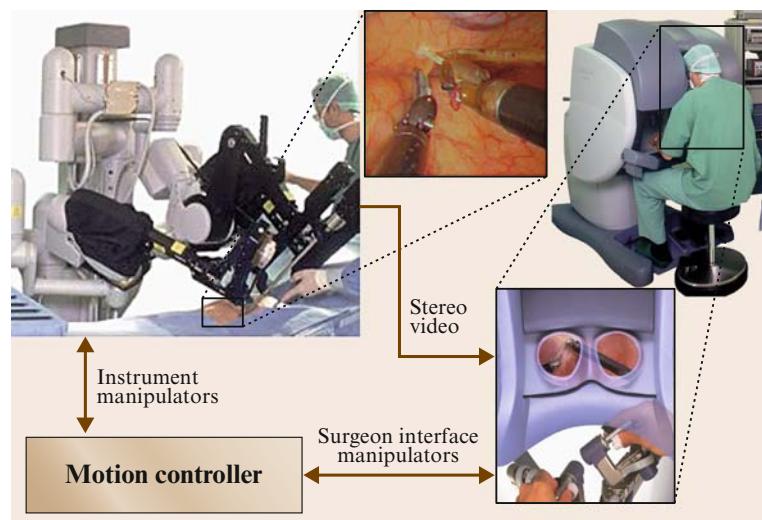

Fig. 52.2 The daVinci telesurgical robot [52.2] extends a surgeon's capabilities by providing the immediacy and dexterity of *open* surgery in a minimally invasive surgical environment. (Photos: Intuitive Surgical, Sunnyvale)

52.1.3 Medical Robotics System Paradigms: Surgical CAD/CAM and Surgical Assistance

We call the process of computer-assisted planning, registration, execution, monitoring, and assessment *surgical CAD/CAM*, emphasizing the analogy to manufacturing *CAD/CAM*. Just as with manufacturing, robots can be critical in this *CAD/CAM* process by enhancing the surgeon's ability to execute surgical plans. The specific role played by the robot depends somewhat on the application, but current systems tend to exploit the geometric accuracy of the robot and/or its ability to function concurrently with X-ray or other imaging devices. Typical examples include radiation therapy delivery robots such as Accuray's CyberKnife [52.5] (Accuray, Inc., Sunnyvale, CA.), shaping of bone in

orthopaedic joint reconstructions (discussed further in Sect. 52.3.2) and image-guided placement of therapy needles (Sect. 52.3.3).

Surgery is often highly interactive; many decisions are made by the surgeon in the operating room and executed immediately, usually with direct visual or haptic feedback. Generally, the goal of surgical robotics is not to replace the surgeon so much as to improve his or her ability to treat the patient. The robot is thus a computer-controlled surgical tool in which control of the robot is often shared in one way or another between the human surgeon and a computer. We thus often speak of medical robots as *surgical assistants*.

Broadly, robotic surgical assistants may be broken into two subcategories. The first category, *surgeon extender robots*, manipulate surgical instruments under the direct control of the surgeon, usually through a teleop-

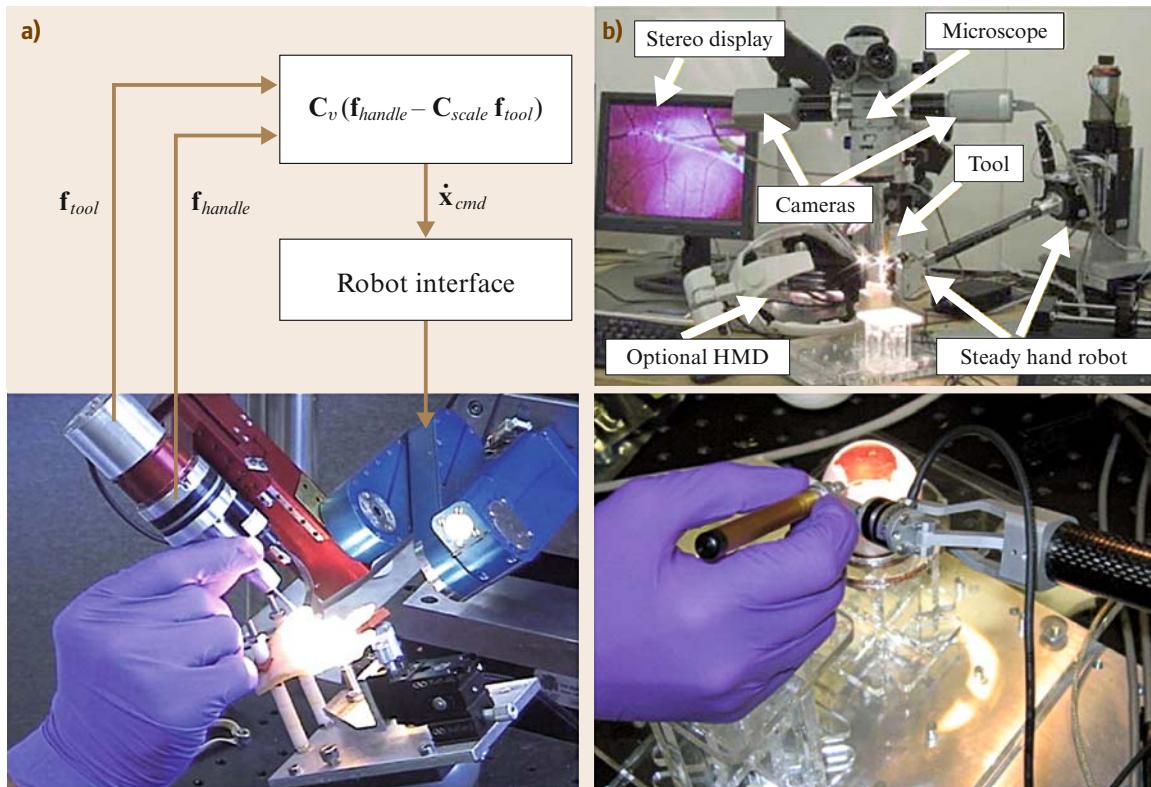

Fig. 52.3a,b The Johns Hopkins *Steady Hand* microsurgical robot [52.3,4] extends a surgeon's capabilities by providing the ability to manipulate surgical instruments with very high precision while still exploiting the surgeon's natural hand-eye coordination. **(a)** The basic paradigm of hands-on compliant guiding. The commanded velocity of the robot is proportional to a scaled difference between the forces exerted by the surgeon on the tool handle and (optionally) sensed tool-to-tissue forces. **(b)** A more recent version of the *Steady Hand* robot currently being used for experiments in microcannulation of 100 µm blood vessels

eration or *hands-on* cooperative control interface. The primary value of these systems is that they can overcome some of the perception and manipulation limitations of the surgeon. Examples include the ability to manipulate surgical instruments with superhuman precision by eliminating hand tremor, the ability to perform highly dexterous tasks inside the patient's body, or the ability to perform surgery on a patient who is physically remote from the surgeon. Although setup time is still a serious concern with most surgeon extender systems, the greater ease of manipulation that such systems offer has the potential to reduce operative times. One widely deployed example of a surgeon extender is the daVinci system [52.2] (Intuitive Surgical Systems, Sunnyvale, CA) shown in Fig. 52.2. Other examples include the Sensei catheter system [52.6] (Hansen Medical Systems, Mountain View, CA.) and the experimental Johns Hopkins University (JHU) *Steady Hand* microsurgery robot shown in Fig. 52.3. Further examples are discussed in Sect. 52.3.

A second category, *auxiliary surgical support robots*, generally work alongside the surgeon and perform such routine tasks as tissue retraction, limb

positioning, or endoscope holding. One primary advantage of such systems is their potential to reduce the number of people required in the operating room, although that advantage can only be achieved if *all* the tasks routinely performed by an assisting individual can be automated. Other advantages can include improved task performance (e.g., a steadier endoscopic view), safety (e.g., elimination of excessive retraction forces), or simply giving the surgeon a greater feeling of control over the procedure. One of the key challenges in these systems is providing the required assistance without posing an undue burden on the surgeon's attention. A variety of control interfaces are common, including joysticks, head tracking, voice recognition systems, and visual tracking of the surgeon and surgical instruments, for example, the Aesop endoscope positioner [52.7] used both a foot-actuated joystick and a very effective voice recognition system. Again, further examples are discussed in Sect. 52.3.

It is important to realize that *surgical CAD/CAM* and *surgical assistance* are complementary concepts. They are not at all incompatible, and many systems have aspects of both.

52.2 Technology

52.2.1 Mechanical Design Considerations

The mechanical design of a surgical robot depends crucially on its intended application. For example, robots with high precision, stiffness and (possibly) limited dexterity are often very suitable for orthopaedic bone shaping or stereotactic needle placement, and medical robots for these applications [52.8–11] frequently have high gear ratios and consequently, low back-drivability, high stiffness, and low speed. On the other hand, robots for complex, minimally invasive surgery (**MIS**) on soft tissues require compactness, dexterity, and responsiveness. These systems [52.2, 12] frequently have relatively high speed, low stiffness, and highly back-drivable mechanisms.

Many early medical robots [52.8, 11, 13] were essentially modified industrial robots. This approach has many advantages, including low cost, high reliability, and shortened development times. If suitable modifications are made to ensure safety and sterility, such systems can be very successful clinically [52.9], and they can also be invaluable for rapid prototyping and research use.

However, the specialized requirements of surgical applications have tended to encourage more specialized

designs. For example, laparoscopic surgery and percutaneous needle placement procedures typically involve the passage or manipulation of instruments about a common entry point into the patient's body. There are two basic design approaches. The first approach uses a passive wrist to allow the instrument to pivot about the insertion point and has been used in the commercial Aesop and Zeus robots [52.12, 14] as well as several research systems. The second approach mechanically constrains the motion of the surgical tool to rotate about a *remote center of motion (RCM)* distal to the robot's structure. In surgery, the robot is positioned so that the **RCM** point coincides with the entry point into the patient's body. This approach has been used by the commercially developed daVinci robot [52.2], as well as by numerous research groups, using a variety of kinematic designs [52.15–17].

The emergence of minimally invasive surgery has created a need for robotic systems that can provide high degrees of dexterity in very constrained spaces inside the patient's body, and at smaller and smaller scales. Figure 52.4 shows several typical examples of current approaches. One common response has been to develop cable-actuated wrists [52.2]. However, a num-

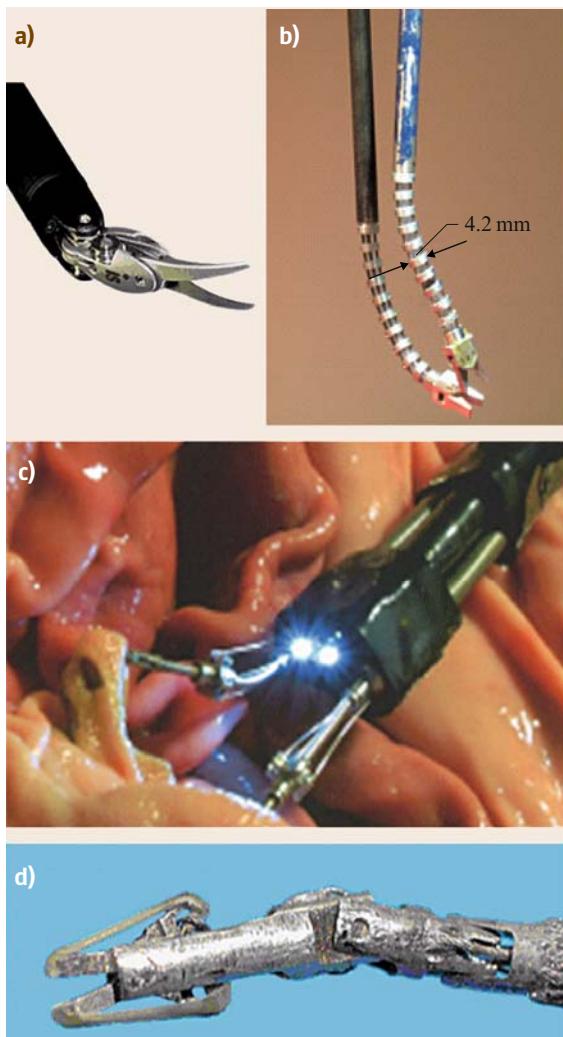

Fig. 52.4a–d Dexterity enhancement inside a patient's body: (a) The daVinci wrist with a typical surgical instrument (here, scissors) [52.2]; (b) The end-effectors of the JHU/Columbia snake telesurgical system [52.18]; (c) Two-handed manipulation system for use in endogastric surgery [52.26]; (d) five-degree-of-freedom 3 mm wrist and gripper [52.27] for microsurgery in deep and narrow spaces

ber of investigators have investigated other approaches, including bending structural elements [52.18], shape-memory alloy actuators [52.19, 20], microhydraulic systems [52.21], and electroactive polymers [52.22]. Similarly, the problem of providing access to surgical sites inside the body has led several groups to develop

semiautonomously moving robots for epicardial [52.23] or endoluminal applications [52.24, 25].

Although most surgical robots are mounted to the surgical table, to the operating room ceiling, or to the floor, there has been some interest in developing systems that directly attach to the patient [52.28, 29]. The main advantage of this approach is that the relative position of the robot and patient is unaffected if the patient moves. The challenges are that the robot must be smaller and that relatively nonintrusive means for mounting it must be developed.

Finally, robotic systems intended for use in specific imaging environments pose additional design challenges. First, there is the geometric constraint that the robot (or at least its end-effector) must fit within the scanner along with the patient. Second, the robot's mechanical structure and actuators must not interfere with the image formation process. In the case of X-ray and CT, satisfying these constraints is relatively straightforward. The constraints for MRI are more challenging [52.30].

52.2.2 Control Paradigms

Surgical robots assist surgeons in treating patients by moving surgical instruments, sensors, or other devices in relation to the patient. Generally, these motions are controlled by the surgeon in one of three ways:

- *Preprogrammed, semi-autonomous motion:* The desired behavior of the robot's tools is specified interactively by the surgeon, usually based on medical images. The computer fills in the details and obtains the surgeon's concurrence before the robot is moved. Examples include the selection of needle target and insertion points for percutaneous therapy and tool cutter paths for orthopaedic bone machining.
- *Teleoperator control:* The surgeon specifies the desired motions directly through a separate human interface device and the robot moves immediately. Examples include common telesurgery systems such as the daVinci [52.2]. Although physical master manipulators are the most common input devices, other human interfaces are also used, notably voice control [52.12].
- *Hands-on compliant control:* The surgeon grasps the surgical tool held by the robot or a control handle on the robot's end-effector. A force sensor senses the direction that the surgeon wishes to move the tool and the computer moves the robot to comply. Early experiences with Robodoc [52.8] and other

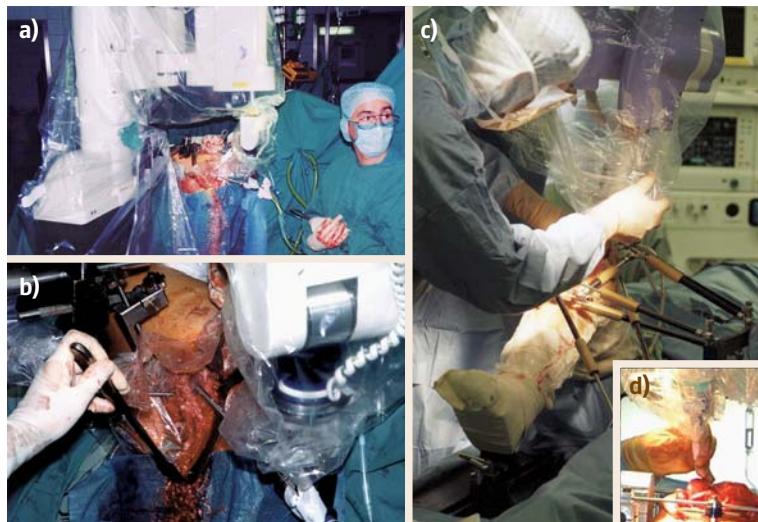

Fig. 52.5a–d Clinically deployed robots for orthopaedic surgery. (a,b)

The Robodoc system [52.8, 9] represents the first clinically applied robot for joint reconstruction surgery and has been used for both primary and revision hip replacement surgery as well as knee replacement surgery.

(c,d) The Acrobot system of Davies et al. [52.31] uses hands-on compliant guiding together with a form of virtual fixtures to prepare the femur and tibia for knee replacement surgery

surgical robots [52.16] showed that surgeons found this form of control to be very convenient and natural for surgical tasks. Subsequently, a number of groups have exploited this idea for precise surgical tasks, notably the JHU *Steady Hand* microsurgical robot [52.3] shown in Fig. 52.3 and the Imperial College Acrobot orthopaedic system [52.31] shown in Figs. 52.5c,d.

These control modes are not mutually exclusive and are frequently mixed. For example, the Robodoc system [52.8, 9] uses hands-on control to position the robot close to the patient's femur or knee and pre-programmed motions for bone machining. Similarly, the IBM/JHU LARS robot. [52.16] used both cooperative and telerobotic control modes. The cooperatively controlled Acrobot [52.31] uses preprogrammed virtual fixtures Sect. 52.1.3 derived from the implant shape and its planned position relative to medical images.

Each mode has advantages and limitations, depending on the task. Preprogrammed motions permit complex paths to be generated from relatively simple specifications of the specific task to be performed. They are most often encountered in surgical CAD/CAM applications where the planning uses two- (2-D) or three-dimensional (3-D) medical images. However, they can also provide useful *macro* motions combining sensory feedback in teleoperated or hands-on systems. Examples might include passing a suture or inserting a needle into a vessel after the surgeon has prepositioned the tip. On the other hand, interactive specification of motions based on real-

time visual appreciation of deforming anatomy would be very difficult.

Teleoperated control provides the greatest versatility for interactive surgery applications, such as dexterous MIS [52.2, 12, 17, 32] or remote surgery [52.33, 34]. It permits motions to be scaled, and (in some research systems) facilitates haptic feedback between master and slave systems. The main drawbacks are complexity, cost, and disruption to standard operating room work flow associated with having separate master and slave robots.

Hands-on control combines the precision, strength, and tremor-free motion of robotic devices with some of the immediacy of freehand surgical manipulation. These systems tend to be less expensive than telesurgical systems, since there is less hardware, and they can be easier to introduce into existing surgical settings. They exploit a surgeon's natural eye-hand coordination in an intuitively appealing way, and they can be adapted to provide force scaling [52.3, 4]. Although direct motion scaling is not possible, the fact that the tool moves in the direction that the surgeon pulls it makes this limitation relatively unimportant when working with a surgical microscope. The biggest drawbacks are that hands-on control is inherently incompatible with any degree of remoteness between the surgeon and the surgical tool and that it is not practical to provide hands-on control of instruments with distal dexterity.

Teleoperation and hands-on control are both compatible with *shared control modes* in which the robot controller constrains or augments the motions specified by the surgeon, as discussed in Sect. 52.2.3.

52.2.3 Virtual Fixtures and Human–Machine Cooperative Systems

Although one goal of both teleoperation and hands-on control is often *transparency*, i.e., the ability to move an instrument with the freedom and dexterity we might expect with a handheld tool, the fact that a computer is actually controlling the robot's motion creates many more possibilities. The simplest is a safety barrier or *no-fly zone*, in which the robot's tool is constrained from entering certain portions of its workspace. More sophisticated versions include virtual springs, dampers, or complex kinematic constraints that help a surgeon align a tool, maintain a desired force, or maintain a desired anatomical relationship. The Acrobot system shown in Figs. 52.5c,d represents a successful clinical application of the concept, which has many names, of which *virtual fixtures* seems to be the most popular [52.35, 36]. A number of groups are exploring extensions of the concept to active cooperative control, in which the surgeon and robot share or trade off control of the robot during a surgical task or subtask. As the ability of computers to model and follow along surgical tasks improves, these modes will become more and more important in surgical assistant applications. Figure 52.6 illustrates the overall concept of human–machine cooperative systems in surgery, and Fig. 52.7 illustrates the use of registered anatomical models to generate constraint-based virtual fixtures. These approaches are equally valid whether the surgeon interacts with the system through classical teleoperation or through hands-on compliant control. See also Chap. 31.

Both teleoperation and hands-on control are likewise used in human–machine cooperative systems for rehabilitation and disability assistance systems. Constrained hands-on systems offer special importance for rehabilitation applications and for helping people with movement disorders. Similarly, teleoperation and intelligent task following and control are likely to be vital for further advances in assistive systems for people with severe physical disabilities. See Chap. 53 for a further discussion of human–machine cooperation in assistive systems.

52.2.4 Safety and Sterility

Medical robots are safety-critical systems, and safety should be considered from the very beginning of the design process [52.37, 38]. Although there is some difference in detail, government regulatory bodies re-

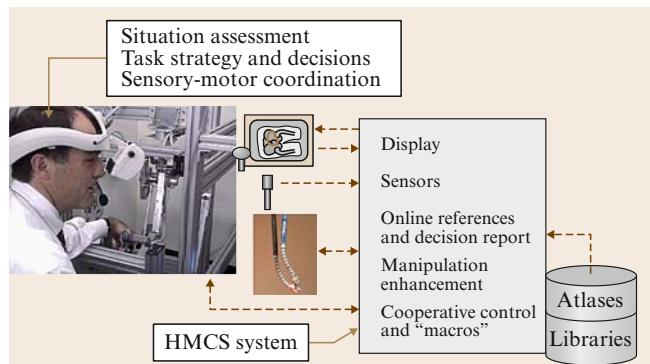

Fig. 52.6 Human–machine cooperative systems (HMCS) in surgery

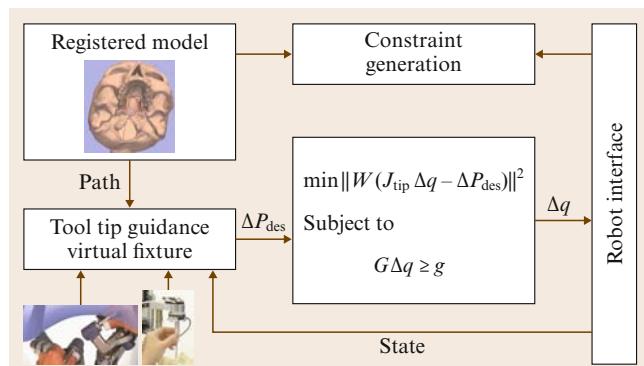

Fig. 52.7 Human–machine cooperative manipulation using constraint-based virtual fixtures, in which patient-specific constraints are derived from registered anatomical models [52.35]

quire a careful and rigorous development process with extensive documentation at all stages of design, implementation, testing, manufacturing, and field support. Generally, systems should have extensive redundancy built into hardware and control software, with multiple consistency conditions constantly enforced. The basic consideration is that no single point of failure should cause the robot to go out of control or to injure a patient. Although there is some difference of opinion as to the best way to make trade-offs, medical manipulators are usually equipped with redundant position encoders and ways to mechanically limit the speed and/or force that the robot can exert. If a consistency check failure is detected, two common approaches are to *freeze* robot motion or to cause the manipulator to go limp. Which is better depends strongly on the particular application.

Sterilizability and biocompatibility are also crucial considerations. Again, the details are application de-

pendent. Common sterilization methods include gamma rays (for disposable tools), autoclaving, soaking or gas sterilization, and the use of sterile drapes to cover unsterile components. Soaking or gas sterilization are less likely to damage robot components, but very rigorous cleaning is required to prevent extraneous foreign matter from shielding microbes from the sterilizing agent.

Careful attention to higher levels of application protocols is also essential. Just like any other tool, surgical robots must be used correctly by surgeons, and careful training is essential for safe practice. Surgeons must understand both the capabilities and limitations of the system. In surgical *CAD/CAM* applications, the surgeon must understand how the robot will execute the plan and be able to verify that the plan is being followed. If the surgeon is interactively commanding the robot, it is essential that the robot interpret these commands correctly. Similarly, it is essential that the robot's model of its task environment correspond correctly to the actual environment. Although careful design and implementation can practically eliminate the likelihood of a runaway condition by the manipulator, this will do little good if the robot is badly registered to the patient images used to control the procedure. If the robot fails for any reason, there must be well-documented and planned procedures for recovery (and possibly continuing the procedure manually).

Finally, it is important to remember that a well-designed robot system can actually *enhance* patient safety. The robot is not subject to fatigue or momentary lapses of attention. Its motions can be more precise and there is less chance that a slip of the scalpel may damage some delicate structure. In fact, the system can be programmed to provide *virtual fixtures* (Sect. 52.2.3) preventing a tool from entering a forbidden region unless the surgeon explicitly overrides the system.

52.2.5 Imaging and Modeling of Patients

As the capabilities of medical robots continue to evolve, the use of computer systems to model dynamically changing patient-specific anatomy will become increasingly important. There is a robust and diverse research community addressing a very broad range of research topics, including the creation of patient-specific models from medical images, techniques for updating these models based upon real-time image and other sensor data, and the use of these models for planning and monitoring of surgical procedures. Some of the pertinent research topics include the following:

- Medical image segmentation and image fusion to construct and update patient-specific anatomic models
- Biomechanical modeling for analyzing and predicting tissue deformations and functional factors affecting surgical planning, control, and rehabilitation
- Optimization methods for treatment planning and interactive control of systems
- Methods for registering the *virtual reality* of images and computational models to the *physical reality* of an actual patient
- Methods for characterizing treatment plans and individual task steps such as suturing, needle insertion, or limb manipulation for purposes of planning, monitoring, control, and intelligent assistance
- Real-time data fusion for such purposes as updating models from intraoperative images
- Methods for human–machine communication, including real-time visualization of data models, natural language understanding, gesture recognition, etc.
- Methods for characterizing uncertainties in data, models, and systems and for using this information in developing robust planning and control methods

An in-depth examination of this research is beyond the scope of this article. A more complete discussion of these topics may be found in the suggested further reading in Sect. 52.4.

52.2.6 Registration

Geometric relationships are fundamental in medical robotics, especially in surgical *CAD/CAM*. There is an extensive literature on techniques for coregistering coordinate systems associated with robots, sensors, images, and the patient [52.39, 40]. Following [52.40], we briefly summarize the main concepts here. Suppose that we have coordinates

$$\begin{aligned}\mathbf{v}_A^r &= (x_A, y_A, z_A) \\ \mathbf{v}_B^r &= (x_B, y_B, z_B),\end{aligned}$$

corresponding to comparable locations in two coordinate systems Ref_A and Ref_B . Then the process of registration is simply that of finding a function $T_{AB}(\dots)$ such that

$$\mathbf{v}_B = T_{AB}(\mathbf{v}_A).$$

Generally, $T_{AB}(\dots)$ is assumed to be a rigid transformation of the form

$$T_{AB}(v_A^r) = R_{AB}v_A^r + p_{AB}^r,$$

where R_{AB} represents a rotation and p_{AB} represents a translation, but nonrigid transformations are becoming increasingly common. There are hundreds of methods for computing $T_{AB}(\dots)$. The most common for medical robotics involve finding a set of corresponding geometric features Γ_A and Γ_B whose coordinates can be determined in both coordinate systems and then finding a transformation that minimizes some distance function $d_{AB} = \text{distance}[\Gamma_B, T_{AB}(\Gamma_A)]$. Typical features can include artificial fiducial objects (pins, implanted spheres, rods, etc.) or anatomical features such as point landmarks, ridge curves, or surfaces.

One common class of methods is based on the iterated closest-point algorithm of *Besl and McKay* [52.41], for example, 3-D robot coordinates a_j may be found for a collection of points known to be on the surface of an anatomical structure that can also be found in a segmented 3-D image. Given an estimate T_k of the transformation between image and robot coordinates, the method iteratively finds corresponding points b_j on the surface that are closest to $T_k a_j$ and then finds a new transformation

$$T_{k+1} = \arg \min_T \sum_j (b_j - Ta_j)^2.$$

The process is repeated until some suitable termination condition is reached.

52.3 Systems, Research Areas, and Applications

52.3.1 Nonrobotic Computer-Assisted Surgery: Navigation and Image Overlay Devices

Medical robots are not ends in themselves. As the late Hap Paul often remarked, “the robot is a surgical tool designed to improve the efficacy of a procedure”. (Dr Paul was the founder of Integrated Surgical Systems. Along with William Bargar, he was one of the first people to recognize the potential of robots to fundamentally improve the precision of orthopaedic surgery.) In cases where the role of the robot is placing instruments on targets determined from medical images, *surgical navigation* is often a superior alternative. In surgical navigation [52.42], the positions of instruments relative to the reference markers on the patient are tracked using specialized electromechanical, optical, electromagnetic, or sonic digitizers or by more general computer vision techniques. After the relationships between key coordinate systems (patient anatomy, images, surgical tools, etc.) are determined through a registration process (Sect. 52.2.6), a computer workstation provides graphical feedback to the surgeon to assist in performing the planned task, usually by displaying instrument positions relative to medical images, as shown in Fig. 52.8a. Although the registration is usually performed computationally, a simple mechanical alignment of an image display with an imaging device can be surprisingly effective in some cases. One example [52.27] is shown in Fig. 52.8b.

The main advantages of surgical navigation systems are their versatility, their relative simplicity, and their ability to exploit the surgeon’s natural dexterity and haptic sensitivity. They are readily combined with *passive* fixtures and manipulation aids [52.43, 44]. The main drawbacks, compared to active robots, are those associated with human limitations in accuracy, strength, ability to work in certain imaging environments, and dexterity inside the patient’s body (Table 52.2).

Because these advantages often outweigh the limitations, surgical navigation systems are achieving widespread and increasing acceptance in such fields as neurosurgery, otolaryngology, and orthopaedics. Since much of the technology of these systems is compatible with surgical robots and since technical problems such as registration are common among all these systems, we may expect to see a growing number of hybrid applications combining medical robots and navigation.

52.3.2 Orthopaedic Systems

Orthopaedic surgery represents a natural surgical CAD/CAM application, and both surgical navigation systems and medical robots have been applied to orthopaedics. Bone is rigid and is easily imaged in CT and intraoperative X-rays, and surgeons are accustomed to doing at least some preplanning based on these images. Geometric accuracy in executing surgical plans is very important, for example, bones must be shaped accurately to ensure proper fit and positioning of components in

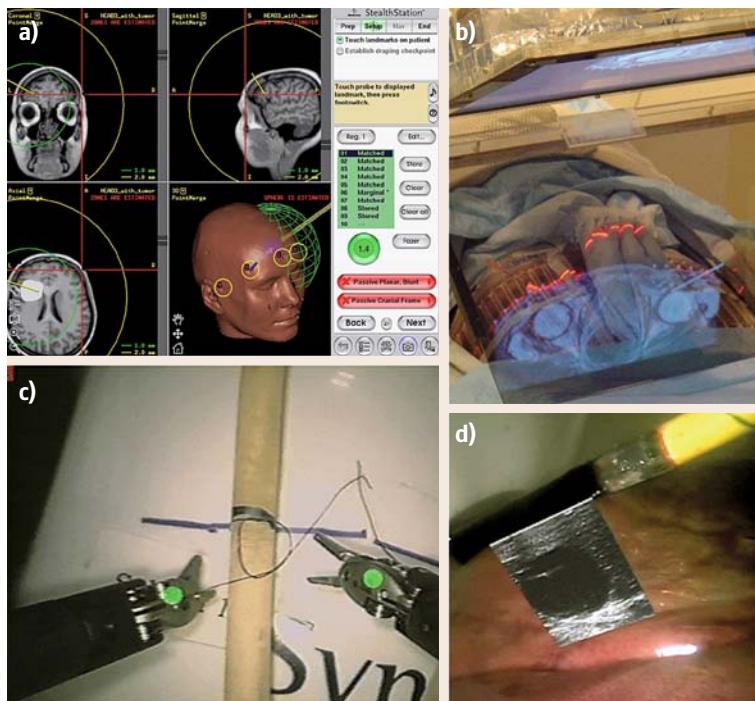

Fig. 52.8a–d Information enhancement for surgical assistance.

(a) Display from a typical surgical navigation system, here the Medtronic StealthStation; (b) the JHU image overlay system [52.45] uses a mirror to align the virtual image of a cross-sectional image with the corresponding physical position in the patient's body; (c) Sensory substitution display of surgical force information onto daVinci surgical robot video monitor [52.46]; (d) Overlay of laparoscopic ultrasound onto the daVinci surgical robot video monitor [52.47]

joint replacement surgery. Similarly, osteotomies require both accurate cutting and placement of bone fragments. Spine surgery often requires screws and other hardware to be placed into vertebrae without damage to the spinal cord, nerves, and nearby blood vessels.

The Robodoc system shown in Figs. 52.5a,b represents the first clinically applied robot for joint reconstruction surgery [52.8,9]. Since 1992, it has been applied successfully to both primary and revision hip replacement surgery, as well as knee surgery. Since this system exhibits many of the characteristics of surgical **CAD/CAM**, we will discuss it in some detail. In the *surgical CAD* phase, the surgeon selects the desired based on preoperative **CT** images and interactively specifies the desired position of the implant components. In the *surgical CAM* phase, surgery proceeds normally up to the point where the patient's bones are to be prepared to receive the implant. The robot is moved up to the operating table, the patient's bones are attached rigidly to the robot's base, and the robot is registered to the **CT** images either by use of implanted fiducial pins or by use of a 3-D digitizer to match bone surfaces to the **CT** images. After registration, the surgeon's hand guides the robot to an approximate initial starting position. Then, the robot autonomously machines the desired shape with a high-speed rotary cutter while the surgeon monitors progress.

During cutting, the robot monitors cutting forces, bone motion, and other safety sensor, and either the robot controller or the surgeon can pause execution at any time. If the procedure is paused for any reason, there are a number of error recovery procedures available to permit the procedure to be resumed or restarted at one of several defined checkpoints. Once the desired shape has been machined, surgery proceeds manually in the normal manner.

Subsequently, several other robotic systems for joint replacement surgery have been introduced or proposed. The references in Sect. 52.4 provide numerous examples. One notable system is the hands-on guided Acrobot system [52.31] for knee surgery shown in Figs. 52.5c,d. Similarly, several groups have recently proposed small orthopaedic robots attaching directly to the patient's bones [52.28].

52.3.3 Percutaneous Needle Placement Systems

Percutaneous (through the skin) needle placement has become ubiquitous in interventional radiology and surgery, as the least invasive actual surgical action practised today. These procedures fit naturally within the broader paradigm of surgical **CAD/CAM** systems. The

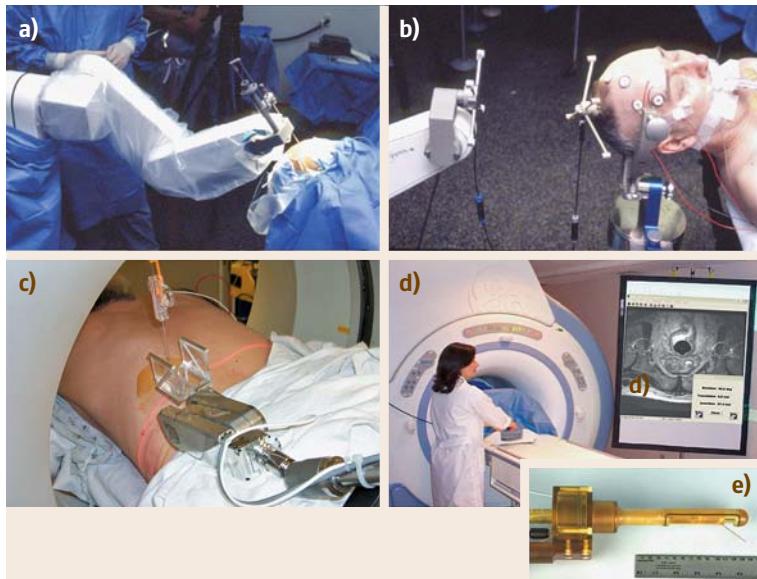

Fig. 52.9a–e Clinically deployed systems for in-scanner needle placement. (a,b) The Neuromate system [52.10] for stereotactic procedures in the brain uses a novel noncontact sensing system for robot-to-image registration; (c) Johns Hopkins system for in-CT needle placement [52.48, 49]; (d,e) Manually activated device for in-MRI transrectal needle placement into the prostate [52.50]

basic process involves use of patient images to identify targets within the patient and planning needle trajectories; inserting the needles and verifying their placement; performing some action such as an injection or taking a biopsy sample; and assessing the results. In most needle placements, an accuracy of 1–2 mm is acceptable, which is not easy to achieve freehand, because the target is not directly visible, soft tissues tend to deform and deflect, and needles often bend. Hence these procedures typically rely on some form of intraoperative imaging (X-ray fluoroscopy, CT, MRI, and ultrasound) for both guidance and verification. The surgical motion sequence involved in needle puncture typically has three phases:

1. touch down with the needle tip at the entry point
2. orientation of the needle by pivoting around this point
3. final insertion of the needle into the body along a straight trajectory

These motions are most often performed freehand, with varying degrees of information feedback for the physician. However, passive, semiautonomous, and active robotic systems are becoming more prevalent. Figure 52.9 shows several clinically deployed systems for needle placement.

Freehand Needle Placement Systems

Conventional freehand needle placement with CT and MRI guidance typically uses skin markers to locate the exact entry point [52.45], reference to the scanner's

alignment laser to control needle direction, and markers on the needle to control depth. With fluoroscopy, the typical procedure is to align the X-ray system so that it looks directly along the desired needle path, place the needle and stand it up so that its X-ray image is a dot, turn the X-ray system to look from the side, and insert the needle until it reaches the target. With ultrasound, the primary reliance is on surgeon experience or the use of some sort of needle guide to drive the needle to target while it passes in the ultrasound plane. In fact, a variety of simple mechanical guides have been tried out for use with all common image modalities. Several computer-assisted approaches have been proposed to enhance a human's ability to aim the needle during freehand needle placement. These include computer-aimed laser guidance devices [52.51], augmented reality systems [52.52], and surgical navigation [52.42]. In addition, very simple variations of augmented reality have been developed for use with 2-D images such as CT or MRI slices [52.45]. B-mode ultrasound images (Fig. 52.8b) [52.53], where a semitransparent mirror is used together with a flat-panel display to ensure that the virtual image of the display is aligned to the corresponding physical section through the patient's anatomy, have also been used.

Passive and Semiautonomous Devices for Needle Placement

A few researchers [52.54] have proposed use of passive, encoded manipulator arms for image-guided needle

placement. After a registration step, these systems track the position and orientation of a passive needle guide and display the corresponding needle path in real time on **CT** or **MRI** images. Semiautonomous systems allow remote, interactive image-guided placement of the biopsy tool. For example, *Krieger et al.* performed transrectal prostate needle placement procedures in a conventional **MRI** environment [52.50] with a three-degree-of-freedom (**DOF**) manipulator. The device is driven from outside the bore with torsion cables, while the needle driver is tracked in the **MRI** system with active coils and monitored using an interactive graphical interface.

Active Robots for Needle Placement

Neurosurgery was one of the first clinical applications of active robots [52.10, 11, 13]. This is a natural application for surgical **CAD/CAM**. The entry and target points are planned on **CT/MRI** images, the robot coordinate system is registered to the image coordinate system (typically with fiducials affixed to the patient's head), and then the robot positions a needle or drill guide. The fiducial structure may be a conventional stereotactic head frame or, as in the Neuromate system [52.10], registration is achieved by simultaneous tracking of the robot and fiducials attached to the patient's skull. Special constraints of percutaneous access have led to the development of structures achieving *remote center of motion* (**RCM**) or fulcrum motion [52.15, 16]. In these systems, the **RCM** is positioned at the entry point, typically with an active Cartesian stage or a passive mechanical mechanism, and the robot sets the needle direction and (sometimes) the depth.

In order to speed up the sequence of imaging, planning, registration, and execution, one can exploit the robot's ability to work concurrently with imaging devices. This trend, again, began with intracranial applications. For extracranial use, *Stoianovici et al.* developed several variants of an **RCM**-based system deployed with X-ray fluoroscopy [52.15] and **CT** guidance [52.48, 49]. In [52.49], specialized fiducial structures have been incorporated in the needle driver to register the robot with a single image slice.

Magnetic resonance imaging (**MRI**) has an unmatched potential for guiding, monitoring, and controlling therapy, invoking intensive research on **MRI**-compatible robotic systems for needle placement [52.55] and for more complex interactive procedures [52.32].

Ultrasound (**US**) has many advantages for guiding needle placement and other interventional procedures. It is relatively inexpensive and compact, provides real-

time images, does not involve any ionizing radiation, and does not impose significant materials constraints on the robot design. Several robotic systems have been proposed for prostate interventions [52.56] using transrectal ultrasound guidance. There has also been some exploration of **US**-guided robotic systems for other (i.e., nonprostate) needle placement applications. Examples include experimental systems for liver [52.47, 57], gallbladder [52.58], and breast [52.59]. Figure 52.8d shows one example of the use of information overlay to assist in needle placement in a telesurgical application [52.47]. Whatever form of image feedback is available, steering flexible needles to hit desired targets while avoiding obstacles is a ubiquitous problem, having led to several novel approaches [52.60–62].

52.3.4 Telesurgical Systems

The concepts of telemedicine, telesurgery, and telepresence in surgery date from the 1970s. Since then, the potential for telesurgical systems to facilitate effective interventions in remote or hostile environments such as the battlefield, space, or thinly populated areas has continued to be recognized [52.63], and there have been some spectacular demonstrations including a transatlantic cholecystectomy [52.33] in 2001, as well as more nearly routine use in Canada [52.34].

However, the primary uses of telesurgical systems have been with the surgeon and patient in the same operating room. Teleoperated robots have been used for over 15 years in **MIS**, both as auxiliary surgical support systems to hold endoscopes or retractors [52.14, 16, 64, 65] and as *surgeon extender* systems to manipulate surgical instruments [52.2, 17]. There has also been recent work to develop telesurgical systems for use within imaging environments such as **MRI** [52.32].

A primary challenge for auxiliary support systems is to permit the surgeon to command the robot while his or her hands are otherwise occupied. Typical approaches have included conventional foot switches [52.14], instrument-mounted joysticks [52.16], voice control [52.7, 16], and computer vision [52.16, 66, 67].

A common goal in surgeon extender systems is to provide a measure of telepresence to the surgeon, specifically, to give the surgeon the sensation of performing open surgery from inside the patient. In early work, *Green et al.* [52.68] developed a successful prototype system for telesurgery combining remote manipulation, force feedback, stereoscopic imaging, ergonomic design, etc. Subsequently, several commercial telesurgical systems have been applied clinically for **MIS**. Of these,

Intuitive Surgical's daVinci [52.2] has been the most successful, with over 400 systems deployed as of 2007. Experience with these systems has demonstrated that a high-dexterity wrist is often critical for surgeon acceptance. Although originally targeted at cardiac surgery, as well as more general interventions, to date one of the most successful clinical applications has been in radical prostatectomies, where significant improvements in outcomes have been reported [52.69].

One emerging area for research exploits the inherent ability of telesurgical systems to act as *flight data recorders* during surgical procedures. Several authors [52.70–72] have begun analyzing such data for such purposes as measuring surgical skill, learning surgical gestures and motions, and providing data for surgical simulators.

52.3.5 Microsurgery Systems

Although *microsurgery* is not a consistently defined term, it generally indicates procedures performed on very small, delicate structures, such as those found in the eye, brain, spinal cord, small blood vessels, nerves, or the like. Microsurgical procedures are commonly performed under direct or video visualization, using some form of magnification (e.g., microscope, surgical loupes, high-magnification endoscope). The surgeon typically has little or no tactile appreciation of the forces being exerted by the surgical instruments and physiological hand tremor can be a significant factor limiting surgical performance.

There have been several efforts to compare microsurgical anastomosis procedures using laparoscopic telesurgical systems to conventional microsurgery. Schiff et al. [52.73] among others reported significant reductions in tremor with either robot and significantly improved technical quality and operative times compared to conventional microsurgery. A number of groups have implemented telesurgery systems specifically for microsurgery [52.27, 74–76]. These systems are in various stages of development, from laboratory prototype to preliminary clinical experimentation.

Not all microsurgical robots are teleoperated. For example, the cooperatively controlled JHU Steady Hand robots [52.3, 4] shown in Fig. 52.3 are being developed for retinal, head-and-neck, neurosurgery, and other microsurgical applications.. A modified version of this system has also been used for microinjections into single mouse embryos [52.77].

There have also been efforts to develop completely hand-held instruments that actively cancel physiolog-

ical tremor, for example, Riviere et al. [52.78] have developed an ophthalmic instrument using inertial sensors in the handle and adaptive filtering to estimate the tremulous component of instrument motion. A micromanipulator built into the instrument deflects the tip with an equal but opposite motion, compensating the tremor. Simple mechanical devices [52.79] for reducing tremor in specific tasks have also been developed.

An additional type of hand-held microsurgical and micro-therapeutic devices is reported in [52.80], which describes an active microendoscope for neuroendoscopy and therapy of the spinal cord able to safely navigate in the subarachnoid space and to avoid dangerous contact with the internal delicate structures thanks to a system based on hydrojets. Hydrojets come from the lateral surface of the catheter and, appropriately tuned and oriented, allow the tip of the endoscope to proceed without touching the spinal cord internal walls. The shared control system of the neuroendoscope, based on processing, segmentation, and analysis of the endoscopic images, assists the safe advancement of the tool in real time [52.81].

52.3.6 Endoluminal Robots

The term *endoluminal surgery* was first coined by Cuschieri et al. [52.82] as a major component of endoscopic surgery. Endoluminal procedures consist of bringing a set of advanced therapeutic and surgical tools to the area of interest by navigating in the lumina (i.e., the tube-like structures) of the human body, such as the gastrointestinal (GI) tract, the urinary tract, the circulatory system, etc. Currently, most endoluminal robots are designed for gastrointestinal applications, although there has been some initial work for other areas.

Traditionally, catheters and flexible endoscopes for endoluminal procedures have been inserted and manipulated manually from outside the body with the assistance of one or more visualization systems (e.g., direct endoscopic video, X-ray fluoroscopy, ultrasound). One major challenge is limited dexterity making it difficult to reach the desired target. Typically, flexible endoscopes have a bendable tip that can be steered by means of cable drives, and catheters may have only a fixed bend on a guide wire. There is also the inherent difficulty of *pushing a rope*. Once the target site is reached, these limitations become even more significant. Very simple instruments can be inserted through working channels or slid over guide wires, but dexterity is severely limited and there is no force feedback beyond what can be felt through the long, flexible instrument shaft.

These limitations have led a number of researchers to explore integration of more degrees of freedom in the catheter/endoscope body, as well as the design of intelligent tips with higher dexterity and sensing

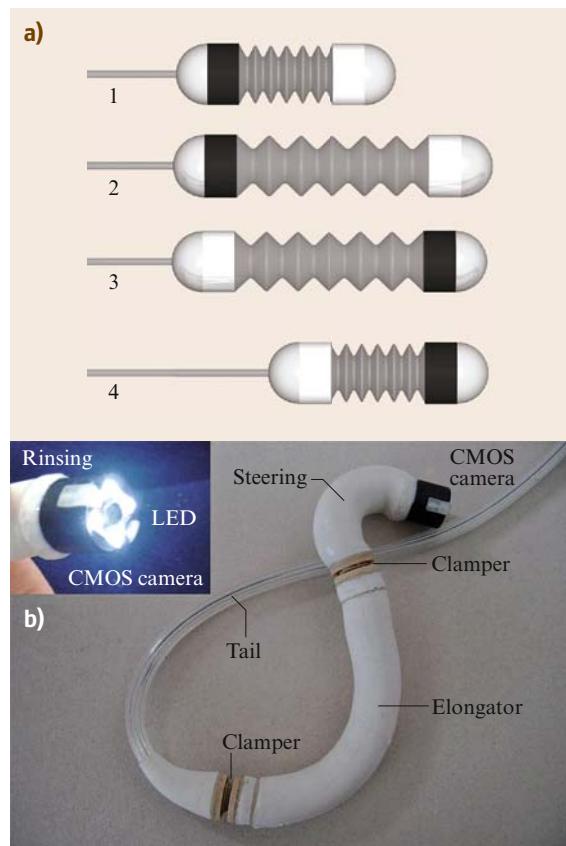

Fig. 52.10a,b Medical robot for colonoscopy [52.25]: (a) the gait cycle of the robot, consisting of: (1) proximal clamping, (2) elongation, (3) distal clamping, and (4) retraction; (b) a recent working prototype used for clinical trials

capabilities. Early work by Ikuta et al. led to the development of a five-segment, 13 mm-diameter sigmoidoscope using shape-memory alloy (**SMA**) actuators. Subsequently, Ikuta developed 3 mm-diameter active endovascular devices using hydraulic actuators incorporating a novel band pass valve fabricated using micro-stereolithographic techniques [52.21].

Several examples exist of instrumented catheter tips with force sensors that allow the right branch of the circulatory systems to be found by estimating the force generated between the tip and the vessel walls. Basically, these sensorized endoluminal devices belong to the larger group of micro-electromechanical systems (**MEMS**)-instrumented surgical devices and the same sensing technologies can be also exploited for micro-surgery. A recent survey article by *Rebello* [52.83] provides an excellent overview of sensorized catheters and other **MEMS**-based devices in endoluminal and microsurgical applications.

A third approach to endoluminal robots is represented by systems that move under their own power through the body, rather than being pushed. Early work on such systems is well summarized in [52.84]. In 1995 Burdick et al. developed an inchworm-like mechanism for use in the colon. This device combined a central extensor for propulsion and inflatable balloons for friction enhancement with the slippery colon tissue. A more advanced inchworm design for a semiautonomous robotic colonoscope was developed by *Dario* et al. [52.25] (Fig. 52.10). This device consists of a central silicone elongator, two clamping systems based on suction and gentle mechanical grasping of the colon tissue, and a silicone steerable tip integrating a complementary metal-oxide-semiconductor (CMOS) camera and a light-emitting diode (LED)-based illumination system. Thanks to its intrinsic flexibility, the robotic colonoscope applies forces on colon tissues that are ten times lower than those produced by traditional colonoscopes. More recent work on legged locomotion for GI applications Fig. 52.11c is reported in [52.20, 85]. Although the application is not endoluminal, the HeartLander system of *Riviere* et al. [52.23] shown in Figs. 52.11a,b shares many of the characteristics of these systems. It uses an inchworm-like gait to traverse the surface of the heart. Recently, Olympus has introduced a wireless gastrointestinal inspection system using external electromagnetic fields to manipulate a capsule camera [52.86]. An earlier application of electromagnetic manipulation of an object within the body was the *video tumor fighter* of *Ritter* et al. [52.87].

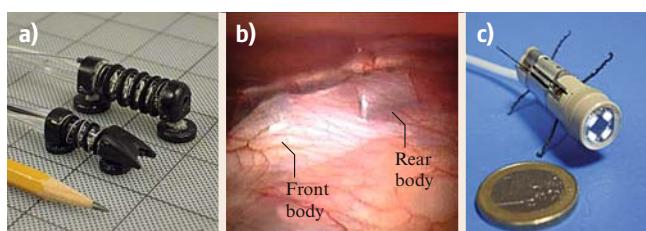

Fig. 52.11a–c Mobility inside the body. (a,b) *HeartLander* device for crawling across the surface of the heart [52.23]. (c) Legged capsule for gastrointestinal diagnosis and therapy [52.20]

52.3.7 Sensorized Instruments and Haptic Feedback

Surgical procedures almost always involve some form of physical interaction between surgical instruments and patient anatomy, and surgeons are accustomed to use their haptic appreciation of tool-to-tissue interaction forces in performing surgical procedures. In situations such as where the clumsiness of instrumentation or human sensory-motor limitations limit the surgeon's ability to feel these forces, surgeons have been trained to rely on visual or other cues to compensate. Apart from the need for haptic feedback for diagnostic procedures and tissue identification, it has been demonstrated that reduced tactile and force information can result in the application of unnecessarily large forces on the patient during surgery, with possible harm to the patient [52.88]. The quality of haptic feedback available in currently deployed surgical robots is poor or nonexistent. Current research addresses the limitations firstly by integrating force and other sensors into surgical end-effectors and secondly by developing improved methods for processing and conveying the sensed information to the surgeon.

Although the most obvious way to *display* haptic information in a telesurgical system is directly through the master hand controllers, this method has several limitations, including friction and limited bandwidth in the hand controllers. Although these issues may be addressed through specialized design (which may raise costs and require other compromises) and improved control, there has been considerable interest in *sensory substitution* schemes [52.89–91] in which force or other sensor information is displayed visually, aurally, or by other means. Figure 52.8c shows one example of sensory substitution for warning when a daVinci robot is about to break a suture [52.46].

Starting in the 1990s, several groups [52.91–93] have *sensorized* surgical instruments for microsurgery and MIS by equipping them with force sensors. Generally, these efforts relied on sensory substitution to display force data, either for freehand or telesurgical application. For example, Poulose et al. [52.92] demonstrated that a force sensing instrument used together with an IBM/JHU LARS robot [52.16] could significantly reduce both average retraction force and variability of retraction force during Nissen fundoplication. Rosen et al. [52.93] developed a force-controlled teleoperated endoscopic grasper equipped with position sensors and actuated by direct-current (DC) motors whose output torque is sensed and fed back through motors inte-

grated in a grasping handle. A similar approach was used by Menciassi et al. [52.94] for a microsurgery gripper equipped with semiconductor strain gauges and a PHANTOM (SensAble Technologies, Inc.) haptic interface.

Several researchers [52.95] have focused on specialized *fingers* and display devices for palpation tasks requiring delicate tactile feedback (e.g., for detecting hidden blood vessels or cancerous tissues beneath normal tissues). There has also been work to integrate nonhaptic sensors into surgical instruments, for example, Fischer et al. have developed instruments measuring both force and tissue oxygenation levels [52.96]. This information can be used for such purposes as assessing tissue viability, distinguishing between different tissue types, and controlling retraction so as not to cause ischemic tissue damage.

Finally, it is important to note that sensorized surgical tools have important application beyond their direct use in surgical procedures, for example, one use is in biomechanical studies to measure organ and tissue mechanical properties to improve surgical simulators.

52.3.8 Surgical Simulators and Telerobotic Systems for Training

Medical education is undergoing significant changes. The traditional paradigm for surgical technical training is often summarized as “see one, do one, teach one”. This method can be effective in open surgery, where the surgical trainee directly observes the expert surgeon hands, sees the instrument motion, and follows the organ manipulation. However, in endoscopic surgery it is difficult to observe the surgeon's hand movements (outside the body) and the surgical tool actions (inside the body and only visible on a video monitor). In addition, endoscopic surgery requires different skills than open surgery, such as spatial orientation, interpretation of 2-D images in 3-D, and manipulating instruments through entry portals. These considerations led to introduction of surgical simulation systems of varying degrees of complexity and realism for endoscopic and other minimally invasive procedures. Nowadays, training simulators have achieved widespread acceptance in the field of anaesthesia, intensive care, flexible endoscopy, surgery, interventional radiology, and other fields. The use of simulators for training is so common that working groups have been set up in order to evaluate these training systems based on shared guidelines [52.97] and many teaching hospitals have extensive simulation training centers.

A recent survey [52.98] divides training simulators into three groups, depending on the type of technology used: mechanical, hybrid, and virtual reality.

Mechanical simulators are boxes where objects or organs are placed and manipulated using surgical instruments. The manipulation is observed through a laparoscope and a screen. The simulated surgical task is observed by an experienced surgeon, who gives feedback to the trainee. Generally, there are no registration processes and the simulator must be reassembled after any training session. The *LapTrainer with SimuVision* (Simulab Inc., Seattle, USA) is a training system with a simulated laparoscope that consists of a boom-mounted digital camera in an open box trainer. The Johns Hopkins Urobotics has also developed mechanical simulators and a set of experiments for training in laparoscopy, which is also able to provide a quantifiable scale of dexterity.

A hybrid simulator uses a box with objects or organs as a mechanical simulator, but in addition the performance of the trainee are monitored by a computer which gives guidance for the task execution and an objective feedback based on preplanned metrics. Thanks to this feedback, the assistance and judgement of an experienced surgeon are not strictly necessary, for example, the ProMIS (Haptica Inc., Boston, USA) is a typical hybrid simulator for training basic skills such as suturing and knot tying. Surgical instruments are passed through dedicated ports and the trainee receives the same haptic feedback as in real surgery during manipulation in the box. In addition, ProMIS analyzes the trainee's performance by tracking the instrument position in 3-D and by measuring the execution time, path length, and smoothness of task execution.

Finally, *virtual-reality* training systems combine visualization and haptic interfaces to enable surgeons to interact efficiently and naturally with real-time computational models of patient anatomy [52.99]. The development of these systems is inherently a multidisciplinary effort, including real-time computer graphics, the development of high-bandwidth haptic devices, real-time biomechanical modeling of organs, tool-tissue interactions, expertise in training assessment, and human-machine information exchange, etc. [52.100]. Research in these areas is closely related to and synergistic with comparable developments in technology and systems for performing real interventions, for example, modeling of organ motion in response to forces is necessary to improve the accuracy of needle placement procedures. Haptic feedback devices must meet similar requirements whether the forces displayed are simulated

or measured directly in telesurgery, and so on. Finally, as noted earlier, *sensorized* instruments and real-time imaging are critical sources of data needed to create realistic biomechanical models.

The variety of interface devices and virtual reality laparoscopic simulators is quite wide and increasing numbers of systems are becoming commercially available. The Phantom interface is used in conjunction with virtual simulators to provide users with realistic haptic feedback (SensAble Technologies Inc., Woburn, MA, USA). The Xitact LS500 laparoscopy simulator (Xitact S.A., Lausanne, Switzerland) is a modular virtual-reality simulation platform with software for training and assessing performance in laparoscopic tasks. It is an open system including all or some of these subsystems: laparoscopic tools, mechanical abdomen, a personal computer (**PC**) providing the virtual-reality scenario, a haptic interface, a force feedback system and a tracking system for the tools. Several other systems for virtual reality simulation exist that exploit the hardware from Xitact or Immersion Medical, Inc. (Gaithersburg, MD, USA) and that are dedicated to specific surgical tasks: Lapmentor [52.101], the Surgical Education platform [52.102], LapSim [52.103], Procedicus MIST [52.104], EndoTower [52.105], the Reachin laparoscopic trainer [52.106], Simendo [52.107], and the Vest system [52.108]. Specifically for training eye surgeons, the surgical simulator EYESi [52.109] uses advanced computer technology and virtual reality to simulate the feel of real eye surgery, making it possible for surgeons at all levels to acquire new skills and perfect their techniques in preparation for surgery on the human eye.

Making a comparison between these different categories of simulators is not trivial. Basically, box trainers and hybrid simulators require some experienced technicians for the set up and some organizational logistics due to legal and ethical factors related to the storage of freshly explanted organs. The most evident advantage of these simulators is that the tactile response from the manipulated objects is the same as in real surgery and complicated models of organs and tissue-tool interaction are not required. On the other hand, completely virtual-reality trainers are potentially very flexible, but they are limited by currently available computer and graphics hardware capabilities, as well as by the quality of current-generation anatomical and biomechanical models. Although demonstrations exist of the ability of simulators to record, objectively score, and hone the psychomotor skills of novice surgeons [52.110], the debate about the real improvement of surgical abilities is still open and conclusions are sometimes controversial.

52.3.9 Other Applications and Research Areas

The research areas described above illustrate major themes within medical robotics, but they are by no means

exhaustive. Many important application areas such as otolaryngology [52.111–114] and radiation therapy have necessarily been excluded for space reasons. For a fuller exploration, readers should consult the further reading suggestions in Sect. 52.4.

52.4 Conclusion and Future Directions

Medical robotics (and the larger field of *computer-integrated interventional medicine*) has great potential to revolutionize clinical practice by:

- exploiting technology to transcend human limitations in treating patients
- improving the safety, consistency, and overall quality of interventions
- improving the efficiency and cost-effectiveness of patient care
- improving training through the use of simulators, quantitative data capture and skill assessment methods, and the capture and playback of clinical cases
- promoting more effective use of information at all levels, both in treating individual patients and in improving treatment processes

From being the stuff of late-night comedy and science fiction 20 years ago, the field has reached a critical threshold, with clinically useful systems and commercial successes. The scope and number of research programs has grown exponentially in the past 5 years, and this chapter is by no means a comprehensive survey of the field. Interested readers are urged to refer to the further reading section for more complete treatments. In particular, the survey articles in listed at the end of this section collectively contain somewhat fuller bibliographies than space permits here.

In the future, we can expect to see continued research in all aspects of technology and system development, with increasing emphasis on clinical applications. As this work proceeds, it is important that researchers remember several basic principles. The first, and arguably most important, principle is that medical robotics is fundamentally a *team* activity, involving academic researchers, clinicians, and industry. Each of these groups has unique expertise, and success comes from effective, highly interactive partnerships drawing upon this expertise. Building these teams takes a long-term commitment, and the successes in recent years are largely the pay-off from investments in creating these teams.

Second, it is important to work on problems with well-defined clinical and technical goals, in which the criteria for measuring success are ultimately related to real advantages in treating patients. In working toward these goals, it is important to have measurable and meaningful milestones and to emphasize rapid iteration with clinician involvement at all stages. Finally, it is essential that all team members recognize the level of commitment that is required to achieve success and that they enjoy what they are doing.

53. Rehabilitation and Health Care Robotics

Rehabilitation

H.F. Machiel Van der Loos, David J. Reinkensmeyer

The field of rehabilitation robotics develops robotic systems that assist persons who have a disability with necessary activities, or that provide therapy for persons seeking to improve physical or cognitive function. This chapter will discuss both of these domains and provide descriptions of the major achievements of the field over its short history. Specifically, after providing background information on world demographics (Sect. 53.1.2) and the history (Sect. 53.1.3) of the field, Sect. 53.2 describes physical therapy and training robots, and Sect. 53.3 describes robotic aids for people with disabilities. Section 53.4 then briefly discusses recent advances in smart prostheses and orthoses that are related to rehabilitation robotics. Finally, Sect. 53.5 provides an overview of recent work in diagnosis and monitoring for rehabilitation as well as other health-care issues. At the conclusion of this chapter, the reader will be familiar with the history of rehabilitation robotics and its primary accomplishments, and will understand the challenges the field faces in the future as it seeks to improve health care and the well-being of persons with disabilities. In this chapter, we will describe an application of robotics that may in the future touch many of us in an acutely personal way.

53.1 Overview

When we become unable to interact physically with our immediate environment as we desire in order to achieve our personal goals through injury or disease, or

when one of our family members, friends or neighbors is in this situation, we seek technology-based solutions to assist us in relearning how to complete our activi-

ties of daily living ([ADLs](#)), or to assist us in actually doing them if we are unable to relearn. While human therapists and attendants can indeed provide the types of assistance required, the projected short-term demographics of China, Japan, and the Scandinavian countries show a growing shortage of working-age adults. Age-related disabilities will soon dominate the service sector job market, put many older and disabled people at risk, and increase the need for institutionalization when there is no viable home-based solution. National programs to develop personal robots, robotic therapy, smart prostheses, smart beds, smart homes, and tele-rehabilitation services have accelerated in the past ten years and will need to continue apace with the ever-increasing ability of health care to allow people to live longer through the repression of disease and improvements in surgical and medication interventions. Rehabilitation robotics, although only a 40-year-old discipline [53.1–3], is projected to grow quickly in the coming decades.

53.1.1 Taxonomy of Rehabilitation Robotics

The field of rehabilitation robotics is generally divided into the categories of *therapy* and *assistance robots*. In addition, rehabilitation robotics includes aspects of artificial limb (prosthetics) development, functional neural stimulation, ([FNS](#)) and technology for the diagnosis and monitoring of people during [ADLs](#).

Therapy robots generally have at least two main users simultaneously, the person with a disability who is receiving the therapy and the therapist who sets up and monitors the interaction with the robot. Types of therapy that have benefited from robotic assistance are upper- and lower-extremity movement therapy, enabling communication for children with autism, and enabling exploration (education) for children with cerebral palsy ([CP](#)) or other developmental disabilities. A robot may be a good alternative to a physical or occupational therapist for the actual hands-on intervention for several reasons: (1) once properly set up, an automated exercise machine can consistently apply therapy over long periods of time without tiring; (2) the robot's sensors can measure the work performed by the patient and quantify, to an extent perhaps not yet measurable by clinical scales, any recovery of function that may have occurred, which may be highly motivating for a person to continue with the therapy; and (3) the robot may be able to engage the patient in types of therapy exercises that a therapist cannot do, such as magnifying movement errors to provoke adaptation [53.4, 5].

Assistive robots are generally grouped according to whether they focus on manipulation, mobility, or cognition. Manipulation aids are further classified into fixed-platform, portable-platform, and mobile autonomous types. Fixed-platform robots perform functions in the kitchen, on the desktop, or by the bed. Portable types are manipulator arms attached to an electric wheelchair to hold and move objects and to interact with other devices and equipment, as in opening a door. Mobile autonomous robots can be controlled by voice or other means to carry out manipulation and other errands in the home or workplace. Mobility aids are divided into electric wheelchairs with navigation systems and mobile robots that act as smart, motorized walkers, allowing people with mobility impairments to lean on them to prevent falls and provide stability. The third main type, cognitive aids, assist people who have dementia, autism or other disorders that affect communication and physical well-being.

The fields of prosthetics and [FNS](#) are closely allied with rehabilitation robotics. Prostheses are artificial hands, arms, legs, and feet that are worn by the user to replace amputated limbs. Prostheses are increasingly incorporating robotic features. [FNS](#) systems seek to reanimate the limb movements of weak or paralyzed people by electrically stimulating nerve and muscle. [FNS](#) control systems are analogous to robotic control systems, except that the actuators being controlled are human muscles. Another related field is technology for monitoring and diagnosing health care issues as a person performs [ADLs](#).

The chapter is organized according to this taxonomy. After providing background information on world demographics (Sect. 53.1.2) and the history (Sect. 53.1.3) of the field, Sect. 53.2 describes physical therapy and training robots, and Sect. 53.3 describes robotic aids for people with disabilities. Section 53.4 then reviews recent advances in smart prostheses and orthoses that are related to rehabilitation robotics. Finally, Sect. 53.5 provides an overview of recent work in diagnosis and monitoring for rehabilitation as well as other health care issues.

53.1.2 World Demographics

The various areas of rehabilitation robotics focus on different user populations, but a common characteristic of these populations is that they have a disability. Disability is defined in the *Americans with Disabilities Act* as “a physical or mental impairment that substantially limits one or more of the major life activities.”

Table 53.1 Prevalence and incidence of disability and aging in selected countries [53.6]

| Country | Number of people with disabilities | Percentage of population with disabilities | Number of elderly people | Percentage of population that is elderly |
|-----------------|------------------------------------|--------------------------------------------|--------------------------|------------------------------------------|
| France | 5 146 000 | 8.3 | 12 151 000 | 19.6 |
| USA | 52 591 000 | 20.0 | 35 000 000 | 12.4 |
| Great Britain | 4 453 000 | 7.3 | 12 200 000 | 29.5 |
| The Netherlands | 1 432 000 | 9.5 | 2 118 808 | 13.4 |
| Spain | 3 528 220 | 8.9 | 6 936 000 | 17.6 |
| Japan | 5 136 000 | 4.3 | 44 982 000 | 35.7 |
| Korea | 3 195 000 | 7.1 | 16 300 000 | 36.0 |

In the industrialized countries (e.g., Japan, US, Canada, and Europe), the incidence of disability varies between 8% and 20%, with differences likely due primarily to varying definitions of disability and reporting conventions (Table 53.1). Age is a risk factor for disability, and lower birth rates and life-extending health care are the dominant factors contributing to the aging of the population and a concomitant rise in disability. In China, the population control policies of the 1970s have created a lack of working-age adults to support the economy. The disproportionate incidence of disability in the elderly population makes it clear that developers of rehabilitation robotics will also be faced with users who, as a demographic group, generally have lower levels of sensory and motor capability, and may have impaired cognition as well. The urgency of making advances in this field is increasing in line with these demographic changes.

53.1.3 Short History of the Field of Rehabilitation Robotics

The history of rehabilitation robotics is almost as old as that of robotics itself, although emanating from very different sources. Several books, chapters, and papers have been written on the history of rehabilitation robotics in more detail than this section [53.1, 7, 8], and numerous papers in the proceedings of the Institute of Electrical and Electronics Engineers (IEEE) International Conference on Rehabilitation Robotics also provide more grounding for historical perspective. The chronology below pays particular attention to early work and to projects with notable clinical and/or commercial impact.

Early robotics, starting in the late 1950s, focused on large manipulators to replace workers in factories for dirty, dangerous, and undesirable tasks. The earliest rehabilitation robots came from the field of prosthetics and orthotics (P&O). The Case Western University arm (1960s) and the Rancho Los Amigos *Golden Arm*

(early 1970s) (reviewed in [53.7]) were both adaptations of replacement mechanical arms meant as powered orthoses [53.1]. The user drove the Golden Arm with a set of tongue-operated switches, joint-by-joint, an arduous means of endpoint control. In the mid 1970s, the Department of Veterans Affairs began funding a group at the Applied Physics Lab under the guidance of Seamone and Schmeisser to computerize an orthosis mounted on a workstation to do activities of daily living (ADL) tasks such as feeding a person and turning pages [53.9]. For the first time, a rehabilitation robot had a command-type interface, not just a joint-by-joint motion controller.

The 1970s also saw the French Spartacus system being developed, guided by the vision of Jean Vertut, for use by people with high-level spinal cord injury as well as children with cerebral palsy [53.10]. This system did not emerge from the P&O field but was developed by the French Atomic Energy Commission (CEA), which used large telemanipulators for nuclear fuel rod handling. One of these was adapted so that people with movement impairment could control it using a joystick for pick-and-place tasks. A decade later, one of the researchers on the Spartacus project, Hok Kwee, began the MANUS project, a dedicated effort to develop the first wheelchair-mounted manipulator designed expressly as a rehabilitation robot, not adapted from a design from another field.

However, in between, several other major programs were begun. In 1978, at Stanford University, and then with decades-long funding from the US Department of Veterans Affairs, Larry Leifer started the vocational assistant robot program, culminating in several clinically tested versions of the desktop vocational assistant robot (*DeVAR*) [53.3, 11, 12], a mobile version, the mobile vocational assistant robot (*MoVAR*) [53.13], and finally the professional vocational assistant robot (*ProVAR*), which had the advanced ability for the user to program tasks in an easy-to-use browser-type environment [53.14]. This step was made since, although *DeVAR* made it briefly

onto the market in the early 1990s, multisite user testing revealed it was still too costly for the functionality it had: ProVAR development ensued, then continued by Machiel Van der Loos. All these versions were based on the Puma-260 industrial manipulator to achieve robust, safe operation. Research shifted in 2006 to the Veterans Affairs (VA) in Syracuse, NY, to integrate sensing and autonomous features and explore new, more cost-effective manipulator options.

In the mid 1980s, from observations on the unsuitability of existing industrial, educational, and orthosis-derived manipulators for rehabilitation applications, Tim Jones at Universal Machine Intelligence (later Oxford Intelligent Machines, OxIM) in the UK began an intensive effort to provide the rehabilitation robotics community with its first workhorse system specifically designed from the ground up for human service tasks. Over ten years, a series of systems, starting with the RTX model, were used in numerous research labs and clinics around the world. The most extensive effort to use the OxIM arm was in France, and a suite of research projects, funded by the French government and the European Research Commission, starting as the robot for assisting the integration of the disabled (RAID), then as MASTER [53.15], developed and clinically tested workstation-based assistive systems based on the RTX and subsequent OxIM arms. When OxIM ceased building its arms, the French company Afma Robotics [53.16] took over efforts to commercialize the MASTER system, which it continues to do today (2007).

The UK was also the site of the first commercially available feeding robot, Handy-I, an inexpensive and well-received device first designed by Mike Topping and then commercialized by Rehabilitation Robotics, Ltd. in the 1990s [53.17]. Primarily aimed to enable people with cerebral palsy to achieve a measure of independence in feeding themselves, task environments later also included face washing and the application of cosmetics, areas of high demand identified by its users.

The history of mobile manipulator applications began in the 1980s with adaptations of educational and industrial robots, and achieved a boost with the funding of the US National Institute on Disability and Rehabilitation Research (NIDRR) for a Rehabilitation Engineering Research Center on Rehabilitation Robotics (RERC) at the Alfred I. duPont Hospital in Delaware from 1993–1997. With its ability to fund dozens of research projects in parallel, it also formed a partnership with a local company, Applied Resources, Corp. (ARC), which developed and marketed several rehabilitation technology products. One of the RERC researchers,

Rich Mahoney, moved to ARC and was instrumental in extending the company's repertoire to the RAPTOR wheelchair-mounted arm [53.18].

In Europe, the most significant mobile manipulator project was the MANUS project [53.19] mentioned earlier. With much of the work done under the direction of Hok Kwee at the Rehabilitation Research and Development Center (iRV) in the Netherlands, the project culminated in a robot specifically designed for wheelchair mounting, with control through a joystick and feedback by a small display on the arm itself. This project has led to numerous follow-on research projects, and, most significantly, to the commercialization of the system by Exact Dynamics BV, in the Netherlands. It is currently offered free on physician prescription by the Dutch government to qualified people with a disability such as cerebral palsy or tetraplegia from a spinal cord injury.

Autonomous navigation systems on electric wheelchairs also began in the 1980s, benefiting initially from the development by Polaroid Corporation of range finders for its cameras using ultrasonic sensors. They were inexpensive, and small enough, at 30 mm in diameter, that dozens of them could be placed around the periphery of a wheelchair to aid medium-range navigation ($\approx 10\text{--}500\text{ cm}$). In the 1990s and early 2000s, with the advent of vision-based servoing and laser range scanners, algorithms for faster, smarter, less-error-prone navigation and obstacle avoidance dominated research advances in this sector. In Korea, for example, *Zenn Bien* at the Korea Advanced Institute for Science and Technology (KAIST) Human Welfare Robotics Center began developing the KAIST rehabilitation engineering system (KARES) line of wheelchair-based navigation systems in the late 1990s [53.20] and the NavChair project at the University of Michigan was the start of a development line that led to the commercialized Hephaestus system at the University of Pittsburgh [53.21, 22].

Therapy robots had a later start than assistive robots, with early exercise devices such as the BioDex [53.23] a first step in programmable, force-controlled, albeit single-axis devices, in the mid 1980s. The first multi-axis concept was published by Khalili and Zomlefer [53.24], and the first tested system by Robert Erlandson at Wayne State University emerged in the mid 1980s as well [53.25]. The RTX manipulator had a touch-sensitive pad as an end-effector, presenting targets at different locations for patients with upper-extremity weakness (e.g., following a stroke) to hit after the screen gave a visual signal. Software logged response times, thereby providing a score that was tallied and

compared to previous sessions. Later robots used advanced force-based control, which required significantly more computer power. The early 1990s saw the start of the MIT-MANUS Project with Neville Hogan and Igo Krebs, followed a few years later by the Palo Alto VA mirror image movement enabler (MIME) project and its derivative, Driver's simulation environment for arm therapy (SEAT), with Charles Burgar, Machiel Van der Loos, and Peter Lum, as well as the Rehabilitation Institute of Chicago ARM project with Zev Rymer and David Reinkensmeyer. Each had a different philosophy on upper-extremity stroke therapy and each was able to demonstrate clinical effectiveness in a different way. All three programs, now a decade later, have made significant technical advances and are still active.

Cognitive robotics had a start in the early 1980s to aid children with communication disorders and physical disorders to achieve a measure of control of their physical space. Using mostly educational manipulators,

several demonstration systems were developed. In the early 2000s, Corinna Latham of Anthrotronix, Inc. commercialized small robot systems to enable children with physical disabilities to play games with simple interfaces. Later, small mobile robots were used in clinics by *Kerstin Dautenhahn*'s group [53.26] with children who have autism; since robots have such simple interfaces, communication with them does not appear to be as challenging as with other humans. The early 2000s also saw the advent of pet robots, such as the Paro seal robot developed by *Shibata* et al. [53.27], as companions for both children and the elderly who are confined to clinics and have limited real companionship.

The applications for robotics continue to increase in number as advances in materials, control software, higher robustness and the diminishing size of sensors and actuators allow designers to attempt new ways of using mechatronics technology to further the well-being of people with disabilities.

53.2 Physical Therapy and Training Robots

53.2.1 Grand Challenges and Roadblocks

The human neuromuscular system exhibits use-dependent plasticity, which is to say that use alters the properties of neurons and muscles, including the pattern of their connectivity, and thus their function [53.28–30]. The process of neuro-rehabilitation seeks to exploit this use-dependent plasticity in order to help people re-learn how to move following neuromuscular injuries or diseases. Neuro-rehabilitation is typically provided by skilled therapists, including physical, occupational and speech therapists. This process is time-consuming, involving daily, intensive movement practice over many weeks. It is also labor-intensive, requiring hands-on assistance from therapists. For some tasks, such as teaching a person with poor balance and weak legs to walk, this hands-on assistance requires that the therapist have substantial strength and agility.

Because neuro-rehabilitation is time- and labor-intensive, in recent years health care payers have put limits on the amount of therapy that they will pay for, in an effort to contain spiraling health care costs. Ironically, at the same time, there has been increasing scientific evidence that more therapy can in some cases increase movement recovery via use-dependent plasticity. As robotics and rehabilitation researchers began to recog-

nize beginning in the late 1980s, neuro-rehabilitation is a logical target for automation because of its labor-intensive, mechanical nature, and because the amount of recovery is linked with the amount of repetition. Robots could deliver at least the repetitive parts of movement therapy at lower cost than human therapists, allowing patients to receive more therapy.

The grand challenge for automating movement therapy is determining how to optimize use-dependent plasticity. That is, researchers in this field must determine what the robot should do in cooperation with the patient's own movement attempts in order to maximally improve movement ability. Meeting this challenge involves solving two key problems: determining appropriate movement tasks (what movements should patients practise and what feedback should they receive about their performance), and determining an appropriate pattern of mechanical input to the patient during these movement tasks (what forces should the robot apply to the patient's limb to provoke plasticity). The prescription of movement tasks and mechanical input fundamentally constrains the mechanical and control design of the robotic therapy device.

There are two main roadblocks to achieving the grand challenge. The first is a scientific roadblock: neither the optimal movement tasks nor the optimal

mechanical inputs are known. The scientific basis for neuro-rehabilitation remains ill-defined, with competing schools of thought. The number of large, randomized, controlled trials that have rigorously compared different therapy techniques is still small, in part because these trials are expensive and difficult to control well. Therefore, the first problem that a robotics engineer will encounter when setting out to build a robotic therapy device is that there is still substantial uncertainty as to what exactly the device should do.

This uncertainty corresponds to an opportunity to use robotic therapy devices as scientific tools themselves. Robotic therapy devices have the potential to help identify what exactly provokes plasticity during movement rehabilitation, because they can provide well-controlled patterns of therapy. They can also simultaneously measure the results of that therapy. Better control over therapy delivery and improved quantitative assessment of patient improvement are two desirable features for clinical trials that have often been lacking in the past. Recent work with robotic movement training devices is leading, for example, to the characterization of computations that underlie motor adaptation, and then to strategies for enhancing adaptation based on optimization approaches [53.5, 31].

The second roadblock is a technological one: robotic therapy devices often have as their goal to assist in therapy of many body degrees of freedom (e.g., the arms and torso for reaching, or the pelvis and legs for walking). The devices also require a wide dynamic bandwidth such that they can, for example, impose a desired movement on a patient who is paralyzed, but also *fade-to-nothing* as the patient recovers. Furthermore, making the devices light enough to be wearable is desirable, so that the patient can participate in rehabilitation in a natural setting (for example, by walking over ground or working at a counter in a kitchen), or even throughout the course of normal activities of daily living. The development of high-degree-of-freedom, wearable, high-bandwidth robotic exoskeletons is an unsolved problem in robotics. No device at present comes close to matching the flexibility of a human therapist, in terms of assisting in moving different body degrees of freedom in a variety of settings (e.g., walking, reaching, grasping, neck movement), or the intelligence of a human therapist, in terms of providing different forms of mechanical input (e.g., stretching, assisting, resisting, perturbing) based on a real-time assessment of the patient's response. Meeting the grand challenge of robotic therapy therefore will require substantial, interrelated advances in both clinical neuroscience and robot engineering.

53.2.2 Movement Therapy after Neurologic Injury

At present, much of the activity in physical therapy and training robots has been focused on retraining movement ability for individuals who have had a stroke or spinal cord injury (SCI). The main reasons for this emphasis are that there are a relatively large number of patients with these conditions, the rehabilitation costs associated with them are high, and because these patients can sometimes experience large gains with intensive rehabilitation because of use-dependent plasticity. Some systems have also been targeted at assisting in cognitive rehabilitation of persons with neurologic injury, as reviewed below.

A stroke refers to an obstruction or breakage of a blood vessel supplying oxygen and nutrients to the brain. Approximately 800 000 people suffer a stroke each year in the USA alone, and about 80% of these people experience acute movement deficits [53.32]. There are over 3 000 000 survivors of stroke in the USA, with over half of these individuals experiencing persistent, disabling, movement impairments. The number of people who have experienced and survived a stroke is expected to increase substantially in the USA and other industrialized countries in the next two decades, because age is a risk factor for stroke and the mean age of people in industrialized countries is rapidly increasing due to the baby boom of the 1950s.

Common motor impairments that result from stroke are hemiparesis, which refers to weakness on one side of the body; abnormal tone, which refers to an increase in the felt resistance to passive movement a limb; impaired coordination, which can manifest itself as an apparent loss in control degrees of freedom and decreased smoothness of movement; and impaired somatosensation, which refers to a decreased ability to sense the movement of body parts. Secondary impairments include muscle atrophy and disuse-related shortening and stiffening of soft tissue, resulting in decreased passive range of motion of joints. Often the ability to open the hand, and to a slightly lesser extent close the hand, is dramatically decreased.

The number of people who experience a SCI in the USA each year is relatively smaller – about 15 000, with about 200 000 people alive who have survived a SCI – but the consequences can be even more costly than stroke [53.32]. The most common causes of SCI are automobile accidents and falls. These accidents crush the spinal column and contuse the spinal cord, damaging or destroying neurons within the spinal cord. The resulting pattern of movement impairment depends strongly on

the vertebrae at which the spinal cord is injured, since nerves branch out to the head, arms, legs, and bladder and bowel at different vertebrae. About 50% of spinal cord injuries are incomplete, meaning that some sensation or motor function is preserved below the level of the injury. Spinal cord injuries are commonly bilateral and thus are often more functionally devastating in comparison to strokes, which at least leave a person with one side of their body that is relatively normal (which we will refer to as the *less impaired* side). Individuals experience especially severe disability if the lesion is high enough to involve the arms as well as the legs.

53.2.3 Robotic Therapy for the Upper Extremity

The following sections describe the best-known clinically tested upper-limb therapy robot systems that have been developed since the 1980s (Fig. 53.1).

MIT-MANUS

The first robotic therapy device to undergo extensive clinical testing, and now to achieve some commercial success, is the MIT-MANUS, sold as the InMotion2 by Interactive Motion, Inc. [53.33]. MIT-MANUS is a planar two-joint arm that makes use of the selective compliant assembly robot arm (**SCARA**) configuration, allowing two large, mechanically grounded motors to drive a lightweight linkage. The patient sits across from the device, with the weaker hand attached to the end-effector, and the arm supported on a table with a low-friction support. By virtue of the use of the **SCARA** configuration, the MIT-MANUS is perhaps the simplest possible mechanical design that allows planar movements while also allowing a large range of forces to be applied to the arm without requiring force feedback control.

MIT-MANUS assists the patient in moving the arm across the tabletop as the patient plays simple video

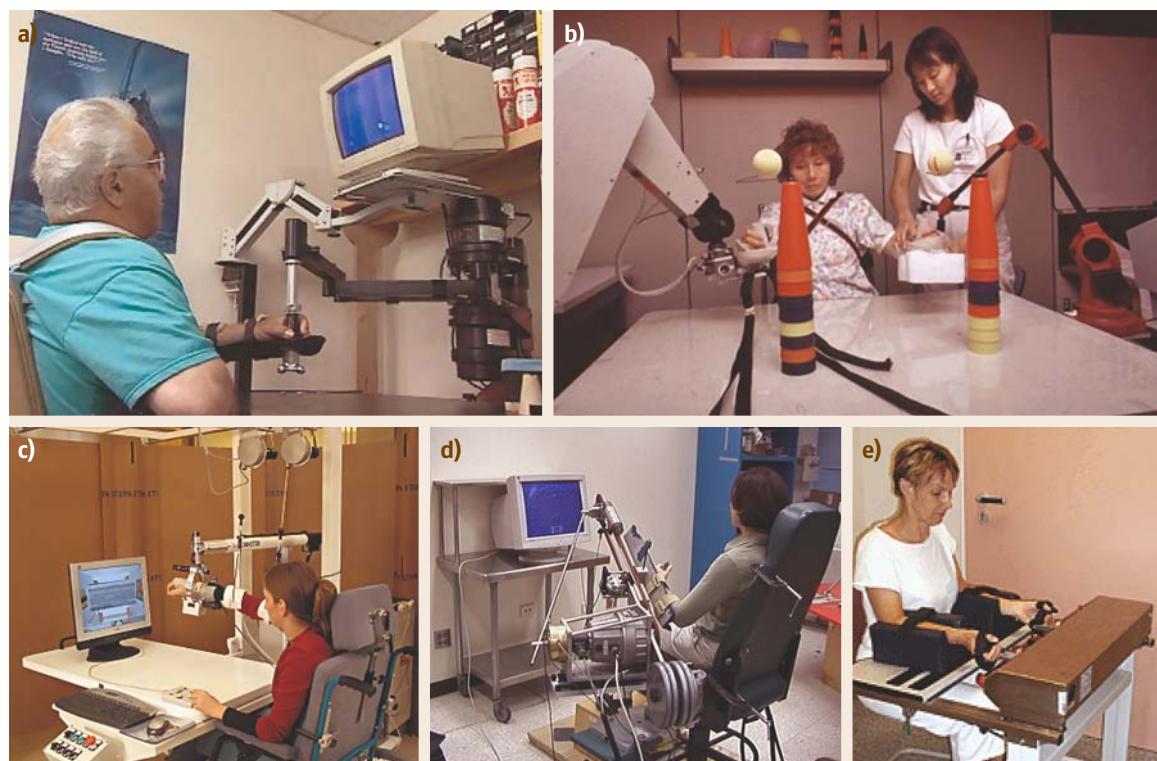

Fig. 53.1a–e Arm-therapy robotic systems that have undergone extensive clinical testing; (a) MIT-MANUS, developed by Hogan, Krebs, and colleagues at the Massachusetts Institute of Technology (USA); (b) MIME, developed at the Department of Veterans Affairs in Palo Alto in collaboration with Stanford University (USA); (c) GENTLE/s developed in the EU, (d) ARM-Guide, developed at the Rehabilitation Institute of Chicago and the University of California, Irvine (USA), and (e) Bi-Manu-Track, developed by Reha-Stim (Germany)

games, such as moving a cursor into a target that changes locations on a computer screen. Assistance is achieved using a position controller with an adjustable impedance. Additional modules have been developed for the device for allowing vertical motion [53.34], wrist motion [53.35], and hand grasp [53.36]. Software has been developed for providing graded resistance as well as assistance to movement [53.37], and for varying the firmness and timing of assistance based on real-time measurements of the patient's performance on the video games [53.38].

MIT-MANUS has undergone extensive clinical testing in several studies, summarized as follows. The first clinical test of the device compared the motor recovery of acute stroke patients who received an additional dose of robot therapy on top of their conventional therapy, to that of a control group, who received conventional therapy and a brief, sham exposure to the robot [53.39]. The robot group patients received the additional robotic therapy for an hour each day, five days per week, for several weeks. The robot group recovered more arm movement ability than the control group according to clinical scales, without any increase in adverse effects such as shoulder pain. The improvements might subjectively be characterized as *small but somewhat meaningful to the patient*. The improvements were sustained at three-year follow-up.

This first study with MIT-MANUS demonstrated that acute stroke patients who received more therapy recover better, and that this extra therapy can be delivered by a robotic device. It did not answer the question as to whether the robotic features of the robotic device were necessary. In other words, it may have been that patients would have also improved their movement ability if they had practised additional movements with MIT-MANUS with the motors off (thus making it equivalent to a computer mouse), simply by virtue of the increased dose of movement practice stimulating use-dependent plasticity. Thus, while this study indicated the promise of robots for rehabilitation therapy, it did not close the gap of knowledge as to how external mechanical forces provoke use-dependent plasticity.

Subsequent studies with MIT-MANUS confirmed that robotic therapy can also benefit chronic stroke patients [53.40]. The device has been used to compare two different types of therapy – assisting movement versus resisting movement – in chronic stroke subjects, but with inconclusive results: both types of therapy produced benefits [53.37]. The device has also been used to compare assistive robot therapy with another technological approach to rehabilitation – electrical stimulation of

finger and wrist muscles [53.41]. Again, significant benefits were found for both therapies, and those benefits were specific to the movements practised, but the benefits were not significantly different between therapies. We note that the lack of a significant difference in these studies may simply be due to the limited number of patients who participated in these studies (i.e., inadequate study power), rather than a close similarity of the effectiveness of the therapies.

MIME

Several other systems have undergone clinical testing. The mirror image movement enhancer (MIME) system uses a Puma-560 robot arm to assist in movement of the patient's arm [53.42]. The device is attached to the hand through a customized splint and a connector that is designed to break away if interaction forces become too large. Compared to MIT-MANUS, the device allows more naturalistic motion of the arm because of its six degrees of freedom (DOFs), but must rely on force feedback so that the patient can drive the robot arm. Four control modes were developed for MIME. In the passive mode, the patient relaxes and the robot moves the arm through a desired pattern. In the active assist mode, the patient initiates a reach toward a target, indicated by physical cones on a table top, which then triggers a smooth movement of the robot toward the target. In the active constrained mode, the device acts as a sort of virtual ratchet, allowing movement toward the target, but preventing the patient from moving away from the target. Finally, in mirror-image mode, the motion of the patient's less impaired arm is measured with a digitizing linkage, and the impaired arm is controlled to follow along in a mirror-symmetric path. The initial clinical test of MIME found that chronic stroke patients who received therapy with the device improved their movement ability about as much as patients who received conventional tabletop exercises with an occupational therapist [53.42]. The robot group even surpassed the gains from human-delivered therapy for the outcome measures of reaching range of motion and strength at key joints of the arm. A follow-on study is being undertaken to elucidate which of the control modes or what combination of MIME exercises caused the gains [53.43].

ARM Guide

The question of the effect of robot forces on movement recovery was also left unresolved by a study with another device, the ARM guide. The ARM guide is a trombone-like device that can be oriented then locked

in different directions and assist in reaching in a straight line. Chronic stroke patients who received assistance during reaching with the robot improved their movement ability [53.44]. However, they improved about as much as a control group that simply practised a matched number of reaches without assistance from the robot. This suggests that movement effort by the patient is a key factor for recovery, although the small sample size of this study limited its ability to resolve the size of the difference between guided and unguided therapy.

Bi-Manu-Track

Perhaps the most striking clinical results generated so far have come from one of the simplest devices built. Similar to a design proposed previously [53.45], the Bi-Manu-Track uses two motors, one for each hand, to allow bimanual wrist–flexion extension [53.46]. The device can also assist in forearm pronation/supination if it is tilted downward and the handles are changed. In an extensive clinical test of the device, 22 subacute patients (i.e., 4–6 weeks after stroke) practised 800 movements with the device for 20 min per day, five days per week for six weeks [53.46]. For half of the movements, the device drove both arms, and for the other half, the patient's stronger arm drove the motion of the more-impaired arm. A control group received a matched duration of electrical stimulation (ES) of their wrist extensor muscles, with the stimulation triggered by voluntary activation of their muscles when possible, as measured by electromyography (EMG). The number of movements performed with EMG-triggered ES was 60–80 per session. The robot-trained group improved by 15 points more on the Fugl-Meyer scale, a standard clinical scale of movement ability with a range from 0 to 66 points in upper extremity function. It assigns a score of 0 (cannot complete), 1 (completes partially), or 2 (completes normally) for 33 test movements, such as lifting the arm without flexing the elbow. For comparison, reported gains in Fugl-Meyer score after therapy with the MIT-MANUS and MIME devices ranged from 0–5 points [53.47].

Other Devices to Undergo Clinical Testing

Other devices to undergo clinical testing are as follows. The GENTLE/s system uses a commercial robot, the HapticMaster, to assist in patient movement as the patient plays video games. The HapticMaster allows four degrees of freedom of movement and achieves a high bandwidth of force control using force feedback. Chronic stroke patients who exercised with GENTLE/s improved their movement ability [53.48, 49]. The Rutgers hand robotic device uses low-friction pneumatic

cylinders to help extend or flex the fingers, and has been shown to improve hand movement ability of chronic stroke subjects [53.50]. Simple force-feedback controlled devices, including a one-DOF wrist manipulator and a two-DOF elbow–shoulder manipulator, were also recently shown to improve movement ability of chronic stroke subjects who exercised with the devices [53.51]. A passive exoskeleton, the T-WREX arm orthosis, provides support to the arm against gravity using elastic bands, while still allowing a large range of motion of the arm [53.52]. By incorporating a simple hand-grasp sensor, this device allows substantially weakened patients to practise simple virtual reality exercises that simulate functional tasks such as shopping and cooking. Chronic stroke patients who practised exercising with this non-robotic device recovered significant amounts of movement ability, comparable with the Fugl-Meyer gains seen with MIT-MANUS and MIME. NeReBot is a three-DOF wire-based robot that can slowly move a stroke patient's arm in spatial paths. Acute stroke patients who received additional movement therapy beyond their conventional rehabilitation therapy with NeReBot recovered significantly more movement ability than patients who received just conventional rehabilitation therapy [53.53]. RehaRob uses an industrial robot arm to mobilize patients' arms along arbitrary trajectories following stroke [53.54].

Other Systems Currently under Development

Several other robotic therapy devices are currently under development. For example, at the high end of cost and complexity are the ARM-In [53.55] and Pneu-WREX systems [53.56], which are exoskeletons that accommodate nearly naturalistic movement of the arm while still achieving a wide range of force control. A system that couples a immersive virtual-reality display with a haptic robot arm is described in [53.57]. A wearable exoskeleton driven by pneumatic muscles is described in [53.58]. At the lower end of cost/complexity are devices that use force feedback joysticks and steering wheels with a view toward implementation in the home [53.59–62]. Examples of recent, novel robotic devices for the hand are given in [53.63–65]: these devices typically follow an active assist therapy paradigm in that they are designed to help open and close the hand. One robotic therapy system for the hand incorporates the idea of using visual feedback distortion to enhance motivation of patients during movement therapy [53.66]. Using robotic force fields to amplify the kinematic errors of stroke patients during reaching may provoke novel forms of adaptation of those patterns [53.4, 67].

53.2.4 Robotic Therapy for Walking

Background

Scientific evidence that gait training improves recovery of mobility after neurologic injury started to accumulate in the 1980s through studies with cats. Cats with SCI can be trained to step with their hind limbs on a treadmill with partial support of the body weight and assistance of leg movements [53.68, 69]. Following the animal studies, various laboratories developed a rehabilitation approach in which the patient steps on a treadmill with the body weight partially supported by an overhead harness and assistance from up to three therapists [53.70–73]. Depending on the patient's impairment level, from one to three therapists are needed for body-weight supported treadmill training (BWSTT), with one therapist assisting in stabilizing and moving the pelvis, while two additional therapists sit next to the treadmill and assist the patient's legs in swing and stance. This type of training is based on the principle of generating normative, locomotor-like sensory input that promotes functional reorganization and recovery of the injured neural circuitry [53.74]. In the 1990s, several independent studies indicated that BWSTT improves stepping in people with SCI or hemiplegia after stroke [53.70–72].

Gait training is particularly labor-intensive and strenuous for therapists, so it is an important target for

automation. The efforts of roboticists have been especially focused on BWSTT rather than overground gait training because BWSTT is done on a stationary setup in a well-defined manner and thus can be more easily automated than overground gait training. Randomized, controlled clinical trials have shown that BWSTT is comparable in effectiveness to conventional physical therapy for various gait-impairing diseases [53.75–80]. These trials support the efforts towards automation of BWSTT, as the working conditions of physical therapists will improve if the robots do much of the physical work, which in the case of BWSTT actually leads to occasional back injuries to therapists. Usually, only one therapist is needed in robot-assisted training, for the tasks of helping the patient into and out of the robot and monitoring the therapy. In the case of SCI patients, a small randomized, controlled trial [53.76] reported that robotic-assisted BWSTT with a first-generation robot required significantly less labor than both conventional overground training and therapist-assisted BWSTT, with no significant difference found in effectiveness.

Gait-Training Robots in Current Clinical Use

Three gait-training robot systems are already in use for therapy in several clinics worldwide: the gait trainer GT-I [53.81], the Lokomat® [53.82], and the AutoAmbulator™ [53.83] (Fig. 53.2).

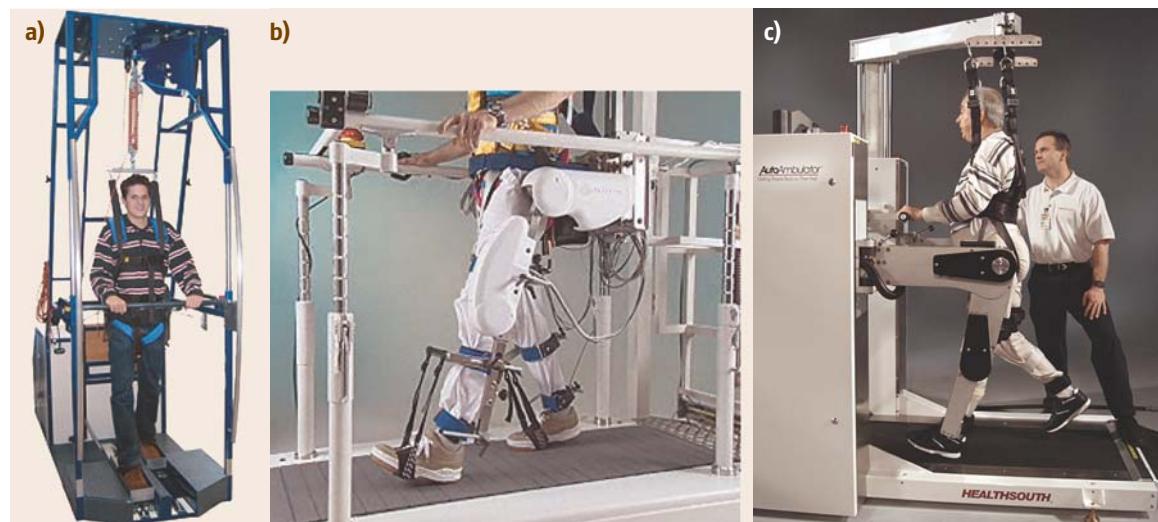

Fig. 53.2a–c Gait-training robotic systems currently in use in clinics; (a) the gait trainer GT-I, developed by Hesse's group and commercialized by Reha-Stim (Germany); (b) the Lokomat®, developed by Colombo and colleagues and commercialized by Hocoma AG (Switzerland), and (c) AutoAmbulator™, developed by the HealthSouth Corporation (USA)

Of these three robot systems, the GT-I is the one that departs most from therapist-assisted BWSTT, since it interacts with the patient's lower limbs through two footplates rather than acting on the shank as human therapists do. It also appears to depart more from natural walking because the footplate principle substantially alters the sensory cues of the foot impact with the ground or treadmill band. The GT-I footplates are driven by a singly actuated mechanism that moves the foot along a fixed gait-like trajectory with a doubled crank and rocker system [53.81]. The stride length can be adjusted between sessions by changing gears. The body weight is unloaded as needed by an overhead harness. The torso is moved sagittally in a phase-dependent manner by ropes attached to the harness and connected by another crank to the foot crank. The GT-I is currently installed in dozens of clinics, mainly in Europe. One randomized, controlled study has been reported that tested the GT-I with 30 subacute stroke patients [53.84]. The robot group improved their overground walking ability more than the control group, although differences were not significant at six-month follow-up. A total of 80% of the patients said they preferred training with the robot rather than the therapists because training with the robot was less demanding and more comfortable. The other 20% of patients stated that swinging of the paretic limb seemed less natural and thus less effective when training with the robot. Robot-assisted training required an average of one therapist per patient, while therapist-assisted training required two therapists per patient on average. A follow-up, randomized controlled study comparing conventional training plus robotic training with the GT-I with a time-matched amount of conventional training alone with subacute stroke patients found that the group that received some robotic training recovered walking ability to a great extent [53.85].

The Lokomat is a robotic exoskeleton worn by the patients during treadmill walking [53.82]. Four motorized joints (two per leg) move the hip and knee. The actuators consist of ball screws connected to direct-current (DC) motors. The legs are driven in a gait-like pattern along a fixed position-controlled trajectory. The device attaches to the thighs and shanks through padded straps. A passive parallelogram mechanism allows vertical translation of the patient's torso, restricting lateral translation. The patient's body weight is unloaded as needed through an overhead harness. The Lokomat is currently being used in dozens of research labs and clinics worldwide. In 2005, Wirz and coworkers [53.86] reported preliminary results of robot-assisted BWSTT

with the Lokomat in 20 chronic incomplete SCI patients. The improvements in overground walking speed and endurance were statistically significant: approximately 50% gain on average in the 16 patients who were ambulatory before training. There were no significant changes in the requirement of walking aids, orthoses or external physical assistance. The improvements appear to be comparable to those achieved by similar SCI patients who received therapist-assisted BWSTT. Hornby and colleagues [53.76] studied the effects of robot-assisted BWSTT with the Lokomat on individuals with subacute SCI. Thirty patients were randomly assigned to one of three training groups: robot-assisted BWSTT, therapist-assisted BWSTT, and therapist-assisted overground ambulation. Improvements in motor and functional abilities were similar in the three training groups, with the robot-assisted BWSTT requiring significantly less labor than the other two therapy methods.

The AutoAmbulator (<http://www.autoambulator.com>) consists of two robotic arms that assist patients to step on a treadmill with their body weight supported as needed. The interface to the patient's legs is through straps at the thigh and ankle. The AutoAmbulator is currently being used in 57 HealthSouth rehabilitation centers, all of them in the United States. A single-blind, randomized clinical trial to assess its effectiveness in stroke patients is currently underway.

Further Research and Development on Robotic Therapy for Walking

Several groups worldwide are working toward improving gait-training robotic technologies. A great deal of effort has been going into incorporating and investigating the ability to assist as needed [53.31, 87–91], that is, the ability of the robot to let the patients contribute to the locomotor efforts as much as they are able. This is likely essential for maximizing locomotor plasticity [53.92]. Some effort has also been directed towards adding more active DOF, particularly for torso manipulation [53.90, 93]. These robotic tools are needed not only for their potential clinical use in therapy, but for studying what aspects of the assistance are important for effective gait training and how best to control and implement them with robotic devices.

The team responsible for the GT-1 has developed the HapticWalker [53.87], which maintains the permanent foot/machine contact but allows the footplates to move along three-DOF trajectories. In addition it incorporates force feedback and compliance control, as well

as haptic simulation of ground conditions (e.g., stair climbing).

An advanced version of the Lokomat integrates force sensors and automatic adaptation of gait patterns to allow for a reduction of the interaction effort between patient and machine [53.88]. It has been tested on unimpaired and SCI patients, who were able to influence the gait trajectories towards a more desired motion by means of their own motor activity [53.88, 94].

The pelvic assist manipulator (PAM) is a five-DOF robot for torso manipulation, and the pneumatically operated gait orthosis (POGO) is a leg robot with two DOFs per leg. PAM's and POGO's actuators are pneumatic, which cost less than electric motors and have higher power-to-weight ratios [53.93]. The robots' ability to control forces and yield to patients and/or therapists has been tested with unimpaired and SCI patients [53.95]. Of particular note here is the development of an adaptive synchronization algorithm that allows these compliant robots to provide assistance at the right time as the patient varies the timing or size of steps.

Based on the string-puppet principle, the String-Man achieves weight bearing and compliant six-DOF torso manipulation by means of seven wires and a force sensor on each wire [53.90]. In addition, a control scheme has been designed for the String-Man to control both the zero-moment-point location and the ground reaction force with the help of foot force sensors.

Veneman and colleagues [53.91] are developing actuation systems for robotic exoskeletons that combine Bowden cables with series elastic actuation. The Bowden cables allow the motors to be mounted remotely in a fixed position, thus reducing the mass to be moved on the exoskeleton links. The spring element connecting the Bowden cables with the joint allows the closing of a force feedback control loop with a position sensor that measures the spring elongation, a concept inspired from the series-elastic actuation concept described by *Pratt* and coworkers [53.96]. In addition, series elasticity is useful to reduce the negative effects that static friction and unmodeled dynamics have on the stability of force control, thus improving the achievable force control bandwidth [53.97, 98], which is especially important for a Bowden-cable-based system. Series elasticity worsens positional accuracy, but this is not a critical issue for gait-training robots. Veneman's first experimental results show that adequate force control bandwidth was achieved by a prototype of their Bowden-cable-based actuation design [53.91], so that a robot incorporat-

ing this actuation concept can plausibly execute both a stiff, position-dominated robot-in-charge mode as well as a compliant, low-impedance patient-in-charge mode.

A different approach to gait training was taken with the KineAssist device [53.99]. KineAssist is a motorized mobile platform that follows patient and therapist as they move over ground and incorporates a smart brace that compliantly supports the patient's trunk and pelvis. This smart support is designed to allow the therapist to adjust its stiffness from fully rigid down to fully compliant. Within a safety zone, the fully compliant mode allows patients to challenge the limits of their stability. A compliant virtual wall catches the patients when they lose balance. The location of this virtual wall is also adjustable. The body weight can be unloaded as needed.

Other efforts include *Ferris* and coworkers [53.100], who are developing foot, ankle, knee, and hip orthoses actuated by artificial pneumatic muscles that may possibly be used to assist in gait training. The Rutgers Ankle is a six-DOF pneumatic system based on a Stewart platform that allows exercise of the ankle [53.101]. Also in the USA, *Agrawal*'s group proposes the use of gravity-balancing leg orthoses for people with gait impairments to practise walking [53.102]. Their designs allow the orthoses to passively support the gravity torque required at the patient's joints. This approach would have the advantage of being safer than powerful robots for clinical use. They have also extended their design to include actuators with reduced torque requirements [53.103]. A robot has been used to provide graded body weight support as a patient who cannot bear his full weight because of a medical problem walks in a circle [53.104].

Other Robotic Movement Therapy Approaches

As reviewed above, most of the work to date in robotic therapy devices has focused on robots that attach to patients to assist them in practising reaching or walking exercises. Other early proposals for using robots for movement therapy included using two planar robot arms to carefully control continuous passive motion of the knee following joint surgery [53.24], and using a multi-axis robot arm to place targets for patients doing reaching exercises [53.105]. An emerging approach toward robotic movement therapy is to provide the therapy at a distance, in a form of tele-rehabilitation, in order to improve accessibility to the therapy [53.59, 106, 107].

53.3 Aids for People with Disabilities

53.3.1 Grand Challenges and Enabling Technologies

Enabling technologies assist people with disabilities to achieve a quality of life on a par with able-bodied individuals through increased functional independence. The main issue with most such technologies is that disability has a highly individualized impact: a solution for one person will not work for someone else, even if their disabilities appear clinically similar. The more a disability impacts function, the more costly the technical intervention tends to be, since the consumer market cannot benefit from economies of scale if each solution must be individualized. As an extreme example, an electric wheelchair with individualized padding, motorized recliner, and customized joystick control costs as much as a mass-produced mid-sized automobile, but has a fraction of the electronics, robustness, and functions. A grand challenge for assistive, enabling technologies is to find a means to make mass-personalization possible, as it has been in the automotive industry, for example. One component is designer focus. If we can re-badge *assistive technology* as *design for well-being products*, the change in focus from *fixing* people to improving their quality of life will have the effect of mainstreaming disability itself so that manufacturers of consumer equipment tend to develop products that can explicitly accommodate a much wider range of functional abilities and therefore provide benefit to a larger, overall lessable, consumer base. As the average age of the baby boomers climbs into retirement years with significant disposable income, this segment will compel the market into providing better solutions to their well-being needs.

Another grand challenge is robotic autonomy. Especially for persons with reduced communication, physical, and/or cognitive abilities, a rehabilitation robot will need to have sensory (e.g., vision, auditory) and motor capabilities, combined with its own software processing capabilities (also termed artificial intelligence), that make it a sufficiently safe and capable system to coexist with and benefit humans. This challenge will to some extent be dependent on continuing increases in computer processing power, but also specifically dependent on the algorithmic developments that issue from the community of robotics researchers.

Research on robotic aids has so far primarily targeted persons with mobility and manipulation limitations, rather than children and adults with cognitive impairments. However, increases in the prevalence of cognitive

impairments related to aging will make the latter focus increasingly important. Research has been limited to the mobility focus due to the difficulty of designing and developing intrinsically safe robots that can coexist with people and exhibit a certain amount of autonomy while performing useful work. Robots today therefore rely on user vigilance and explicit control to be safe. If the user does not have the cognitive capacity to evaluate a robot's safety situation or the ability to communicate efficiently, then the positive value of a function-enhancing robot is nullified by the harm that it could inflict on the user or bystanders. Coupled with the fact that the design of interfaces to personal robots is still in its infancy, a challenge for robotic aid developers is a significant improvement in intrinsic safety without a decrease in function (strength, speed, etc.) from what is typical today in industrial robotics.

Disabilities and Functional Limitations Served by Robotic Aids

Assistive robots have been designed for people who have become severely disabled as a result of, for example, muscular dystrophy or a high-level SCI, for children who have cerebral palsy (CP), and more generally for anyone who lacks the ability to manipulate household objects. A market research study conducted ten years ago specifically for rehabilitation robotics clients conservatively projected a US market of 100 000 people [53.108]. With the incidence of disability increasing exponentially, and the niches that robots can fill in rehabilitation applications multiplying with advances in robotics and rehabilitation science, it is clear that the market for rehabilitation robotics can only continue to increase.

Human–Robot Interface Design for Assistive Robots

A fundamental difference between using industrial and assistive robots is the interface required to command, control, and ultimately benefit from them. An industrial robot commonly has a combination of a manual controller and a programming language interface to allow an operator to teach a robot where to go and to enter the specific motion, grasping, tool changing, and error-recovery steps it must follow repeatedly in its factory automation scenario. A rehabilitation robot, on the other hand, typically has three main differences and challenges: (1) the operator is not by definition a roboticist or engineer, so the interface must make accessible all the functions of the robot to allow its user to complete the required tasks;

(2) the user of a rehabilitation robot is, by definition, a person with a disability, which means that physical, sensory, communication, and/or cognitive limitations in accessing the commands and controls of a robot need to be handled on a systems level by the designers of robots and their interfaces, with critical attention to universal design principles; and (3) all rehabilitation robots require individualization of the interface to each user by the engineering and therapy professionals in charge of prescription and fitting, since disabilities vary considerably in how they restrict adaptability to standard configurations [53.109].

Interfaces of assistive robots tap into the residual communication capabilities of each user. For example, many people with tetraplegia retain the ability to move a hand, arm, foot or the head in a repeatable even if range-limited way, and possibly even in two axes, such as forward–backwards and left–right. With proper placement of push buttons, a joystick, or non-contact position measurement device, a rehabilitation engineer and therapist can develop a custom solution for each of their clients with disabilities to control a wheelchair computer and robot. In addition, adaptive hardware and software for control of a computer, such as head-position cursor control, eye-trackers, speech recognition systems, track balls, and special keyboards, can be used to provide access to computer-based robot functionality.

Even more so than for able-bodied computer and robot users, redundancy in input modality is important for persons with disabilities to prevent a system from becoming inoperable due to a simple interface malfunction or calibration problem. Providing two means of creating a mouse click action (for example, a separate button placed next to a cursor-control track ball, as well as dwell time on a software *button* on-screen), even if one is inherently slower than the other, allows continued and uninterrupted use of the computer without outside assistance even if one of the two fails.

For therapy robots, physical interfaces resemble those for physical and occupational therapy equipment in general and have a commonality with sports equipment interfaces as well, with adjustable hook-and-loop-type straps, heat-formable plastic cuffs, soft rubber, foam-based materials, and durable coverings for abrasion resistance and long wear. After a session or two for fitting and adaptation, a person using a therapy robot can often use the same interface for a long period of time.

In summary, the keys to interface design are customizability, individualization, functional redundancy, adaptability, and patience in getting the interface to

a comfort and functional level appropriate for effective use of the robot.

53.3.2 Types and Examples of Assistive Rehabilitation Robots

As mentioned in the Introduction, assistive robots can be divided into three main categories: manipulation aids, mobility aids, and cognitive aids. Each can be subdivided as follows. Manipulation aids are commonly divided into fixed, portable, and mobile subtypes. Mobility aids are divided into electric wheelchairs with autonomous navigation features and smart walkers. Cognitive aids are divided into communication aids such as pet robots and autonomous caretaker robots. These categories are introduced below, and representative systems that have undergone scientific user studies or are commercial products are presented (Fig. 53.3). Other examples are mentioned in the history in Sect. 53.1.3.

Manipulation Aids: Fixed Base

Common robots of this type are [ADL](#) and vocational manipulation aids and kitchen robots. In the [US](#), the professional vocational assistive robot ([ProVAR](#)) is a research prototype based initially on a PUMA-260 robot arm mounted on a 1 m transverse overhead track that allows the robot to manipulate objects and operate devices on side shelves and the tabletop, bringing objects (like a drink of water or throat lozenge) to the robot's operator. The interface is via a Java or virtual-reality modeling language ([VRML](#)) plug-in to a common Internet browser, delivering high-level control to disabled office workers in a conventional pull-down menu and control screen interface [53.14, 110]. This system and its predecessor [DeVAR](#) have been field tested by over 50 subjects at five rehabilitation clinics to assess feasibility and acceptability [53.111, 112]. At a cost of over [US\\$ 100 000](#) currently, it is poised to be re-engineered with a simpler, cheaper arm for eventual product introduction.

In the European Union (EU), following a development path parallel to [ProVAR](#)'s, is the [AfMASTER/RAID](#) workstation, whose concept, instead of being built into a workstation, includes a 2 m × 3 m robot work area in the user's office to store objects and place appliances, next to the user's own office space. The system has been developed over a 20 year span and is in limited production [53.16].

The kitchen robot [Giving-A-Hand](#), developed at the Scuola Superiore Sant'Anna in Pisa, Italy, is a low-degree-of-freedom device for mounting on the front rail of a kitchen counter and able to move food contain-

ers to and from appliances such as refrigerators and ovens [53.113]. With an integrated control system, it can also make use of the internal controls of the devices to, for example, set cooking times and open doors.

The UK-developed Handy-1 is a domestic robot with three degrees of freedom designed for one-switch operation by persons with cerebral palsy [53.17]. Originally designed to allow a person to eat a meal one bite at a time, its application areas have been extended to face hygiene and cosmetics. A commercial product selling for about US\$ 6000, it has been a commercial success due to its simplicity and application focus. An even simpler feeding robot, the UK's electric Neater Eater [53.8] is on sale worldwide at about US\$ 5000, and is designed for eating only.

While a robot conventionally connotes a stand-alone system with some automation features, a smart bed and a smart home can legitimately be termed robots since they sense and act with motors under the shared control of its human users and its real-time software programming. Smart beds such as SleepSmart measures body position and temperature, as well as trends and anomalies over the course of a night. Restlessness can be measured, and bed geometry (tilt of bed segments) and ambient conditions (light, temperature, sounds) can be adjusted according to presets and preferences [53.114].

Smart homes, such as the domotic environment at Georgia Tech, NL-iRV, and the University of Tokyo [53.115], provide integrated climate, security, lighting, entertainment, and transport assistance, which is enabling especially to persons with severe functional disabilities. Coupled with health-care-related functionality (see the next section), these robotic homes can allow a person with a cognitive or physical disability to control many **ADL** functions and live safely through monitoring.

Manipulation Aids:

Wheelchair Manipulator Arm Systems

A need for electric wheelchair users is the manipulation of objects while navigating a home or a public place such as a restaurant or grocery store. The assistive robot service manipulator (ARM, Exact Dynamics, Netherlands) – previously known as MANUS – is a commercial robot arm that can be attached to an existing wheelchair to the side of the lap tray and controlled by the wheelchair's own joystick or a number pad [53.19, 116] (Fig. 53.4). The robot has undergone numerous user studies with persons who have muscular dystrophy, a high-level **SCI**, or cerebral palsy. Worldwide, this is currently the only commercial rehabilitation robot arm that can be prescribed

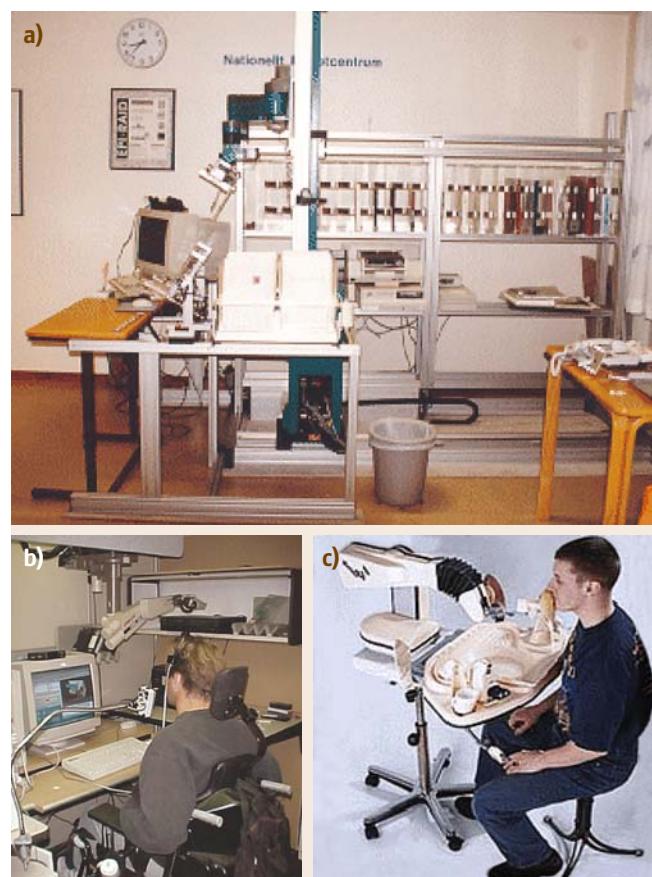

Fig. 53.3a–c Workstation-type robots: (a) AfMaster, developed by the French Muscular Dystrophy Association, (b) ProVAR, developed at the VA Palo Alto Rehabilitation R&D Center, and (c) Handy-1, developed by RehabRobotics, Ltd. (UK)

by a physician and that is reimbursed by a government health care system.

Manipulation Aids:

Mobile Autonomous Systems

The most commonly conceived form of a robot is that of an autonomous, mobile system with arms, having sensorimotor functionality similar to that of a human being, while serving people in performing menial physical tasks. Chapter 56 of this Handbook explores the domain as well. Since locomotion is a key requirement for humanoid robotics, other robots with wheeled bases have been developed before the first walking robots were invented to explore more applied domains with more short-term usefulness. In film, robots such as Star Wars' R2D2 have made this form factor commonly known

Fig. 53.4 Wheelchair manipulator robot MANUS developed at the Rehabilitation R&D Center, Hoensbroek, and marketed by Exact Dynamics (The Netherlands)

Fig. 53.5a,b Wheelchair navigation aids: (a) Wheelesley and (b) Hephaestus

around the world. More recently, real robots such as the HelpMate [53.117] have been employed in US hospitals as fetch-and-carry robot orderlies, using floor maps and short-range ultrasonic sensors for navigation and obstacle avoidance. The Italian MovAid research robot platform [53.118] adds manipulation and vision to these capabilities to navigate in home-like environments to provide object manipulation and device operation to individual users. The German Care-O-bot [53.119] has explored advanced navigation and sensing in a wheeled

robot that can also be used as a physical support to people requiring mobility and stability assistance. It has also doubled as a mobile kiosk, moving around a trade show floor and delivering information to attendees.

Mobility Aids: Wheelchair Navigation Systems

A critical function for people who use electric wheelchairs for their mobility impairment and who in addition have communication or cognitive disability is semi-autonomous navigation assistance (Fig. 53.5). Add-ons to commercial wheelchairs have been developed by numerous research groups for this service. The NavChair [53.120] was one of the first to demonstrate robust wall-following, door passage even with narrow doorways, and speed adaptation to people walking in front of the wheelchair, all using only short-range ultrasonic and other sensors, but not vision. The Hephaestus [53.22] is a next-generation system made specifically as a commercial accessory for a variety of wheelchair brands, tapping into the joystick controller and power system. The Wheelesley [53.121] and KARES [53.20] robots have explored similar functionality using a vision system for scene analysis and way-finding.

Mobility Aids: Walking Assistance Systems

A third type of mobile robot for stability assistance has the particularity that it is underactuated and has similarity with a *co-bot* in that the wheels are not driven, but are actively steered and braked (Fig. 53.6). The Pam-Aid [53.122] looks like a closed-front walker on wheels and has bicycle-type handlebars. The person walking behind the device turns the handlebars, causing the wheels to turn in the correct direction. If the ultrasonic sensors detect an obstacle in front of it, the brakes prevent the user and device from colliding with it. The Care-O-bot (see before), designed originally as a mobile autonomous robot of approximately human size, has a similar set of handlebars to Pam-Aid so it can be used as a smart walker. The larger mass of the Care-O-bot, however, requires it to be motorized.

Cognitive Aids

There has recently been increased interest in using robots as motivational and educational agents during rehabilitation therapy. This approach typically involves small, pet-like, toy-like, approachable devices that do not physically interact with the patient, but exist primarily to engage the patient in an affective way that promotes personal health, growth and interaction. For example, the

Fig. 53.6a–c Human assistance robots: (a) Care-O-bot, developed by the Fraunhofer Research Institute (Germany). (b) Helpmate by Transitions Research Inc., USA. (c) Pam-Aid (aka Guido), developed in the UK

PARO robot looks like a baby harp seal, and can respond to sound, contact, light, and tilt by moving its head and eyelids [53.123]. The device has been used to facilitate interaction with children with autism and elderly adults. The CosmoBot, a small humanoid robot with multiple degrees of freedom and a control panel, has been used to motivate speech and motor behavior by children with cerebral palsy, Down's syndrome, and autism [53.124]. The Japanese Wakamaru robot [53.125] was announced by Mitsubishi Heavy Industries in 2003 as a home health monitoring robot to assist persons living alone but at risk of falls and in need of information services and reminders related to their own health care. An interesting feature of this robot is that its arms and programmable facial features are used for gesturing only, not manipulation and sensing, to assist in effectively communicating to its users. A small, talking mobile robot was recently developed to motivate and measure rehabilitation exercises by stroke patients [53.126]. There is also extensive related work in the development of virtual-reality interfaces for motivating rehabilitation therapy [53.127].

As an example using robots to motivate therapy, Dautenhahn and colleagues have studied the use of robotic toys as tools to stimulate communicative and social skills and facilitate human contact in children with autism. Children and adults with autism often avoid social interactions and have difficulty interpreting facial expressions and other social cues in interactions with people. As reviewed by *Dautenhahn* [53.26], research

suggests that children with autism generally feel more comfortable in predictable environments. Human social behavior is subtle, elaborate, and unpredictable. Many children with autism are however interested to play with mechanical toys or computers. In addition, Dautenhahn's studies show that children with autism have greater interest in interactions with autonomous robotic toys than with inanimate toys. In a study spanning several months [53.128], four children with autism were comfortable interacting with a humanoid robotic doll called Robota, participating in imitation, turn-taking, and role-switching. The children even started, by their own initiative, to include the investigator in their shared experience with the robot. Robins et al. suggest that robots could be used to encourage social interactions by children with autism, to allow care-givers to observe and monitor the children's play behavior and progress and to address specific therapeutic goals by targeted programming.

Other cognitive aids are focused on caretaker tasks such as monitoring vital signs and performing reminding functions. *Joseph Engelberger* popularized the concept with the HelpMate robot prototype in the 1990s [53.129], and Mitsubishi Heavy Industries commercialized the Wakamaru robot [53.130] for home use, with clinical trials pending. Even though it is not capable of manipulating objects, it uses its arms to gesture and provide communication cues to people in the home, in addition to using speech output and speech recognition.

53.4 Smart Prostheses and Orthoses

53.4.1 Grand Challenges and Roadblocks

In 2005, the Defense Sciences Office (DSO) of the US governmental research agency, the Defense Advanced Research Projects Agency (DARPA) launched a program to revolutionize prosthetics in a four year timeframe. According to the agency website (<http://www.darpa.mil/dso/thrust/biosci/revprost.htm>), this program will

deliver a prosthetic arm for clinical trials that is far more advanced than any currently available. This device will enable many degrees of freedom for grasping and other hand functions, and will be rugged and resilient to environmental factors. In four years, DSO will deliver a prosthetic for clinical trials that has function almost identical to a natural limb in terms of motor control and dexterity, sensory feedback (including proprioception), weight, and environmental resilience. The four-year device will be directly controlled by neural signals. The results of this program will allow upper limb amputees to have as normal a life as possible despite their severe injuries.

This program announcement lays down the grand challenge for prosthetics research in an ambitious timeframe: develop an artificial limb that has functionality and durability at least as good as a natural limb.

There are several roadblocks to meeting this challenge. First, providing an intuitive way for individuals to control and coordinate multiple joints of a robotic limb is challenging. Second, robots do not yet match the human arm in terms of the combination of range of force, weight, and duration of use with a portable power source. Third, human limbs are rich with tactile and movement sensors. Installing artificial sensors on a robotic limb, and then returning information from those sensors in a way that is usable by the user is challenging. Thus, solving the grand challenge will require better sensory-motor interfaces for prosthetic limbs, as well as lighter stronger actuators and better power sources.

Substantial progress has recently been made in improving sensory-motor interfaces for prosthetic limbs, and this progress is the focus of this section. For the current state of robotic actuators that could be used in prosthetic devices, the reader is referred to Chap. 62 on neurorobotics. For an overview of the design of conventional prosthetic hands and arms, the reader is referred to [53.131].

53.4.2 Targeted Reinnervation

Standard prosthetic arms and hands are commonly controlled with a cable drive or by EMG signals from residual muscles. For example, to open and close an artificial hand, one common technique is to place a Bowden cable around the shoulders in a harness, and connect the cable directly to the artificial hand. The user can then shrug the shoulders to move the cable and open and close the hand. Alternately, electrodes can be placed on a muscle in the residual limb or on the user's back, for example, and then used to control a motor on the artificial hand. The cable technique has the advantages of simplicity, and of having the property of extended physiological proprioception (EPP), which refers to the fact that the grip force is mechanically transmitted back to the user's shoulder muscle force sensors so that the user can gauge the strength of the grasp. Because of their simplicity and EPP, cable drives (or body-powered prostheses) have been more popular than myoelectric (or externally powered) prostheses. However, the body-powered technique is amenable to controlling only one degree of freedom at a time, although chin switches, for example, can be used to switch between degrees of freedom in a somewhat cumbersome way. The myoelectric approach can be used to control multiple degrees of freedom, but such control is nonintuitive and cumbersome. Also, multiple control sites for reading out EMG are not available for people who have lost their entire arm. Thus, prosthetic control systems are typically limited to one or two degrees of freedom, while functional arm and hand movement benefits from at least four degrees of freedom (three to position the hand, and one to open and close it).

Kuiken et al. [53.132] recently developed a novel approach to improving control of a multijointed prosthetic arm. In this targeted reinnervation technique, they rerouted the nerves that previously innervated the lost limb to a spared muscle, and then read out the user's intent to move the limb using electromyography at the spared muscle. They demonstrated this technique in a bilateral shoulder disarticulation amputee who had lost both of his arms in an electrical power accident. They took the residual brachial plexus nerve for the left arm, which normally innervates the left elbow, wrist, and hand, and moved it to the pectoralis muscle. The subject could still contract his pectoralis muscle, but this muscle was no longer useful to him since it used to attach to his now-missing humerus. A surgeon dissected por-

tions of the nerve associated with different muscles in the elbow, wrist, and hand, and innervated three bundles of the pectoralis muscle. After three months, the nerve reinnervated the bundles so that the patient could cause the bundles to twitch by trying to bend his missing elbow, for example. Surface EMG electrodes were placed over the bundles. Then, when the user willed to open his hand, for example, a pectoralis muscle bundle contracted, and this contraction was detectable with the EMG electrodes. The EMG signal was in turn used to control the hand motor of the prosthetic arm. The net result was that the user could will his different (missing) anatomical joints to move, and the corresponding joints on the robotic arm would move. He could simultaneously operate two joints, such as the elbow and the hand. The user became able to do tasks that he was not able to do before with his conventional myoelectric controlled arm, such as feeding himself, shaving, and throwing a ball. A secondary remarkable finding was that the sensory neurons in the rerouted nerves reinnervated sensors, so that now when the person's chest is touched, the person perceives it as a touch to his missing limb. This sensory reinnervation could possibly be made into an interface to provide tactile sensation from the artificial limb. These findings were recently confirmed in another person who received targeted reinnervation [53.133]. It has also recently been shown that direct electrical stimulation of a residual peripheral nerve can provide usable information regarding force to a person with an amputation [53.134].

53.4.3 Brain–Machine Interfaces

There has also recently been progress in decoding movement-related signals in real-time directly from the brain (see the cover story and related articles in *Nature*, Vol. 442 [53.135]). The ability to decode an intended movement directly from brain activity could make it possible to control a prosthetic limb or orthotic device directly by thought.

Brain–computer interfaces can be divided into non-invasive and invasive approaches. In noninvasive approaches, electrical activity is recorded from the surface of the skull using surface electrodes to form an electroencephalogram (EEG) (for a review see [53.136]). Individuals can learn to control the amplitude of the EEG signal as a function of time, or the amplitude of specific frequency components of the EEG signal, with a moderate amount of practice (several hours to several days). The level of control is sufficient to operate a typing program on a computer, or to control the movement of a cursor to multiple targets.

Invasive approaches involve implanting electrodes on the surface of the brain (electrocorticogram) or into the brain itself. Electrodes implanted inside the brain can detect action potentials from single neurons. The first demonstration of this technique in humans [53.137] was in a person with end-stage amyotrophic lateral sclerosis (ALS), a disease that paralyzes muscles but leaves cognition intact. A cone electrode was implanted in the motor cortex, along with growth factors that encouraged growth of neurites, or branches of neurons, into the cone. Stable action potentials were recorded for several months, and the patient was able to increase or decrease the firing rate of the action potentials recorded by the electrode.

Subsequent work in monkeys demonstrated that recordings from multiple neurons (ranging from as few as tens to hundreds) can be used in real time to decode the three-dimensional trajectory of the arm using straightforward signal processing (see review [53.138]). The first human volunteer, a person with tetraplegia due to spinal cord injury, has now been implanted with the BrainGate electrode array, and has been able to control the movement of a cursor on a computer screen [53.135]. Other work in brain–machine interfaces has focused on detecting higher-level control signals, such as the intent to move, preferences for different rewards, and motivation to perform a task [53.139].

Given this progress, it appears that future control systems for smart prosthetics and orthoses will have the option to rely on direct interfaces to the brain, which should allow control of multiple joints through thought alone. The initial work on both targeted reinnervation and brain–machine interfaces has allowed three to four degrees of freedom of control in a naturalistic manner, which is an advance over conventional prosthetic control techniques.

53.4.4 Advances in Neural Stimulation

Unlike people who suffer an amputation, individuals who suffer from paralysis due to neurologic injury retain their limbs. Frustratingly, however, they often do not achieve as good of control as people with artificial limbs. The situation is ironic because the actuator in the limb muscle, is very sophisticated and can still be activated by stimulating the nerves that innervate the muscles. Thus, one viewpoint of the problem of restoring motion for paralyzed people is that excellent hardware for solving the problem already exists (i. e., the limbs themselves), but that we must find ways to replace the control system to control it.

Functional neural stimulation techniques (**FNS**) seek to stimulate the residual nervous system electrically to reanimate the limbs. **FNS** for standing, walking, reaching and grasping has been demonstrated, but these techniques have met with limited commercial success because of a combination of factors, including ease of use of systems that use surface electrodes, duration of use before fatigue, risk from implantation and complexity of the associated control problems. The systems that have been most successful are foot-drop stimulators, which aid individuals who suffer from neurologic conditions in lifting a drooping foot while walking. These systems detect the phase of the gait cycle (using a foot switch or accelerometer, for example) and then stimulate a nerve in the leg to lift the foot at the appropriate time.

Two recent innovations may help move the **FNS** field forward. The first innovation is a hardware innovation. The bionic neuron (**BION**) is an injectable stimulator the size of a very large grain of cooked rice [53.140]. The initial version is powered through electromagnetic transduction via a coil on the outside of the body, but versions are under development that include a battery. Communication with the individually addressable, programmable stimulator on the **BION** is through radio frequencies. Sensors, including accelerometers, can also be packaged into the capsule, so that the multiple implanted devices could communicate with themselves to calculate limb position. Two potential advantages of the **BION** which may make **FNS** more practical are that it can be inserted without surgery (using a large-gauge needle), and that it may be more robust and resistant to infections, since it does not require implanted wires that can become roadways for infections to spread.

The second innovation that may push **FNS** forward is stimulating the control circuits in the nervous system rather than individual muscles. For example, it has been shown that locomotor-like movements can be elicited in multiple muscles of the cat hind limb by stimulating regions of the spinal cord directly (see review [53.141]). The key realization here is that there

exists modular circuitry in the spinal cord, and perhaps elsewhere, that can be electrically activated in order to produce coordinated patterns of muscle activity in multiple muscles. Thus, one electrode can produce coordinated, multijoint muscle activity, reducing the number of needed control sites, and perhaps improving the smoothness and time to fatigue of the resulting contractions because of use of more natural muscle recruitment mechanisms.

53.4.5 Embedded Intelligence

Recent robotics-related advances for prosthetic legs have included embedding microprocessors and passive braking systems into artificial knees, so that the knees can, for example, be made relatively stiff during the stance phase of gait, and free to move during the swing phase of gait (see the review in [53.142]). The first microprocessor knee introduced was the Otto Bock C-Leg, introduced in 1999. The C-Leg uses a servomotor to adjust valves to hydraulic pistons. The rechargeable battery lasts about 24 hours. The pattern of resistance throughout the gait cycle can be adjusted for each user. A dramatic example of the benefit of the C-Leg is the story of a man who made it down from the 70th floor of the World Trade Center on 9th September 2001 with only minor bruising to his residual stump [53.143]. Other microprocessor-controlled knees are the Endolite adaptive prosthesis, which uses pneumatic and hydraulic valves, the Rheo Knee (Ossur hf, Iceland), which uses magnetorheologic fluid to vary the knee impedance, and the Intelligent Prosthesis.

The first powered knee that can generate power, rather than just dissipate energy, is currently being commercialized by Ossur as the Power Knee. The system combines an electromechanical power source that will be controlled with input from sensors on the sound leg shoe. Initial reports suggest that this is the first knee that allows the user to walk up stairs with a step-over-step pattern.

53.5 Augmentation for Diagnosis and Monitoring

53.5.1 Introduction: Grand Challenges and Enabling Technologies

A critical aspect of rehabilitation is health maintenance with age-related or degenerative functional decline and after a medical intervention. In-home diagnostic equipment, devices worn on or in the body for vital signs

monitoring, tele-health services, and institution-based monitoring automation are all examples of systems being developed to improve the quality of life for both persons at risk as well as their care-givers. Institutional systems of this nature, more properly part of the field of clinical engineering, are incorporating more robotic, networked, and autonomous devices to take more accurate

diagnostics, provide better information to physicians, and provide faster alerts. Key enabling technologies in this field are advanced materials and nanotechnologies. For all devices that are worn on the body, the interface must be skin compatible. A grand challenge for this field in the near term is the better incorporation of active and sensing elements with textiles. Several prototype sensor shirts show promise, but rehabilitation will have a much richer toolset for diagnosis and monitoring with advances in this area. Nanotechnology, an enabling technology for the longer term, has the promise to miniaturize virtually everything mechatronic that is currently macroscopic. Injected devices such as nanorobotic drug dispensers and clot-busters will aid in rehabilitation.

53.5.2 Smart Clinics with Automated Health Care Monitoring and Care

A special class of fixed-station rehabilitation robots is an automation system designed to provide a safe environment to assist and monitor a person with a disability living at home or in an institutionalized setting such as an assisted living facility or nursing home.

Smart Nursing Home Automation

An assisted living, hospice or nursing care institutional facility will include residents who have mild to severe cognitive impairment in addition to physical disabilities. The facility may have zones to separate residents who have different levels of dependency since the architectural, monitoring, and personnel needs are different. To better serve residents and guests, to optimize function, and to minimize cost, only the areas for persons with high dependency have a 24 hour staffed vital signs monitoring and alert capability, for example. Facility care is highly staff-intensive, though automation through diagnostic vital signs monitoring, electronic surveillance, and patient tracking continue to improve safety and efficiency. Robotics and automation are beginning to find applications in the physical tasks associated with patient care, therapy, and oversight. Some examples are described below.

Examples of the State of the Art

Wandering, especially at night, is a significant problem for institutional facilities with ambulatory residents who are cognitively impaired. Simple architectural modifications include painting the hallway in front of doors black to make them look like deep holes. An automated voice system triggered by a motion detector to say *Go back to bed* is effective, but not fool-proof, either. Resident

detection systems based on identity badges with embedded radiofrequency identification (**RFID**) chips that can be sensed in a hallway work, but only if the resident is wearing it. A robotic sentry system, including mobile platforms to aid in solving this problem, especially at night, has not yet been developed.

A serious rehabilitation issue in institutionalized facilities is the transfer of residents from bed to wheelchair and other surfaces. A number of manual, electric, and robotic devices have been developed to assist the nursing staff to safely transfer residents and patients who may be significantly heavier than they are. This remains an unmet clinical need, though not for lack of innovative attempts [53.144, 145].

53.5.3 Home-Based Rehabilitation Monitoring Systems

Numerous smart homes have been developed for non-rehabilitation as well as assistive purposes [53.146]. These systems have as their goal the safety of people with disabilities living in the home and communication with care-givers outside of the home. Care-givers can be live-in family or attendants who, even when they are not home, need to be kept informed on the status of the disabled person, as well as clinicians who need to be sent regular vital signs and other medical/therapy reports. In-home systems typically feature the same principal elements:

1. sensors to monitor both ambient as well as people- and object-specific parameters (e.g., person location, stove-top operation); actuators to modify ambient conditions (heat, lighting, sound system, etc.) and operate devices (doors, refrigerator, etc.);
2. a means to network all the sensors and actuators for uni- or bidirectional communication with the host computer. This network can be wireless (e.g., 802.11g), wired (e.g., coaxial cable), or dependent on an existing network (e.g., signals superimposed on current carried by the electrical mains or phone wiring);
3. a host computer that allows all sensor states to be displayed and actuators to be operated from one or more locations in the home by the inhabitant(s) using common computer input/output (**I/O**) devices. Higher-order functions are built upon this basic capability;
4. an external network to allow communication with the Internet via phone, cable, satellite or other means. This capability allows for remote monitoring and

operation, sending of alarms and discussions with rehabilitation professionals at medical centers.

The host computer software may also have higher-order features, for example, timers for repetitive actuation of lights and monitoring for anomalous sensor readings (e.g., call security when the smoke detector activates, alert inhabitants with an in-home alarm when stove-top power is on and no pot is on the stove). More advanced features that involve multi-input and multi-output control and adaptive, predictive, context-aware operation [53.147] are areas of active research, and especially important to the rehabilitation community.

53.5.4 Wearable Monitoring Devices

One component of an automated rehabilitation environment is the subsystem that a person wears to be

able to measure, analyze, and communicate physiological signals to an external computer wirelessly. Systems such as the LifeShirt (VivoMetrics, Inc.) [53.148] have been and are being developed for front-line soldiers and rescue operation personnel whose health may become imperiled when out of touch with and unable to communicate verbally with their base command. For rehabilitative purposes, for example the Intel Proactive Health Initiative [53.149] is an example of a system that use on-person position and motion sensing to detect potentially dangerous or undesirable situations.

The most significant obstacles to the widespread adoption of these technologies in the short term are cost, false-positive alarms, inconvenience, and encumbrance. Advances in microelectronics, nanotechnologies, software algorithms, and networking capabilities will drive the research and consumer acceptance of this technology sector.

53.6 Safety, Ethics, Access, and Economics

Rehabilitation robots interact closely with humans, often sharing the same workspace and sometimes physically attaching to humans, as is the case of robotic movement-training devices and prosthetic limbs. Furthermore, the devices are by necessity powerful enough to manipulate the environment or the user's own limbs, which means that they are also often powerful enough to injure the user or another person nearby by colliding with them or moving their limbs inappropriately. Safety is clearly of paramount importance. See Chap. 56 for an in-depth discussion of safety and robotics.

A common strategy for ensuring safety is to incorporate multiple, redundant safety features. A device can be designed to be mechanically incapable of moving itself or the user's limbs in such a way as to cause injury. Limits can be placed on the range, strength, and speed of actuators so that they can accomplish the desired task but no more. Breakaway attachments can be used to attach to users' limbs. Covers can protect the user from pinch points in the device. Redundant sensors can be included, so that if one sensor malfunctions another sensor can identify the malfunction and help shut down the machine safely. Watchdog timers can monitor the health of the control computer. Software checks can limit forces, motions, speeds, and user adjustments to control parameters, as well as check for sensor health and other dangerous situations. Control strategies can be designed so that the device is mechanically compliant,

reducing the risk of forcing a limb into an undesirable configuration, or of a high-impact collision. A manual override switch can be incorporated so that the user can shutdown the system. Finally, the user can be instructed on how to safely operate the device and avoid dangerous situations. Safety ultimately depends, however, on careful and rigorous failure mode analysis and remediation by the system designers.

From a systems perspective, when all else fails actively to protect the user, it must be the design itself that makes the robot inherently unable to injure its user. Part of the solution is in reducing the weight, rounding the surface characteristics and making appropriate materials choices. The goal of inherent safety, however, is often at odds with high performance and adequate payload for real-life tasks. Recently, several approaches to designing personal robots – in other words the class to which assistive rehabilitation robots belong – have sought to address both goals by dividing the two tasks of compensating for gravity (arm plus payload) and moving the payload around in space [53.150]. The solution is to provide two actuators per joint on the joints that support the arm segments and payload against gravity: one slow, gear-reduced motor and energy-storing device such as a large spring or compressed air volume, and one small, back-drivable motor that provides the power needed to move objects around quickly and precisely. Most robot manipulators have approximately a 1:10 (or worse) payload-to-weight ratio. A system with a dual,

parallel actuator system that requires only the small, fast actuator to be carried in the arm, leaving the slow energy-storage system on the base and not contributing to the inertia of the arm itself, can lead to a 1:1 payload-to-weight ratio that is more in line with a human's own arm characteristics, and thereby provides a safe yet high-performance solution. An added benefit of this type of arrangement is that the movements of the arm will tend to be more human-like, providing a measure of confidence to the user that the robot is performing properly and moving in a safe way.

Strategies for improving safety have been proposed and methods to assess safety have been developed and adapted for rehabilitation robotics [53.151, 152] based on accepted risk analysis methods. While industrial robots have benefited from International Organization for Standardization (ISO) user safety regulations since 1992 (ISO 10218), the fundamental issue of human proximity to robots for the personal, service, and rehabilitation sectors have prevented any consensus to date for a similar standard. Currently, the existing industrial standards, augmented with provisions from medical equipment standards and buttressed by engineering best practices and adherence to professional codes of ethics by designers, have guided rehabilitation robotics designers. Clearly, as products appear on the market and the expected rapid expansion of this sector happens, better regulations must be developed.

Beyond safety, there are other ethical concerns that will emerge as robotics technology becomes more intelligent with advances in cognitive software, more invasive with nanotechnologies, and better integrated with human systems through bioengineering advances. Ethicists and roboticists are starting to deal with these issues [53.153, 154], which to date have been the purview of only futurists and science fiction writers. Chapter 64 in this Handbook deals with these issues in detail.

An economic advantage has not yet been demonstrated in a decisive way for most rehabilitation robotics. For example, the therapeutic benefits conferred by robotic therapy devices, and the assistive benefits conferred by wheelchair-mounted robots relative to the device cost, have not yet been large enough to cause widespread adoption. Improvements in their efficacy and reductions in their cost will increase their usage. For example, a robotic therapy device that helps people learn to walk after a stroke in a way that is decisively better than other training techniques would become widely used very quickly. Likewise, a wheelchair-mounted robot that gives a disabled person a substantial and efficient increase in autonomy at a reasonable cost would also quickly become widely used. An example of a robotics technology that has achieved an attractive cost–benefit ratio and thus is commercially successful is the powered wheelchair.

53.7 Conclusions and Further Readings

Rehabilitation robotics is a dynamic application area because its grand challenges are at the forefront of both robotics and biology research. The ongoing major themes of the field can be summarized as the development of robotic therapy devices, smart prostheses, orthoses, functional aids, and nurses that match or exceed the capabilities of their human counterparts. Rehabilitation robotics is also a highly motivating field because the technology developed will directly help people who are limited in major life activities. The field will continue to grow because of the dramatic aging of the populations of industrialized countries that is just beginning.

The grand challenges of rehabilitation robotics are grounded in the distinguishing features of the field: functional involvement with humans, a physical user interface, and behavior that is intelligent, adaptive, and safe. These characteristics require high levels of redundancy, sensorimotor capability, adaptability, and

multilevel software architecture. The grand challenges therefore span the domains of electromechanical design, software design, and, due to the applied and innately human-focused nature of rehabilitation robotics, all aspects of user interface design, including physical, communication, learning, emotional, and motivational factors. The first products in this field have come on the market in only the last ten years; worldwide demographic trends will provide the force to accelerate product development in the future.

For further investigation on rehabilitation robotics, there are three major sources of published information: (1) books on personal, service, and rehabilitation robotics such as [53.155–157]; (2) review articles in journals and periodicals such as [53.158–161]; and (3) articles that deal with individual topics, such as those in the reference list below, and conferences such as the International Conference on Rehabilitation

Robotics (ICORR), Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) conferences, RO-MAN, and the Association for the Advancement of Assistive Technology in Europe (AAATE) conferences, which are also represented in the refer-

ence list. Cutting-edge research will be reported on the websites of investigators at academic, government, and corporate research labs, and it is recommended to start at the sites of the researchers cited in this chapter.

Domestic Robotics

Erwin Prassler, Kazuhiro Kosuge

Who would not want to have a robot at home that vacuums the house, cleans the kitchen or the bathroom, loads or unloads the dishwasher, or polishes the shoes? In spite of the hundreds of millions of potential customers and users surprisingly few such robots exist. In this chapter, we first look into what it means not only to develop but also to commercialize a domestic robot. Using domestic cleaning robots as a representative example we look into the task details and its context. We also discuss the economic context and the market situation, and the technical challenges which slow down the triumphal procession of domestic robots. We will then have a look at the latest developments of domestic floor cleaning robots, robotic pool cleaners, and window cleaning robots. The survey of domestic cleaning robotics concludes with an outlook to new technologies that might help to solve some of the problems discussed at the beginning. The subsequent section then gives an account on the state of the art in robotic lawn mowing. The Section *Smart appliances* briefly surveys the latest developments in ironing robotics, intelligent refrigerators, and digital wardrobes. The Section *Smart homes* looks into a selection of ongoing and completed research projects in the field of smart environments and smart homes.

The section *Domestic robotics: It is the business case that matters* finally concludes with a contemplation of the market situation for domestic robots, business models, and some crucial insights into the commercialization of service robots.

The dream of having a robot in everybody's home is as old as the word *robot* itself. In Karel Čapek's famous play *Rossum's Universal Robots* there was already a commercial (poster) advertising for a personal robot: "... Cheap labor. Rossum's Robots. Robots for the tropics. 150 dollars each. Everyone should buy his own robot. Do you want to cheapen your output? Order Rossum's Robots."

Vacuuming the house, cleaning the kitchen and the bathroom, cleaning up the chaos in the children's play-

room, loading and unloading the dishwasher or the laundry machine, polishing the shoes, doing the ironing, stowing away the content of the shopping basket: the list of applications of robots in our homes seems endless. So the question seems appropriate: where are all these smart mechanical helpers that can take care of all these unpleasant tasks? Isn't there a huge market for such devices? Almost everybody would buy one.

There is good news and there is bad news regarding these questions. The good news is: domestic robots are

coming. The bad news is: they are coming very slowly, some of them may be more expensive than many people would like, and most of them will not be the 100% substitute of a robot housemaid or butler, which everybody would like to have.

In this chapter, we will present the state of the art in domestic robotics. We will describe some of the most recent developments in domestic cleaning robotics and a number of other smart appliances, including robotic lawn mowing, ironing robots, and digital wardrobes. We also include a section on smart homes. This may be considered as a borderline area of domestic robotics. However, since smart homes often use sensor, actor, and communication technologies which are very similar to that in *regular* domestic robotics, it is certainly more appropriate to include this topic rather than to exclude it.

Ideally, we would not only present the latest developments in all of the applications and areas above, but also look deeper into the task context, the economic context and market situation, and the fundamental technical problems and challenges. Ideally, we would also identify the emerging key technologies for each of these areas. This may, however, get a bit out of hand and also lead

to many redundancies. For example, the technical problems and challenges for domestic cleaning are not that different from the problems for robotic lawn-mowing. The same holds for the economic situation. So for the sake of a comprehensive treatment we provide a deeper investigation of these problems only for domestic cleaning robotics and confine ourselves to a report on the latest developments for the remaining applications.

Furthermore, since domestic cleaning robotics and robotics for professional cleaning are not entirely different subjects, we will try to provide a broader picture of the technical problems and the economic situation covering both areas. We will see that, especially for professional cleaning robots, the market analysis is somewhat easier to capture, since there are better statistics and more concise business models. Domestic cleaning and domestic robotics in general is still a bit of a gadget market, which is difficult to analyze and predict. So, the excursion to the professional application, while we are contemplating the more economic aspects of domestic and cleaning robotics, may be forgivable.

A discussion on the technology push, the market pull, and the pitfalls in which technology and business developers can easily be trapped concludes this chapter.

54.1 Cleaning Robots

54.1.1 The Task and Its Context

Task Analysis

On an abstract level, the task appears always the same: clean some workspace in the presence of obstacles. The instantiations of cleaning task, however, may differ significantly from environment to environment and from task context to task context. Assume, for example, the task is to clean a swimming pool. Most swimming pools have a rather simple geometric shape – most of them are rectangular – and hence the cleaning task is straightforward to automatize. Using odometry or some low-cost digital compass the pool cleaner should be able to sense and control its orientation and position. Area coverage is a matter of meandering between the walls at the bottom of the pool until the device is turned off or the battery is empty. Obstacle avoidance is mostly unnecessary in such a setting. Not surprisingly, automatically guided pool cleaners are well-established products, which have been on the market for many years. They are not always called robots though.

Now assume a large facility such as a shopping mall or a hospital or an airport with several floors, endless,

narrow and cluttered hallways and with many people moving around. Cleaning such an environment is apparently a different story. The cleaning robot most likely has to face an arbitrarily structured and cluttered three-dimensional (3-D) environment extending over many rooms and possibly over many floors and levels. *Optimal* navigation and operation basically requires 3-D sensing and 3-D modeling. How else should the robot be able to account for 3-D obstacles and navigate in a collision-free manner. Also area coverage becomes significantly more difficult.

The operation and maintenance of large facilities such as airports, shopping malls, or hospitals often involves work flows with a very tight schedule. Often the facilities are large enough to employ a fleet of cleaning robots rather than just one. Fleet management and multirobot coordination are required for optimal execution of the cleaning task. This is even more so when time matters and cleaning has to take place within small time windows. So the use of cleaning robots in such facilities means more than just turning on an off the robots and charging the batteries. It requires a careful integration of the automated service into a sensitive set of work flows.

The above two instances clearly illustrate the variations between cleaning tasks, and at this point we have not even looked into the specific needs and requirements of the surface which needs to be cleaned. Carpet apparently needs to be treated in a different manner from hard floor coverings such as wood or stone. The former needs to be vacuumed or brushed while the latter often requires wet cleaning. Vacuuming requires a significant amount of energy, which makes autonomous vacuuming by battery-powered cleaning robots almost impossible for large areas, scrubbing requires less energy, however often entails heavier devices, since the robots may have to carry nonnegligible volumes of cleaning liquid and dirty water.

In the following we have tried to list some of the typical *dimensions* of a cleaning task:

- containment of work space (enclosed, open)
- *complexity* of work space (cluttered, uncluttered, narrow, wide, static, dynamic)
- scale of work space (small, medium, large)
- dimension (2-D, 3-D)
- surface structure and orientation (even, uneven, horizontal, vertical, slanted)
- cleaning requirements

Economic Context and Market Situation

According to a figure from 1995 [54.1] the professional cleaning services only in Europe total approximately USD 50 billion per year. It can be expected that this figure has further increased in the past 10 years. Of these USD 50 billion about 78%, or USD 39 billion, account for labor, while the remaining USD 11 billion cover equipment, material, and overheads. All in all professional cleaning is a huge market. If one could only automatize a small fraction of these services it would be a billion-dollar or billion-euro business. These figures do not include the domestic market. In Germany alone there are about 40 million households and each needs to be cleaned and in each there is a vacuum cleaner, which is replaced every 6–8 years. If only 15% of these vacuum cleaners would be replaced by a robotic vacuum cleaner there would be a market volume of 1 million units per year.

Engineers and business people realized this potential a long time ago and have been developing cleaning robots for almost 20 years now. Surprisingly we did not see many of those cleaning robots until recently. Apparently, there must have been some problems, which were not only of technical nature. We will discuss these in greater detail at the end of this chapter, after having pre-

sented what is out there already. It should be mentioned, though, that the situation changed significantly, when a little inexpensive device, more of a toy than a cleaning machine, named Roomba came onto the market in 2002.

54.1.2 Technical Challenges

Besides the economical challenge to identify meaningful business cases, the automation of cleaning by means of robots also poses a number of technical challenges. From a scientific point of view these challenges seem to be (almost) solved, but many solutions are not much more than proofs of concept. These theoretical solutions basically work under laboratory conditions but have not been subjected to industrial conditions or faced any extended field tests under real working conditions. Companies that want to develop products often have to reinvent those solutions and adapt them to industrial needs.

The following list gives a short overview of such technical challenges inherent in the design of cleaning robots for domestic as well as professional use. Since the majority of developments in cleaning robotics have been mobile robots for floor cleaning, the list below may be slightly biased towards this application.

- absolute positioning
- area coverage in unknown, dynamic environments
- sensor coverage for robust obstacle avoidance
- error recovery
- safety
- operation interface/human–robot interaction
- multirobot coordination
- power supply

Absolute Positioning. Knowing its current position is essential for the operation of a cleaning robot that needs to cover thousands of square meters of cluttered work space. A cleaning robot must recover its position at every location in its workspace with a reasonable accuracy no matter how far it has traveled already. A robot which loses its position will not be able to execute its task reliably. For the customer this means that the service cannot be delivered regularly and reliably, which is not acceptable. The same holds for other reliability issues (see below), which can easily become liability issues.

There are a number of solutions to the absolute positioning problem. Landmark-based position estimation using passive artificial or natural landmarks is one approach to solve the problem. Position estimation with

active beacons (sonar, IR, radio) is another one. Both approaches are particularly suited for applications where the position has to be estimated sufficiently accurately over arbitrary distances.

Although positioning technology has matured sufficiently enough to enable reliable solutions not only for indoor but also for outdoor applications, one can find significantly more proofs of concepts than off-the-shelf solutions. This holds even more so for solutions with a reasonable price-to-performance ratio. In a later section we will briefly discuss some recent approaches based on smart sensor networks and radiofrequency identification ([RFID](#)) technology which may fill this need.

For a detailed discussion and comparison of the above and other approaches we refer to Chap. 37 *Simultaneous Localization and Mapping* or [54.2], where the latter is an excellent, but somewhat outdated state-of-the-art survey on robot positioning.

It is worth mentioning that existing domestic cleaning robots operate almost entirely without absolute position information. Without reliable position information, however, these robots cannot move in a deliberate manner. They can only move randomly in a *bang-and-bounce* mode and/or execute some hard-coded motion patterns. *Bang and bounce* means that the robot moves until it *bangs* into or sees an obstacle and then *bounces off* like a ball by turning around and moving on in an opposite direction. The area-covering performance of such an approach is rather poor (see the next paragraph).

Area Coverage. Motion planning for covering an unknown dynamic environment and absolute position estimation are key functions for systematically cleaning a workspace. The coverage problem – by nature a geometric problem – has been intensively studied in the literature (see [54.3] for a good overview) and quite a few interesting solutions have been proposed even for unknown environments. What is not straightforward at all is the transfer of these solutions from 2-D simulation environments into 3-D real world environments. Particularly the assumptions regarding the perception of the environment and the sensing modalities are often far more ideal than what has to be faced in the real world.

Again it should be noted that available domestic cleaning robots do not provide any systematic coverage of their workspace. They combine random motion with hard-coded motion patterns to achieve some minimal coverage. Given the moderate cost of these devices such a solution is acceptable for many private customers. For professional applications coverage by random mo-

tion has a far lower acceptance, or it may not be accepted by professionals at all. Professional cleaning has a strong association with a certain, guaranteed degree of coverage – it does not necessarily have to be 100% – and not with random motion.

Sensor Coverage. A comprehensive perception of the robot's surrounding is essential for safe, collision-free motion and also for the observation of unknown parts of the environment. So it is important for the safety of the robot and the surrounding objects or nearby animals or humans beings as well as for the successful completion of a mission or a task. Coverage means that the robot does not only perceive some small limited portion of its workspace – e.g., a 2-D range image taken at a certain height above the ground – but has a perception which enables it to account for every known or unknown obstacle or hazard in its surrounding environment. From an academic point of view this is again an almost solved issue. Sensor coverage in 3-D can be achieved by means of stereo vision or 3-D laser range finders. There is an abundance of literature treating this issue.

What remains to be solved is sensor coverage under everyday conditions including changing and adversarial lighting conditions, surfaces with little or no reflection or with little or no texture, and other unfavorable conditions.

The above holds primarily for cleaning robots for professional use. Cleaning robots for private homes have almost no sensors at all. For a device which must not cost more than say 300 USD, a sensor which costs 20 USD is a very expensive component. So adding more and more sensors to make the robot behave more intelligently is not necessarily a good solution as it may significantly increase the price of the robot.

Error Recovery. Every technical system is susceptible to errors. This seems to be a fundamental principle and no design can prevent this or account for every possible error. What is needed are mechanisms which either allow the robot to recover from possible or frequent failures or reach a failsafe position. A very frequent failure situation for a cleaning robot is being trapped in some obstacle structure. The control system must be able to recognize this and provide some escape mechanism or strategy. Other frequent errors are false sensor readings. The robot should be able to identify whether or not its sensors function properly. In the case of malfunction the faulty components should be switched off.

The ability to recover from errors is desirable for every robot, be it a cleaning robot or not. For a commer-

cial device this ability is, however, not only a desirable system property but also has an important economic aspect. Every malfunction which the device cannot recover from will cause a call to the service hotline and a request for repair or maintenance.

Safety. To operate an automatically guided vehicle such as a cleaning robot in a public environment a variety of machinery directives must be obeyed. According to the standard EN954, for example, every automatically guided vehicle needs a front bumper as a personnel protection device in the main travel direction. If the vehicle can reverse its direction it also needs a rear bumper. There are numerous other directives such as ANSI/ASME B56.5-2004 or EN1525:1998 which have to be taken into consideration and obeyed. An interesting insight into this subject is given, for example, in [54.4].

Domestic cleaning robots, given their low weight and low power, hardly create any danger for themselves or the environment. If they get annoying they are often small and light enough to be even kicked away. So the safety requirements for domestic robots are commonly less demanding than they are for professional cleaning robots. Still, many if not all available domestic robots have safety precautions, which satisfy for example EN954. Many have precautions to prevent falling over a cliff or staircases or being picked up and turned upside down or carried away.

Operation Interface/Human–Robot Interaction. The complexity of the operation interface of a device has a strong influence on its acceptance. Given that cleaning devices are typically operated by nontechnical personnel, the operation interface of a cleaning robot which is supposed to replace an existing cleaning device has to account for the needs and expectations of those users or operators. If the use of a cleaning robot would require special education, its use and acceptance would be severely limited. This suggests that the operation interface, for domestic as well as for professional cleaning robots, should be intuitive and straightforward.

Such a conclusion is certainly not false but also not entirely true. The operation interface of any device should allow the user to advance his/her skills in using the device. It should allow but not urge the interested user or operator to also use advanced features, e.g., advanced control or programming of the device.

The design of the operation interface is also influenced by the operation mode in which the robot is used. A fully autonomous robot may only need an on/off switch and an emergency button, while a teleoper-

ated device may have some sophisticated remote control including a sophisticated graphical user interface (GUI).

Multirobot Coordination. Cleaning a large workspace or large facility may easily exceed the capacity of a single robot in terms of onboard power, or cleaning liquid and other consumables, or time constraints imposed by the facility management. For cleaning large facilities the use of a multirobot system is self-suggesting. This raises a few questions, however.

The first one is task planning and coordination for multiple robots. For this central fleet management is required. The degree of automation provided by such a central fleet management may vary considerably. The fleet management might involve a sophisticated task planner, which autonomously decomposes the entire cleaning task and the workspace into subtasks and subworkspaces, which are then allocated to single robots. In such a setting the fleet management also needs to control the proper execution, i.e., by monitoring the position of the robots, and provide help in the case of errors. In a less automated solution, the fleet management is just a control center for a human operator. Task allocation and monitoring is then done by the human operator.

The fleet management can also be the *bridge* between the robots and the surrounding facility and the automated components therein, for example, the fleet management could open electric doors or call the elevators to allow the robots to move between several floors.

Another problem when using several robots is caused by active sensors such as sonar, infrared, or laser range finders. A robot might interpret a sensor signal which is actually emitted by another robot as the echo of its own sensors. Such false sensor readings severely affect position estimation, map building, and collision avoidance. Therefore the sensor signals of different robots either need to be synchronized or assigned a unique identifier so that the signals can be uniquely assigned to distinct robots.

Power Supply. Covering an area is not only an algorithmic problem. It requires traveling over considerable distances and therefore leads to a considerable power consumption. Since autonomous motion in a cluttered workspace rarely allows a power cord to be pulled behind the robot, power supply is typically provided by batteries and is typically limited. The limitations are due to the weight and the capacities of today's batteries. Domestic cleaning robots as described below claim to have an average operation period of 30–60 min per

charge. Professional cleaning robots often use regular 24 V lead-acid batteries for cars. They achieve longer operation periods per charge accordingly. The price for that, however, is a significant increase of weight, which in turn increases the requirements for safety precautions.

The limited power which is provided today by common battery technology also has an effect on the cleaning technology which can be used for autonomous cleaning. For example, it is nearly meaningless to design a true robotic vacuum cleaner for professional cleaning of larger areas as the energy consumption of vacuum cleaning is prohibitive. The weight of the batteries and the short operation periods per charge make it almost impracticable to use true vacuuming in cleaning robots. Industrial vacuum cleaners are rarely battery driven but typically have power cords.

In the following section we provide an overview of commercial domestic cleaning robots. Not included in this overview are academic proofs of concepts or industrial prototypes. This is partially due to the fact that academic research in this area has almost disappeared since the release of commercial products. Exempted from this are domestic window-cleaning robots. Although the technology is also available this application is still in its infancy and there are no commercial products.

We have divided our overview of domestic cleaning robots into three major categories: *floor-cleaning robots*, *pool cleaners*, and *window cleaners*. We intend to provide a representative but not complete overview of existing systems.

54.1.3 Domestic Floor-Cleaning Robots

Since the year 2000, more than a dozen domestic floor-cleaning robots have been released and a few more have been announced. In the following, we will glance over a total of 13 domestic floor-cleaning robots which were or are commercially available. We have excluded those that have only been announced but do not seem to be available (yet).

Trilobite 2.0, AB Electrolux (Sweden). In 2001, AB Electrolux in Sweden launched the home cleaning robot Trilobite 1.0. This was a milestone in the history of cleaning robotics. After some first developments of domestic cleaning robots in the beginning of the 1990s and even more developments but not very successful market launches of professional cleaning robots, Trilobite was the first home cleaning robot that became commercially available as a *mass product*. Trilobite uses a very sophisticated sonar system for navigation. This sonar

Fig. 54.1 Electrolux: Trilobite 2.0

system allows Trilobite to sense nearby environment and thereby detect and avoid collisions with obstacles. This is a capability which many of the cheaper systems described below do not have. The sonar system also allows Trilobite to follow the contour of obstacles such as walls. After undocking from its charging station, Trilobite explores its workspace by following the delimiting walls until it returns to its starting point. While on its exploration tour Trilobite integrates its sensor information into a map of the workspace. Having information about its workspace allows Trilobite to show a significantly better coverage performance than can be achieved by a pure random motion. Trilobite is not able to determine its position reliably, however, so it is not capable of real systematic coverage of the workspace. Special magnetic strips can be used to lock Trilobite in a room. They act as a wall and can be placed in doorways and other openings. An infrared sensor allows Trilobite furthermore to discover cliffs and stair cases. The price of a Trilobite 2.0 has dropped from around 1900 EUR at the time of the market launch in June 2004 to 1000 EUR in summer 2006.

Robocleaner RC3000, Kärcher GmbH (Germany). Four years after it was announced in 1999, Kärcher's Robocleaner RC3000 was launched in October 2003. RoboCleaner cleans a room by following a random motion pattern. By so doing it gradually covers the entire area which is to be cleaned. Through a sensor which monitors the pollution of the air sucked in it is even able to detect areas which are particularly polluted. When such an area is discovered RoboCleaner increases its suction power accordingly. It has an average cleaning performance of $15 \text{ m}^2/\text{h}$. Robocleaner RC3000 does not have a sophisticated sonar system like Trilobite 2.0 but uses only tactile sensors to discover collisions with obstacles. It even has tactile *cat-ear-shaped*

Table 54.1 Domestic cleaning robots in Europe

| Manufacturer | Electrolux | Karcher | Zucchetti | Friendly Robotics | RoboMop International |

sensors at its top which prevent it from getting stuck under a bed or a couch. While it is in many respects similar to the low-cost systems described below Robocleaner RC3000 has a unique feature which seems to be appreciated by its users: robocleaner very reliably returns to

its docking and charging station, once its battery gets low, which is typically after half an hour of operation. While Robocleaner recharges its batteries, its dust bin is emptied by the docking station which itself is a vacuum cleaner. So Robocleaner RC3000 can work unattended

Fig. 54.2 Kärcher: Robocleaner RC3000

for an extend period of time. With a price of about 1500 USD Robocleaner RC3000 is a rather high-priced device. The Robocleaner RC3000 was discontinued by Kärcher and is meanwhile distributed by Bosch-Siemens-Haushaltsgeräte under their own brand name.

Orazio, Zucchetti (Italy). Unlike Trilobite 2.0 and Robocleaner RC300, which are dry cleaners sweeping and vacuuming the floor, Orazio manufactured by Zucchetti, has an additional wet cleaning mode. Altogether it offers five cleaning modes: *continuous vacuuming*: vacuums continuously without use of detergents or cloths, carpets are recognized and get intensive care; *wet cloth*: floor surfaces are processed with a cleansing cloth dampened by detergent solutions, carpets are considered as obstacles and avoided; *dry cloth*: cleanses surfaces without the use of water or vacuuming, carpets are considered as obstacles and avoided; *wet cloth with vacuuming*: surfaces are processed with the cleansing cloth dampened by detergent solutions, when an obstacle is reached, Orazio backs off and vacuums accumulated particles for several seconds, carpets are considered as obstacles; *dry cloth with vacuuming*: cleanses surfaces without the use of water, when an obstacle is reached, Orazio backs off and vacuums accumulated particles, carpets can be considered as obstacles and be avoided or recognized for intensive treatment. Orazio uses only tactile sensing. If it bumps into an obstacle it bounces off and backs up for 5 cm, turns a random angle and then continues. Without any position and range sensing Orazio cannot achieve systematic coverage. Orazio's price ranges from 1299

Fig. 54.3 Zucchetti: Orazio

Fig. 54.4 Friendly Robotics: Friendly Vac

USD for single-floor apartments to 1799 USD for apartments with staircases (staircase detection is included in this case).

Friendly Vac, Friendly Robotics (Israel). Friendly Robotics released a robotic vacuum cleaner called Friendly Vac in 2004. Friendly Vac has a true vacuuming unit and hence claims to have a better cleaning performance than other home cleaning robots. It has an operation time of around 90 min per charge and can clean 100 m² during this time. Friendly Vac has range sensors which enable it to avoid collisions with obstacle and it can also sense stair cases and cliffs. Friendly Vac moves along parallel tracks to cover the cleaning area. If it encounters an obstacle it turns and moves in the opposite direction. With a height of 33 cm Friendly Vac is taller than any other home cleaning robot. It therefore lacks the ability to get underneath most furniture in a home. Also Friendly Vac has no docking station and therefore needs to be recharged manually. Friendly Vac costs 1450 USD.

Roomba and Scooba, iRobot Inc. (USA). The by far most-sold service robot is Roomba developed by iRobot Inc. in Burlington USA. According to an official statement in July 2006, iRobot has sold more than two million units since the product was released in 2002. Both of these events, the market launch of the first version of Roomba in 2002, and record sales figures reached four years afterwards, can certainly be counted as milestones in the history of service robotics. This overwhelming success, however, has little do to with Roomba's performance as a cleaning device – which is not paramount. It exclusively has to do with Roomba's price. Depending on the version, *Roomba Red*, *Roomba Discovery*, *Roomba Discovery SE*, *Roomba Scheduler*, the price for a Roomba ranges between 150 and 330 USD (July

2006). Regardless of its performance, Roomba was the first robotic appliance to have a price comparable to

**Fig. 54.5** iRobot: Roomba

a manually operated device. The robotic technology of Roomba is very simple. Roomba has a differential drive with two rubber wheels and a caster wheel in the front, which give good maneuverability. Roomba's chassis is suspended. If it is lifted the motors are shut off to prevent damage or injuries. The cleaning mechanism consists of a rotating cylindric brush at the underbody and a spinning side brush on the right. The cleaning mechanism is very sensitive to hairs, carpet tassel, and the like, which can block the mechanism. Roomba has four infrared cliff sensors, which protect it from following down staircases or other cliffs. It has further an infrared sensor which allows it to sense the distance to obstacles on its right and to follow the contour of walls or furniture. Roomba furthermore has a suspended front shield which is used as

a tactile sensor to discover collisions with objects. More recent versions of Roomba have also a dust sensor to recognize areas which are more heavily polluted. Roomba combines several locomotion heuristics to cover a certain area: *following a wall or the contour* of an obstacle using its infrared sensor, a *hard-coded spiral motion*, and a *randomized (zig-zag) motion* which is also used to escape from collisions. Roomba comes with a number of accessories. Roomba's workspace can be confined through so-called virtual walls. These are infrared beams emitted from separate virtual wall units, which can be sensed by Roomba and treated like obstacles. More recent versions of Roomba also come with a charger station, to which the robot returns once its battery gets low. The latest version *Roomba Scheduler* allows the user to program operation intervals in which Roomba shall become active.

A more recent development of iRobot is Scooba, a floor washer. Scooba has a different design and apparently uses a different cleaning technology, but otherwise it uses the same technology. It has the same differential drive system, the same sensor equipment, and uses the same navigation strategies. The price for a Scooba ranges from 300 to 400 USD (July 2006).

eVac Robotic Vacuum, The Sharper Image Inc. (USA). One of the strongest competitors of Roomba is the eVac Robotics Vacuum by The Sharper Image Inc. released in June 2004. The eVac Robotic Vacuum has an eye-catching design which looks more like the latest design of a modern vacuum cleaner than the flying saucer design of many of its fellows. According to Sharper Image eVac is a true vacuum cleaner with a traditional vacuuming motor. It does not only sweep dirt particles into a dust bin like many other so-called robotic vacuum cleaners. It must be stated though that eVac's vacuuming performance is still far below that of regular AC-powered vacuum cleaners. Except from the 5 inch wheels the drive system is very similar to that of Roomba. Also the navigation system is comparable apart from some details. eVac does not have any range sensors but only relies on tactile sensing. eVac has touch sensors in its front bumper. When this bumper comes into contact with an obstacle such as a wall or a piece of furniture it backs up a little, makes a slight turn, and then continues. Using its bumper eVac can quasi feel its way around an obstacle or along a wall. Like Roomba, eVac combines this contour-following behavior with random motion and with a hard-coded motion pattern. The hard-coded motion pattern consists of parallel tracks along which eVac moves back and forth. Underneath its bumper eVac has two infrared

Fig. 54.6 The Sharper Image: eVac Robotic Vacuum

sensors to detect drops and edges. Unlike Roomba, eVac does not use virtual walls. Instead it comes with four traffic cones which can be used to block a possible escape from the cleaning area. Since the cones can only be sensed by touch they are far less effective than Roomba's virtual walls. The eVac Robotic Vacuum can operate autonomously but can also be controlled by an operator through a radiofrequency (RF) remote control.

While the systems described so far all had some unique features the following two robots seem to be more or less Roomba clones.

CleanMate, Metapo Inc. (USA). The cleaning robot CleanMate 365, released by Metapo in 2005, has five preprogrammed moving patterns: spiral, special bounce, along wall, s-shape, and polygonal spiral. It iterates through a fixed sequence of these patterns as long as it is in operation, moving at a speed of 35 cm/s. CleanMate 365 has a suspended front shield, which it uses as bumper, and photosensors that detect stairs and prevent CleanMate from falling down. Cleanmate 365's *uniqueness* comes from two minor features. It has a light sensor which enables it to show a helpful behavior. Once its battery gets low CleanMate 365 searches for more light. It moves from darker areas, e.g., from underneath a bed,

Fig. 54.7 Metapo: CleanMate 365

Fig. 54.8 Black & Decker: Zoombot Vacuum

to brighter areas. So, it can be easily found when it has run out of power. Also Cleanmate 365 has an ultraviolet tube attached which can generate ozone to provide disinfection. CleanMate 365 sells for around 200 USD.

Zoombot, Black & Decker Inc. (USA). Nearly unbeatable in terms of price is Black & Decker's Zoombot RV500, which sells for less than 100 USD. In spite of this low price, the robotic technology is basically the same as for a Roomba or for a Karcher Robocleaner RC 3000, which is more than ten times as expensive. Zoombot uses a touch sensor in its front shield for collision detection. After a collision it backs up, turns around, and continues cleaning. It uses motion patterns such as spirals, wall-following, zig-zagging and a random motion to cover the cleaning area. Zoombot has cliff sensors under the bumper to detect drops such as ledges and stairs. It seems, however, that the mechanical design and also the cleaning technology and hence the cleaning performance of Zoombot are clearly inferior to that of all other home cleaning robots discussed so far. It leaves dirt behind and moves considerably slower than its competitors. Zoombot, however, is not the cheapest cleaning robot, as we will see in the next paragraph, although this even cheaper fellow hardly deserves to be called a robot.

RoboMop, RoboMop International (Norway). RoboMop is not what we would consider a typical mobile robot. It merely consists of two parts: a self-propelled *robotic ball*, which pushes an aluminum *cleaning frame*. Attached to the underside of the cleaning frame is a disposable electrostatic pad, which picks up dust as RoboMop moves. RoboMop does not have any motion or coverage strategy or algorithm. It keeps rolling straight as long as nothing blocks its motion. Once it hits an object it physically bounces off the surface like a ball and then keeps moving again. So there is no robotic in-

Fig. 54.9 RoboMop International: RoboMop (RoboMaid in the US)

telligence whatsoever behind RoboMop. RoboMop is really just a self-propelled ball or sphere. There are no sensors which prevent RoboMop from falling down staircases or becoming hung by a cord. However, in spite of the obvious shortcomings of RoboMop it is still an amazing device. It shines in terms of the simplicity of its technology, and it sells for less than 30 EUR. For this amount, the price-to-performance ratio is almost unbeatable, even if it gets stuck every once in a while and cannot vacuum the carpet. The maintenance is manageable and so is the number of components which can break. One simply must not step upon it.

Ottoro, Hanool Robotics Inc. (South Korea). The Cadillac amongst the home cleaning robots is Ottoro made by Hanool Robotics and released in 2003. This comment holds in any respect, including its price of 3400 USD. Ottoro has the most luxurious sensor configuration of all the robots described in this chapter. It has two digital cameras onboard. One of them is specifically devoted to estimate Ottoro's position using a light pattern projected onto the ceiling by Ottoro's base and charge station.

Fig. 54.10 Hanool Robotics: Ottoro

| Status (06/2007) | Available (only in Asia) | Available (only in Asia) | Available (only in Asia) | Available |

With this, Ottoro is possibly the only domestic cleaning robot that can estimate its position with respect to the base's reference system. According to the product specifications Ottoro senses its position with an accuracy of ± 3 cm. A problem of course arises if Ottoro leaves the area from which the light pattern on the ceiling is visible. Besides the two cameras Ottoro uses 12 pairs of ultrasonic sensors for safe navigation and obstacle avoid-

ance. Furthermore *highly sensitive* air bumper sensors are wrapped around Ottoro's chassis. With the ability to estimate its position with a reasonable accuracy, Ottoro does not have to rely on random motion or other motion heuristics to cover the cleaning area. Based on a map of the work space Ottoro can plan a systematic cleaning path, monitor its execution by its location sensor, and also register the cleaned area to avoid multiple vis-

its and inefficient coverage. Ottoro not only has a unique sensor configuration but also uses a unique drive system and a suction spout (*Ottoro's hand*). Its drive systems consists of three *moveable* wheels (three-wheel synchro-drive), which allows Ottoro to move instantly in any direction from any location. Its suction spout allows Ottoro to clean corners and spots which are out of reach for any other domestic cleaning robot.

In summary, Ottoro is a rather unique exemplar amongst existing domestic cleaning robots as it makes full use of the state-of-the-art technology in mobile robot navigation. Apparently this does not come for free. It is unknown how many units of Ottoro have been sold.

RoboKing V-R4000, LG (South Korea). The second out of the four South-Korean-made domestic cleaning robots is Roboking (model name: V-R 4000). Roboking's sensory equipment and design is not as luxurious as that of Ottoro and not as expensive, but is still impressive. Roboking is controlled by a 32 bit digital signal processor (DSP). It uses a gyro sensor to monitor its motion and control its position. This is a valuable extension to position control based purely on odometry, but it does not give absolute position like Ottoro's localization system. Besides the gyroscope Roboking has seven infrared sensors for obstacle avoidance, three cliff sensors, two shaft encoders, three bumper sensors, a wheel-sinking sensor, a dust amount and dust bag sensor, and two rotational brush driving sensors. Depending on the *cleaning circumstances* Roboking can switch between four cleaning patterns: *immaculate cleaning/gyro matrix moving*, in which the robot moves in a left-to-right lattice pattern followed by an up-and-down lattice pattern; *perfect cleaning/variable matrix moving*, in which the robot moves in a small lattice pattern and expands its motion pattern when reaching larger free space; *intensive cleaning/spiral moving*, in which the robot spirals around a specific space to clean it; *fast cleaning/random moving*, in which the robot moves randomly and not on a fixed pattern. LG further advertises the powerful

Fig. 54.12 Samsung: VC-RP30W Robotic Vacuum

brushless direct current (**BLDC**) suction motor (120 W) and the lithium polymer (Li-Po) batteries of Roboking. Roboking sells for around 900 USD.

VC-RS60 Robotic Vacuum, Samsung (South Korea). Not much information is available on the VC-RS60 Robotic Vacuum announced by Samsung in November 2003. It has a webcam which can even be accessed through the Internet, so that the user can control the operation while elsewhere. The VC-RS60 can be programmed to work at specific times like Roomba Scheduler. Is is said to create a 3-D map of the environment to identify its relative location, enabling faster and more efficient cleaning of a defined area. In July 2006, Samsung released a revised model, the VC-RS60, which even offers voice control. The new model, which seems to be available only for the Korean market at this time, sells for approximately 750 USD.

Iclebo, Yujin Robotics (South Korea). While its three compatriots were distinct enough in their technical design not to be put into one class with the Roomba family, the design of Iclebo and its upgrades is very similar to that of Roomba. It combines a number of heuristics such as bump and bounce, wall following, moving on parallel tracks or on a circular trajectory. It has a set of seven infrared sensors to monitor the surrounding workspace and uses three optical cliff sensors to keep it away from

Fig. 54.11 LG: RoboKing V-R4000

Fig. 54.13 Yujin Robotics: Iclebo

staircases and ledges. Iclebo has three filter systems: an antibacterial filter, an electrostatic filter, and a semi-high efficiency-particulate airfilter (HEPA). Iclebo was released by Yujin Robotics in summer 2005 and sells for around 500 USD.

54.1.4 Pool-Cleaning Robots

Domestic cleaning robots, in spite of promising sales figure, are still struggling to get rid of the reputation of being exotic devices or toys and to become regular appliances. Pool-cleaning robots never really had such problems. Robotic pool cleaners have been established products for years. This may be due to the fact that the challenge of cleaning a rectangular pool is rather modest and so is the *robotic technology* used in robotic pool cleaners. Given the liquid surrounding there is not much sensing other then motor encoders and measuring the motor current for obstacle detection. In the following we only describe the three cleaners which are the most established.

Aquabot, Aqua Products (USA). Aquabot is an automatic pool cleaner for residential pools. It uses two sealed high-quality motors. One motor causes the drive belts and drive tracks to move the unit. They also cause the front and rear scrubbing brushes to clean the pool surface, walls, and steps. The second motor is the pump motor, which generates extremely powerful suction so that Aquabot is not only able to filter the water but can also climb up the pool walls to the waterline. Aquabot has an external power supply through a floating power cord. Aquabot and Aquabot Turbo alternate between two cleaning patterns. One is a zigzag motion, where the wall is used as a navigational aid. Whenever Aquabot hits the wall of the pool it reverses its direction and moves to-

Fig. 54.14 Aqua Products: Aquabot

wards the pool center at a certain angle. On each pass it covers roughly 60% of the pool area. The second pattern is a rectangular meander pattern, where again the wall is used as a navigational aid. Augabot has a sensor to detect obstacles such as walls or heavier objects at the bottom of the pool appearing in front of it. Once it discovers a collision it reverses direction and continues moving in the opposite direction. Aquabot (Turbo) has a cleaning performance of 315 square meters per hour and sells for approximately 850 USD.

TigerShark Pool Cleaner, Aquavac (USA). TigerShark is the basic model of a product line of xShark robotic cleaners by Aquavac Systems. The basic design of TigerShark is very similar to that of Aquabot. It is equipped with two polyurethane drive tracks. TigerSharks motors – one for locomotion, one for the suction unit – are sealed in a motor unit. It has a *calculated* ground speed of 15 meters per minute and a work cycle of 5 h. TigerShark's cleaning unit consists of a suction pump with a suction rate of 300 liters per min and a removable, reusable, cartridge filter. TigerShark's suction power creates enough adhesion to let it climb up the walls of the pool. Very little information is available on TigerShark's control system and its coverage strategy. According to the user manual TigerShark is equipped with an adaptive seek control logic (**ASCL**) microprocessor which can sense the pool contour and calculate an efficient motion pattern to achieve coverage. Unfortunately, it remains a secret exactly how the contour is sensed and how the motion pattern is calculated. A reasonable guess is that both Aquabot and TigerShark measure the motor current to sense an obstacle in their way. Like Aquabot, TigerShark sells for around 850 USD.

Fig. 54.15 Aquavac: TigerShark Pool Cleaner

Fig. 54.16 Maytronics: Dolphin Diagnostic 2001

Dolphin Diagnostic 2001, Maytronics (Israel). Dolphin Diagnostic 2001 is the best-selling member of a whole family of Dolphin automatic pool cleaners manufactured by Maytronics in Israel. Dolphin Diagnostic 2001 seems to differ from TigerShark by Aquavac only in color. A careful look into the user manuals and into the technical drawings is required to identify differences in the mechanical design. Dolphin Diagnostic 2001 is slightly lighter than TigerShark and has slightly less suction power. It has a ground speed of 15 m/min and a coverage rate of 350 m²/h. Dolphin Diagnostic 2001 is capable of exploring the size and shape of a pool and calculating an efficient cleaning pattern. As for the Tigershark it remains unclear how the exploration and calculation of a cleaning pattern work. The manufacturer, Maytronics, does not reveal any information on this. Dolphin Diagnostic 2001 has an integrated air sensor which will detect if the cleaner has left the water, turn itself around, and crawl back into the water to continue cleaning. Maytronics advertises Dolphin's diagnostic capabilities. The cleaner runs a constant self-diagnostic program and allows technicians to instantly download information about the operation of the unit for in-the-field diagnostics and on-site repair. Dolphin automatic pool cleaners range from 800 USD for residential cleaners to 5000 USD for professional cleaners used for public pools.

54.1.5 Window-Cleaning Robots

While robotic pool cleaners and also domestic floor-cleaning robots have become established and accepted products, the automation of another area of domestic cleaning is still in its infancy: window cleaning. The reasons for this are not too difficult to find. Windows in private homes are cleaned far less often than the floor. Who would buy a robot for automatizing a task

which needs to be done every once in a while and how much would he or she pay for it? The answer is certainly frustrating for somebody who wants to develop window-cleaning robots for domestic applications. While floor cleaners do not bother about gravity and falling down unless they are near staircases or ledges, gravity is an essential problem for window-cleaning robots, and the solutions are usually not very cheap. Special mechanism have to be designed for secure motion. Typically special tether mechanism prevent the robots from falling. Special locomotion mechanisms have to create enough adhesion force to hold a robot attached to a flat, vertical, damageable surface such as glass and at the same time move the body up and down and sideward. These mechanisms have to be small and light and create enough adhesion forces and must have low energy and resource consumption. The cost for those mechanisms are typically far beyond the price even of expensive appliances. This may explain why there are no commercial domestic window-cleaning robots available at present.

Robots which have to climb up even vertical surfaces often use caterpillar drives which are equipped with passive or active suction cups. Passive means that the system does not actively create a vacuum in the cup. Rather a small valve aerates or seals the suction cup depending on the position of the cup along the drive. Drives with passive suction cups have the advantage of moderate energy consumption. They have, however, one severe disadvantage. They tend to lose their adhesion after a while. The reason for this is a torque which acts on the center of gravity of the system. Due to this torque there is a traction force acting on the upper cups while at the same time pressure is exerted on the lower cups. Without any attractive force acting on the upper cups the adhesion there gets weaker and eventually the system falls. Therefore passive suction cups are rarely practicable.

An apparent solution to this problem is the use of active suction pumps, which generate a vacuum under the upper suction cups. This solution prevents the system from falling. However, supplying the vacuum to the cups makes the system significantly more complex, heavier, and larger. Researchers at Fraunhofer IPA [54.5] have therefore invented a smart solution which gets by with passive cups, but gets around the problem of decreasing adhesion. The solution uses a spacer at the rear of the vehicle. This spacer (see Fig. 54.17) neutralizes the torque around the center of gravity which is typical for a systems with passive suction cups. The spacer causes a traction force which acts on the lower suction cups. This traction force creates a torque around the spacer,

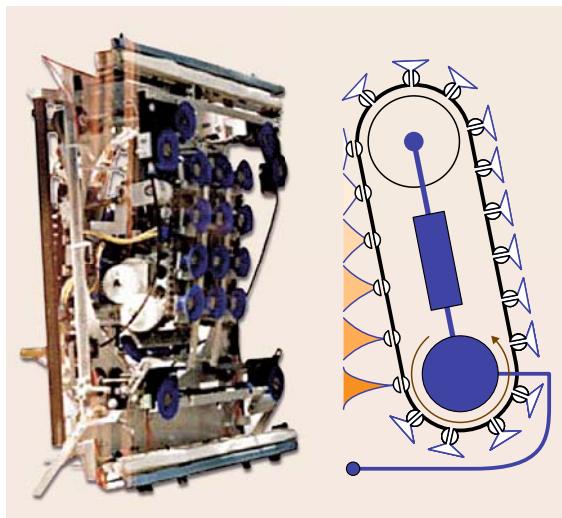

Fig. 54.17 Fraunhofer IPA: climbing robots with passive suction cups

which counteracts the torque around the center of gravity and also causes a pressure on the upper suction cups.

RACOON, Fraunhofer IPA/Procter & Gamble, (Germany). RACOON is a window-cleaning robot which was developed in a joint venture between Procter & Gamble and Fraunhofer IPA and was presented during the Hannover Fair 2002. RACOON uses passive suction cups with a spacer as described above. RACOON was developed as a demonstrator for automatic domestic window cleaning. Given its size and weight, the design shown in Fig. 54.18 below was not really intended to become a product.

Fig. 54.18 Fraunhofer IPA: the window cleaner Raccoon

Fig. 54.19 Fraunhofer IPA: bottom view of QUIRL

Fig. 54.20 Fraunhofer IPA: QUIRL design study

QUIRL, Fraunhofer IPA, (Germany). With the window cleaner QUIRL Fraunhofer IPA presented a successor of RACOON with a totally revised design. In QUIRL, the number of components, the weight, and the size of the system were significantly optimized, as can be seen in the figures 54.19 and 54.20. The main functions *cleaning*, *holding*, and *moving* were unified in one single component. The prototype of QUIRL consists of two vacuum cups which are attached to a common frame and which are driven by two separate motors and rotate independently of each other. The overall motion of QUIRL can be controlled by selecting the velocities and rotational directions of the vacuum cups. If the motor of one vacuum cup is turned off and the cup does not rotate, QUIRL rotates around this fixed cup. If both motors and cups rotate in the same direction this leads to an overall rotation of QUIRL about its vertical axis. If both drives rotate in the opposite direction at exactly the same velocity then QUIRL makes a linear motion. If both drives rotate in the opposite direction but their velocities are not identical then the translational motion is superimposed by a rotational motion and QUIRL moves along a curved trajectory. In order to clean the surface some cleaning mechanism or tool needs to be fixed to the vacuum cups. By attaching, for example, specific cleaning

towels in the cups the abrasion effect is increased and a very good cleaning performance can be achieved. In summary, by implementing the cleaning, holding, and moving function by one single mechanism the system complexity of QUIRL, its weight, its size, and not to forget its cost could be significantly reduced. QUIRL is described in more detail in [54.5]. There is only one problem: QUIRL is still waiting to become a product.

54.1.6 Old Problems, New Technologies

In this section we discuss some new technologies which seem to have the potential to solve some of the pressing technical issues discussed in Sect. 54.1.2. The following is a list of the most promising of such enabling technologies:

- low-cost (3-D) sensing (photonic mixer device (**PMD**) or other technology in mass manufacturing)
- low-cost absolute localization (local positioning systems), sensor networks
- new energy concepts such a fuel cells

Should the promises come true and the potential of these enabling technologies materialize then they might in fact lead to a considerable increase of the acceptance and use of cleaning robots in domestic as much as in professional environments.

3-D Sensing (at Low Cost). We have learned above that sensor coverage and a comprehensive perception of the workspace are fundamental for the safe operation of a cleaning robot. Sensor coverage at present is certainly possible but at a high price. This situation seems to be changing with the arrival of small 3-D time-of-flight range cameras such as the SwissRanger SR-3000 [54.6]. These cameras use highly sensitive, custom-made complementary metal–oxide–semiconductor (CMOS)/charge-coupled device (**CCD**) image sensors and measure the time of flight (**TOF**) of an emitted light wave in the near-infrared spectrum.

The development of this sensor technology was primarily driven by the automotive industry for safety applications. Hence the expectation is that there is a mass market and the sensor can be produced and distributed at a reasonable price. It was predicted that the price of these 3-D range cameras would come down to the level of an expensive webcam. At present the price for a single unit is still in the order of 5000 EUR, which means that its enabling features are somewhat hampered by the cost.

Absolute Localization (at Low Cost). A radical solution to the absolute positioning problem is to cast the workspace with a sufficiently large and dense network of artificial markers or beacons, which can be sensed by the robot nearly from everywhere in the workspace. An overview of such approaches and systems developed in the recent past is given in [54.7].

A very recent approach has been developed in a joint venture of two German companies: Vorwerk Teppichwerke, a carpet manufacturer, and InMach Intelligente Maschinen, a developer of robot control and navigation systems. This approach uses a so-called *smart floor* [54.8] to support robot position estimation and navigation over large distances. The core idea of the smart floor is to distribute and integrate **RFID** transponders in the floor in an area-covering manner and use the transponders for various purposes. Since integration into the floor covering itself would complicate the manufacturing and increase the price of the floor covering and would have to be implemented separately and specifically for every type of floor covering, Vorwerk Teppichwerke has developed a so-called *smart underlay* (see Fig. 54.21).

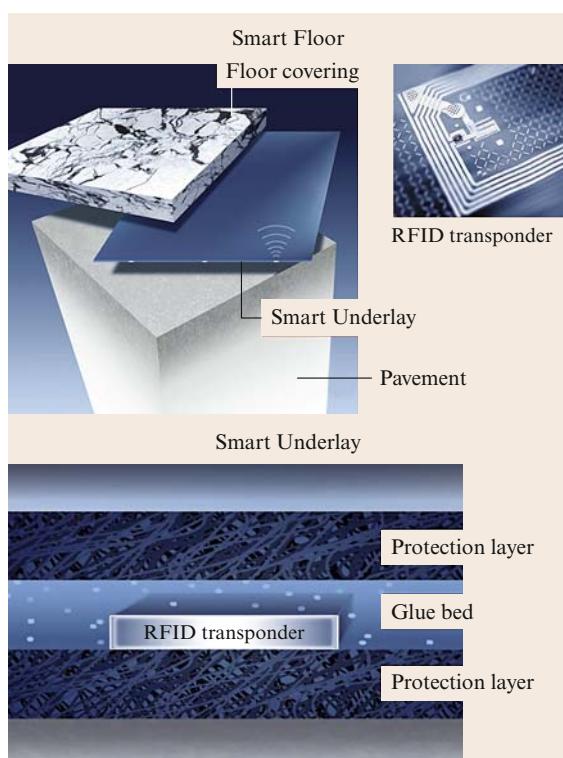

Fig. 54.21 The design of smart underlay and smart floor

Fig. 54.22 CeBIT 2006: smart underlay placed under carpet, laminate, tile, and PVC

Fig. 54.23 Professional cleaning robot Robo40 navigating on smart floor

The smart underlay is a separate mat-like textile, in which the **RFID** transponders are integrated, typically in a regular grid. This underlay can be placed nearly below every nonmetallic floor covering. During CeBIT 2006, the world's largest information technology (IT) fair, the smart underlay concept was demonstrated to the public. The smart underlay was placed under four different floor coverings: carpet, laminate, tile, polyvinyl chloride (PVC) (see Fig. 54.22). The Swiss-German cleaning robot Robo40, shown in Fig. 54.23, is the first one to operate and navigate on such a smart floor. It is equipped with **RFID**-based navigation system which uses the **RFID** tags integrated into the underlay to estimate the position and control the locomotion of the robot [54.9].

The above system is not per se low-cost or much cheaper than other ones involving expensive sensors and sensing. That is true even if the cost of a **RFID**

tag, which is around 30 to 40 EUR cents at present, are dropping further. After all, several thousands of square meters may have to be equipped with **RFID** tags or other sensors or markers with additional costs of up to several euros/dollars per square meter. Whether or not such an investment pays off and whether the price-to-performance ratio is acceptable for the customer very much depends on the specific application. In many applications only the automation of cleaning and some logistic and transportation functions justify and pay-off the investment in a smart infrastructure or a smart floor. Often there is a range of additional services or functions facilitated by such a smart environment, e.g., location-based services and other ubiquitous computing functions, which yield an even better return on investment. A common feature of solutions such as those described is undoubtedly that they enable robust and reliable absolute position estimation over arbitrary distances.

An alternative solution to wide-area indoor localization is the NorthStar system developed by Evolution Robotics. The idea underlying NorthStar is to project infrared light patterns onto the ceiling above the robot's workspace and use these patterns for position estimation very much like old sailors used the stars in the sky, including the north star, to determine their positions in the vastness of the seas. NorthStar consists of two types of components: one or more IR projectors, which emit a collimated IR beam with a unique signature which leaves a unique IR light pattern on the ceiling, and a detector which uses a triangulation algorithm to estimate the position and heading in relation to the IR light pattern on the ceiling. The basic setup of a NorthStar system is shown in Fig. 54.24. The distance between

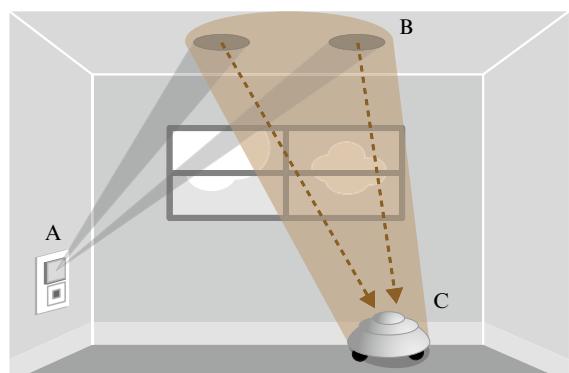

Fig. 54.24 Basic setup of a NorthStar system with an IR projector(s) mounted at fixed positions and a mobile detector carried, for example, by a robot

the detector plane and light plane must not exceed 6 m according to the product specification. Covering a larger workspace requires a rather dense network of projectors to be installed. Given that one projector sells for around 600 USD, this may become quite costly. It may be the case, however, that for a larger installation the price for one projector unit comes down significantly.

New Energy Concepts. In the preceding section it has become evident that energy consumption and power supply have a significant impact on the design and use of cleaning robots. A cleaning device which needs to be

recharged every hour is useless for professional cleaning. Therefore better and more efficient power supply concepts are a burning issue in cleaning robotics.

A promising solution for the power supply problem, although not exhaustively investigated, may be fuel cells. A first practical application has been reported in [54.10]. The Tokyo-based company Sohgo Security has been developing a sentinel robot equipped with a fuel-cell battery that is supposed to work round the clock for one week without a recharge. The fuel-cell battery is to be supplied by Yuasa Corp., a Japanese battery manufacturer.

54.2 Lawn-Mowing Robots

As popular as domestic cleaning robots are robotic lawn-mowers. It may be somewhat surprising that the first commercial robotic lawn mower was released as early as 1995, long before any commercial domestic cleaning robot was in sight. This may be due to the fact that lawn-mowing is a domain where the performance requirements are not as critical and the customer expectations are not as high as in domestic cleaning.

Cleaning robots and lawn-mowing robot share a great deal of technical problems (see Sect. 54.1.2) and also solutions. Apart from the different services, cleaning versus mowing, and the different application-specific processing units, there are just minor differences in the basic system designs. Most lawn-mowing robots have differential drive systems with castor wheels. They use sensor equipment for navigation similar to that of cleaning robots and they use similar coverage strategies, mostly a bang-and-bounce strategy.

Since robotic lawn-mowers work outdoors, they can run away. To prevent this they are often kept enclosed by virtual fences. These are wires buried in the ground that emit an electromagnetic field which can be sensed by the robots and push them back. All robotic lawn-mowers have lift protection as an essential safety mechanism. The cutting mechanism is immediately shut off once the robot is lifted or falls upside down.

Given that the majority of humankind lives in cities, the market size for robotic lawn-mowers is certainly smaller than that for robotic cleaning devices. This may explain why the number of brands of robotic lawn-mowers that are available is also smaller than that of cleaning robots. In the following we describe the three most established commercial system and a fourth system which was introduced recently.

AutoMower, Husqvarna/Electrolux (Sweden). The father of all domestic robots, if not of all commercial service robots, is the predecessor of the AutoMower manufactured by Husqvarna, a subsidiary of the Electrolux group, Sweden. This predecessor, SolarMower, was released as early as 1995: earlier as any other known commercial domestic service robot. Unlike SolarMower, which was powered by a solar panel placed on top of the robot, AutoMower is powered by nickel–metal hydride batteries. When running out of power AutoMower returns to a charging station and recharges its batteries. A normal recharge takes approximately 1.5 h. Fully charged AutoMower can operate for up to 2 h. AutoMower is a lightweight amongst the robotic lawn mowers, weighing only 8.5 kg.

AutoMower's cutting mechanism consists of a rotating disc with three razor-like blades which automatically retract into their mountings if AutoMower is stopped unscheduled, for example, if it hit an obstacle or is lifted. It is important for the proper functioning of AutoMower that the lawn which is to be cut is not too high. This in turn requires a rather regular if not continuous operation of AutoMower. With regular use of AutoMower the

Fig. 54.25 Husqvarna/Electrolux: AutoMower

grass cuttings are short enough to quickly decompose into nutritious compost, so there is no need to remove the cuttings after the lawn is mowed.

AutoMower has no position or range sensors which would allow keeping track of its motion. It uses a random motion pattern to cover its work space and keep the lawn at an equal height. To prevent AutoMower from running away from its workspace a low-voltage induction cable is buried around the lawn. Once AutoMower senses this cable it stops, reverses its direction away from the cable, and then moves on towards the inner area of the workspace. Using this random motion and a bang-and-bounce strategy AutoMower can maintain an area of up to 1500 m^2 . AutoMower is sold for approximately 2000 EUR.

RoboMower, FriendlyRobotics (Israel). Friendly Robotics (formerly Friendly Machines) also started developing a robotic lawnmower *Lawnkeeper* in 1995. Several product iterations finally led to the current product family RoboMower RL 850 and RoboMower RL 1000. With a weight of 22.5 kg without batteries RoboMower is significantly heavier than Automower. It is powered by two maintenance-free $2 \times 17 \text{ AH}$ sealed lead-acid batteries with a charging time of approximately 20 h.

RoboMower is equipped with touch sensors around its hull. If it collides with an obstacle it senses the contact, stops, turns around, and moves on in the opposite direction. RoboMower has furthermore sensors to detect the wire which is buried around RoboMower's work space. Although it has no position or range sensor RoboMower does not move entirely randomly. By using the buried wire as a reference and moving in a zigzag pattern in the confined area it can achieve a better coverage performance than a pure random motion would allow. To achieve good cutting performance RoboMower still needs to cover its workspace several

Fig. 54.26 Friendly Robotics: RoboMower 850

Fig. 54.27 Zucchetti: LawnBott Evolution

times. Using this strategy RoboMower RL 850 can mow and maintain an area of approx. 1000 m^2 . RoboMower RL 850 without a docking station sells for USD 1000. RoboMower RL 1000 with a docking station sells for 1500 USD.

LawnBott, Zucchetti (Italy). A whole series of lawn-mowing robots have been developed by Zucchetti, Italy. LawnBotts (Professional, Deluxe, Evolution, Quattro) come with slightly different designs, features, and prices but do not substantially differ in their robotics technology. Also, the differences with respect to the previously described systems are minor.

LawnBott's workspace needs to be delineated by either an induction wire buried around the cutting area or by a fence which is at least 10 cm high. LawnBott uses a bang-and-bounce strategy to deal with obstacles. Coverage is achieved by random motion. LawnBott senses the height of the grass. If it discovers a spot with high grass, it stops moving randomly and enters a specific motion pattern. Starting at the spot with the higher grass it moves along a spiral until it reaches an area where the grass has nominal height again.

All LawnBott models are equipped with a wet grass sensor, which discovers when rain starts falling and sends the robot back to its base station. LawnBott's base and recharging station looks like a small garage and accommodates the robot entirely, so it is protected against rain and storms. All LawnBott models have a coverage performance of around $270 \text{ m}^2/\text{h}$ and can cover an area of 3300 m^2 in total. The price of the LawnBott models ranges between USD 1850 and 2500.

RobotCut, Brill (Germany). A rather recent development with an eye-catching design is RobotCut, developed by the German companies Brill and InMach Intelligente Maschinen and commercialized by Brill. RobotCut was

Fig. 54.28 Brill: RobotCut

presented at GAFA 2006, an international fair for garden equipment, in Cologne, Germany. Unlike its competi-

tors, which all use a rotating disc as cutting mechanisms, RobotCut uses a spindel cutting system, which claims to create a rather uniform cutting image. RobotCut has two rather large propelled front wheels which give the vehicle additional stability. RobotCut has a cutting width of 38 cm. The cutting height can easily be adjusted by screws at the rear castor wheels. RobotCut's brain is the so-called *optimized guidance system*, which enables the robot to move along parallel tracks and avoid random motions. RobotCut is designed to cover an area of 2500 m². RobotCut will be delivered in several versions, with a high-end version also being equipped with sonar for obstacle avoidance. RobotCut is announced for 1500 EUR.

54.3 Smart Appliances

The term *smart appliance*, although well established and widely used, seems to be everything but well defined. A Google search returned no fewer than 27 400 entries for *smart appliance* at the time when this text was written. Very often the term *smart* is used as a synonym for *networked*, referring to devices which are connected to and can communicate with the Internet. Smart appliances are often referred to in the context of home automation and ambient intelligence.

Our understanding of this term is somewhat narrower. What we have in mind when we talk about *smart appliances* are appliances which in one way or another use robotic technology (sensors, actors, smart control systems). Although it might seem to be more appropriate to then talk about *robotic appliances* we refrain from doing so, since we do not see a need to draw a clear line between *robotic appliances* and *smart appliance* at large.

One reason for this is that there are not that many *robotic appliances* other than the cleaning and lawn-mowing robots, which we have already described. In spite of the endless list of tasks which people might want to delegate to some kind of robot we found only two more applications which might be counted as *some kind of robot* in a colloquial sense. In both applications there is a degree of actuation and automation involved, which is enough reason for us to include them in a chapter on domestic robotics. The three applications described in the following three sections are: *ironing robots*, *intelligent refrigerators*, and so-called *digital or smart wardrobes*.

54.3.1 Ironing Robots

The plural in the title may raise wrong expectation. During our search we actually came only across a single device which was called as ironing robot even by its inventors: *Siemens Dressman* (also distributed as *Bosch ShirtMaster*).

Dressman, Siemens (Germany). The Siemens Dressman ironing robot complies with the definition of a robot

Fig. 54.29 Siemens: Ironing robot Dressman

only in the wider sense. It is a machine which automatizes a certain service, which is disliked by many people: ironing. More specifically, Dressman is designed to *iron* shirts. It does so by means of an inflatable torso made of parachute silk material. Once the shirt is stripped over the torso it is inflated with hot air in its interior. This hot air presses and dries the shirt. Creases are removed during this process. The hot air is created in a heater box in the underbody of the device. The torso adjusts perfectly to that of the garment, allowing the pressing of all kinds of shirts, including short-sleeved ones. When the ironing process has finished Dressman exhausts cold air for one minute in order to stabilize the cloth and prolong the ironing effect. The inflatable torso can accommodate shirts in European sizes of 35 to 50 (XS to XXXXL) and in US sizes of 38 to 52 (S to XXL). When fully set up Dressman measures $173 \times 36.5 \times 45$ cm and weights 28 kg. During operation it consumes approximately 3300 W. Dressman was released in 2004 and sells for around 1000 EUR.

54.3.2 Intelligent Refrigerators

While the plural *ironing robots* in the headline of the preceding section was an overstatement, talking about intelligent refrigerators definitely is not. There are at least four so-called intelligent refrigerators out in the market: LG's *Internet Refrigerator*, Siemens' *CoolMedia fridge freezer*, Samsung's *HomePAD's Refrigerator*, and Electrolux' *ScreenFridge*. As indicated in the introduction to this section, *intelligent* in the context of refrigerators means *networked*. The share of robotic technology involved in an intelligent fridge is negligible. For this reason we only briefly discuss one representative of this class of smart appliances, namely the Electrolux ScreenFridge (see Fig. 54.30), which is one of the latest developments. ScreenFridge has a wireless connection to the Internet and to the TV. Its user interface is a 15-inch touch screen and pop-up keyboard. In addition to Internet, email, phone, radio, and MP3 player ScreenFridge also offers an advanced calendar and video messaging system. In spite of some visionary's expectations, there is currently no intelligent refrigerator on the market which can call the supermarket and order a six pack of beer when it notices that the beer stock gets low. There is no fundamental technical problem to implementing such a vision. What may be a barrier is the lack of an infrastructure to support such a service.

Although we do not want to further elaborate on this, it should be mentioned that large appliance manufacturers

Fig. 54.30 Electrolux: intelligent refrigerator *ScreenFridge*

such as LG and Samsung have apparently discovered the Internet for refining their appliances. Both companies do not only offer networked refrigerators but also other devices. LG and Samsung, for example, both offer an *Internet microwave oven*. LG even has an *Internet turbo drum washer* on the market. How big the market for such *intelligent* appliances currently is or in the future will be, is hard to predict. It may not be in everybody's budget to pay around USD 9000, for example, for a ScreenFridge.

54.3.3 Digital Wardrobes

The idea of fully automatizing not only the handling and maintenance of clothing but also to have support in the selection of the right dress for the right circumstances has led to the concept of *digital wardrobes*. Although this is a fascinating idea, which might especially be interesting for one or another bachelor who is in dire need of support in this respect or for those who have a significant collection of clothes and shoes, the implementation of the idea into products is still pending. We have come across only one design study for a digital wardrobe. This design study includes a business plan but otherwise awaits implementation. The design study uses little conventional robotics technology. The emphasis is more on the information technology side rather than on the physical handling.

EDWard – The Intelligent Wardrobe, Technical Univ. Darmstadt (Germany). The appearance of EDWard is

not particularly unique. It does not differ from any regular wardrobe. What makes EDWard unique is what the inventors call *clothes awareness*. EDWard knows about every piece of clothing which is stored in it. This includes shoes, as well as hats and ties. This clothes awareness is implemented by means of a database and a tracking system, which notices whenever an item is taken out of or put into EDWard. The database contains an entry for every piece of clothing stored in EDWard. It also contains information on how pieces of clothing can be combined to form an attractive outfit or for which temperatures or weather conditions they are suitable for. To keep track of what is going in and out of EDWard, every item needs to be marked by an **RFID** tag, which carries a unique identifier and other information which might be better stored directly on the item rather than in EDWards database. The computer which hosts the database is also connected to an **RFID** reader. Whenever a piece of clothing is taken out or put into EDWard it passes the reader and the antenna attached to it. In this way EDWard maintains a full record of what is stored in it.

Apart from the basic storage and retrieval function the inventors propose a range of additional functions such as search for clothing in the wardrobe, a *tie assistant*, a *shopping assistant*, which cares for compatibility and complementary in the dress and show collection, a *travel assistant*, which proposes the right dressing for the journey depending on the climate and weather con-

Fig. 54.31 Technical University Darmstadt: the intelligent wardrobe EDWard

ditions at the destination and the business to be done, a *washing assistant*, and many more.

As already mentioned there is not too much robotic technology involved in EDWard at present. However, there are quite a few robotic function which could be added, for example a *robotic packing assistant*, which not only proposes clothing for the trip but also packs it into the suitcase.

54.4 Smart Homes

Several attempts have been made in the literature to define the term *smart home*, for example, in [54.11] the term is defined as the “the latest expression of the various ways in which technology in the home has developed”. In [54.12], the notion of a *smart home* is defined more explicitly as “a residence equipped with computing and information technology which anticipates and responds to the needs of the occupants, working to promote their comfort, convenience, security and entertainment through management of technology within the home and connections to the world beyond”. Smart homes typically comprise elements such as network of sensors and actuators, and also entire robotic systems. Current smart home technology includes video monitoring, motion detectors, fall detectors, pressure mats, environment control, health monitoring such as blood pressure, pulse rate, body temperature, weight, and human computer

interaction (**HCI**) technology, for example, to recognize gesture.

The development of smart homes requires a number of technical questions and challenges to be addressed [54.11]: how to convert current home structures and architectures into a smart home, how to standardize smart home components, for example, sensor networks, how to keep the equipment cost at a reasonable level, and how to deal with security and privacy issues.

In the following sections we will describe a number of prominent smart home developments, the Japan Electronics and Information Technology Industries Association (JEITA) house, the *Aware Home* at Georgia Institute of Technology, the *Gator Tech Smart House* at the University of Florida, the *Robotic Room* at the University of Tokyo, the sensorized environment for life (**SELF**) at AIST (the Japan National Institute of

Advanced Industrial Science and Technology). These developments show that current smart home technology goes significantly beyond existing home automation. Accounting for the significant increase in elderly population in the near future many of today's smart home developments pay special attention to improving the quality of life of elderly people. The descriptions below will also address the question on how to integrate robotics systems into smart home concepts.

JEITA House (JEITA, Japan). The Japan Electronics and Information Technology Industries Association (JEITA) house project was carried out from 1999 to 2001 [54.13]. It was implemented in a two-storey Japanese house by several companies that participated in the project. The features of the JEITA house include a keyless system which unlocks the door with fingerprint scanners for personal identification. Based on the fingerprint data, a robot dog AIBO (SONY) would greet the persons entering the house. Functions such as opening curtains, turning on lights, or tuning on the air conditioner could be remotely controlled. The plants could be watered and pets could be fed using cellular phones as remote control devices. This would allow the residents to stay away from the house over longer periods. The components of the JEITA house had their own private IP addresses and were connected to a network.

The JEITA house was equipped with health monitoring sensors for elderly family members. For example, if the system detected something unusual, such as an irregular heartbeat, it sent a message to other members of the family through their cellular phones. Such health monitoring functions are extremely important when an elderly person lives independently. The house could also adapt to the habits of family members. This was an important and interesting novelty, since typically the situation is the other way around: the occupants have to adapt to the system. Lastly, the JEITA house also demonstrated the possibility of integrating robotic systems into homes.

Gator Tech Smart House (Univ. of Florida, USA). The Gator Tech Smart House was built at the University of Florida [54.14]. It addresses the needs of elderly people to live independently and maintain dignity and quality of life at a high age. The house is equipped with many *smart devices* such as smart floors tracking the motion of the occupants of the house, smart blinds automatically adjusting ambient light, smart display, smart cameras, smart phone that can act as remote control to other appliances, location tracking, smart leak detectors, or smart

beds. The exterior of the house has a smart mailbox which alerts residence if mail is delivered and a smart front door which can sense home owners using an **RFID** tag, which allows keyless entry to home owners.

The kitchen of the Gator Tech Smart House includes a smart microwave which uses **RFID** on food packages. This allows the microwave to adjust the settings for cooking the meal. It also informs the resident about the readiness of the meal. The kitchen further comprises a smart refrigerator that monitors food availability and consumption, and detects expired food items. The smart refrigerator can create shopping lists automatically and has an integrated meal preparation advisor based on items in the refrigerator and pantry.

The implementation of such a complex system has raised a number of technical issues and questions, including the development of the smart devices, data handling of networks of sensors, or interconnecting smart devices to other devices in the environment. These questions led to some new research tracks on smart houses, primarily grouped into pervasive computing and mobile computing network research.

Aware Home (Georgia Institute of Technology, USA). Aware Home is a living laboratory for research in ubiquitous computing for everyday activities. This project is conducted at Georgia Institute of Technology [54.15]. The major objective of the Aware Home project is to build an environment that is capable of being aware and keeping track of the states and activities of its inhabitants. Aware Home creates a partnership between human and surrounding sensing and computing technologies. This opens several fields of research not only from the technology point of view but also in terms of the social aspects of the inhabitants. The main research agenda of Aware Home spans human-centered

Fig. 54.32 Georgia Institute of Technology: Aware Home

and technology-centered research, software engineering, and social implications.

Technology and application-centered research focuses on sensor networks, distributed computing, context awareness and ubiquitous sensing, individual interaction with the home, smart floors, or finding lost objects. Research on context awareness is inspired by the fact that humans communicate with each other very successfully by referring to what is called shared context. For communication between humans and computer system, this shared context must be made explicitly. Sensor systems which facilitate the extraction of context need to be developed.

The human-centered research focus on support for the elderly and other social issues. A key concept in supporting the elderly is *aging in place*. Aware Home is designed to support the elderly and allow them to be independent instead of moving them to elderly care facilities. Supporting the elderly leads to the study on cognitive support such as to remind elderly when to take their medicines, guide them whenever they are lost, and locate lost items.

Robotic Room (University of Tokyo, Japan). We have discussed some implementations of Smart Homes. So far, helping the elderly to improve their quality of life is a common goal and this was done in a partly passive way. The term passive implies that there is no physical contact to support the elderly. On the other hand, active support of the elderly requires systems that can physically interact with the elderly and can be augmented to a smart home. The system can also be controlled and can communicate with other smart home devices. With this system, the goal of independent living will be further enhanced. Examples of this system include a robotic partner, robotic walking support system, etc. The discussion below will focus on the goals of and research on such a system, which is an environment-type robot system and which has some elements of a robotic system that can physically interact with humans. This system is referred to as a *robotic room*.

The *Robotic Room* project is being conducted at the University of Tokyo [54.16]. The key concept of the Robotic Room is an environment-type robot system which will provide service to humans. In contrast to industrial robotic systems, which interact with objects, the robotic system in the Robotic Room interacts with humans. There are several target implementations of the Robotic Room, which are more user oriented. One illustration of the Robotic Room is shown in Fig. 54.33,

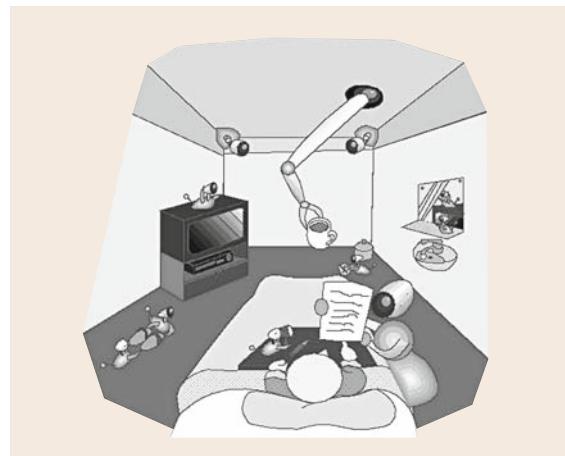

Fig. 54.33 University of Tokyo: the Robotic Room concept

which shows a robot arm mounted on the ceiling to serve a sick person.

This implementation of the Robotic Room has been considered for a robotic sickroom and one area of research that has been studied is behavior media research, which considers behavior as a communication media between human and robot system. The study of behavior media is further subdivided into behavior measurement and recognition, and behavior expression. An example of behavior measurement is the use of cameras to monitor breathing. This is an unconstrained behavior measurement. Behavior expression by robotic systems can be conveyed by motion, such as dancing to indicate joy.

The second target implementation of the Robotic Room is as a sensing room. As a robotic system, it can accumulate behavior and this leads to the study of behavior accumulation or behavior content. This accumulated behavior can be used for system decision making. This is motivated by the observation that older people are more experienced and can decide correctly based on a certain situation due to their accumulated experience.

The third Robotic Room implementation is as a distributed actuation room. In this robotic room, behavior adaptation research is studied. The robotic systems are designed to accumulate personal behavior information and behave based on the user's behavior. Behavior adaptation research can be subdivided into environment support and operational support. In environment support, the room contains a robotic kitchen which adjusts its height with respect to the user and a robotic lamp that adjust its position and brightness depending on the user's behavior.

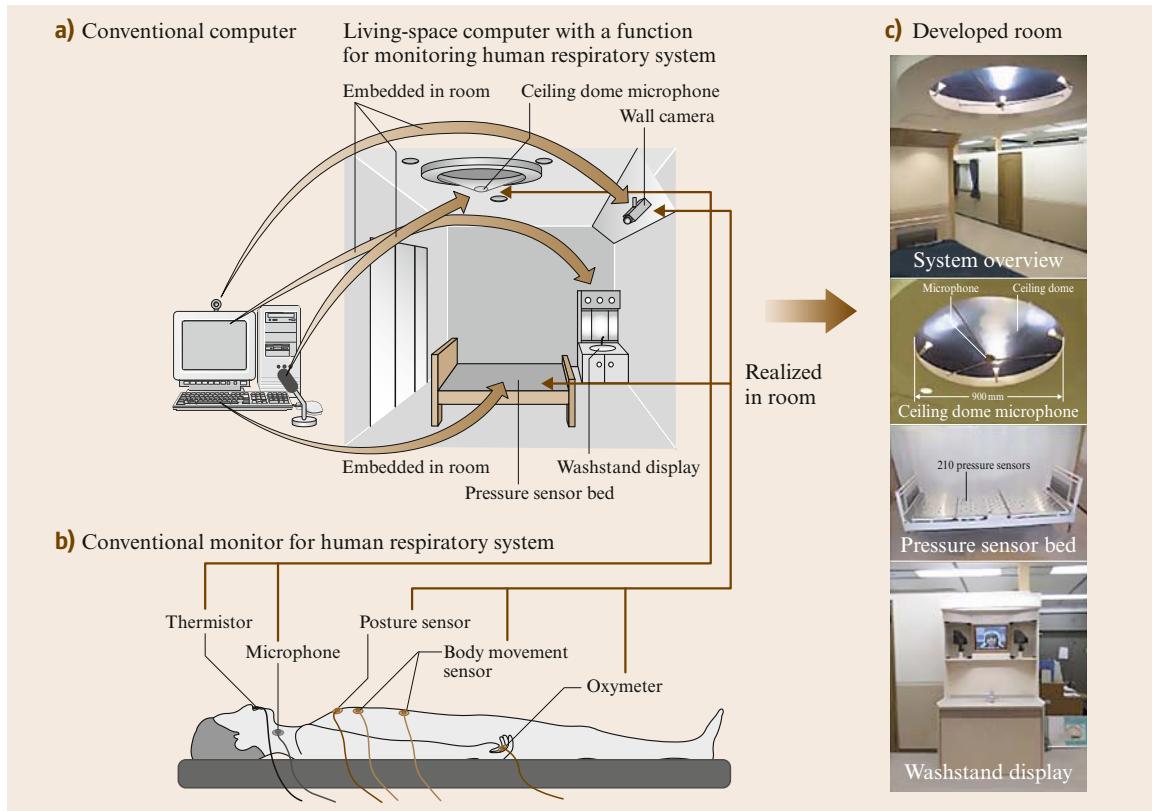

Fig. 54.34 AIST, the sensorized environment for life

SELF – *Sensorized Environment for LiFe (AIST, Japan)*. **SELF** stands for Sensorized Environment for LiFe [54.17]. The objectives of **SELF** are to develop a network of sensors which are embedded in the environment, information gathering using the network sensors, storing and analyzing the information, and reporting of useful information to assist and maintain good health. The basic advantages of **SELF** due to the embedded nature of the sensors are: (1) no size limit, weight, and power source, (2) it does not disturb the human, (3) it does not impose physical restrictions, and (4) sensors are rarely broken since they are fixed to the environment.

SELF can be viewed as a system that monitors a person's behavior or activity and represents the data objectively in an approach known as self-externalization. The motivation of **SELF** is that humans sometimes cannot notice a change in their condition which greatly

affects their health status without a medical doctor. Therefore, the use of network sensors to monitor human behavior and report useful information that greatly affects the health status will further improve quality of life.

The **SELF** study considers behavior as a means of communication and sensors embedded into the environment as one way to observe a person's behavior. The **SELF** implementation is shown in Fig. 54.34, which shows a bed with a sensor, a ceiling with microphones, a washstand with a display, etc. The bed with sensors can determine the time the subject sleeps and wakes up, their posture during sleeping, and their breathing pattern. The microphones attached to the ceiling can detect snoring or normal breathing sounds. Based on the monitored data, the washstand display is used as an output device to provide the subject's health status and thus create feedback to the subject.

54.5 Domestic Robotics: It Is the Business Case Which Matters

After having seen the plethora of domestic robots in the previous sections, we are tempted to say that domestic robotics are no longer a dream or a vision, they are a reality. More than two million domestic cleaning robots sold within four years appears to be a tremendous success story. Of course, as we stated earlier, this is certainly a milestone in the development of domestic robotics and service robotics in general. It is a success story since Roomba created a market. Compared to the sales figures for industrial robots, which are coarsely estimated to be around 100 000 units per year [54.18], the figures for domestic cleaning robots are five times as high.

However, the figures themselves present a naive fallacy. The estimated annual market volume for industrial robots totals around 3 billion EUR. The annual market volume for domestic cleaning robots, given the published figures, is estimated to be around 0.15 billion EUR, which is 20 times smaller. Furthermore, the market size for full-size household vacuum cleaners in the US was estimated to be close to 20 million units in 2003 [54.19]. So the ratio between domestic cleaning robots sold worldwide from 2002 to 2006 and regular vacuum cleaners sold only in the USA during the same time is 1:40. Conservatively estimated, this ratio may be around 1:400 or worse worldwide. Given these figures domestic cleaning robots still seem to be considered to be gadgets rather than appliances.

Is that a reason for joy? Of course, it is. The growth potential is enormous. If only 2% of all domestic vacuum cleaners sold per year were robots this would mean a growth of 800%. Having realized that, shall we now all invest in domestic cleaning robot manufacturers and then order a Ferrari? After all, a growth rate of 800% is an impressive target. As the reader might guess there is a problem here. Housewives (and househusband) are like companies and business people. They ask for a return on their investment. They invest in new equipment only if there is a return on investment and only if the new equipment has a competitive price-to-performance ratio. If it is cheaper to hire a cleaning person than to buy a cleaning robot, why should one buy a cleaning robot. The same holds if the device is cheap but does not do the job, as you still need to do the cleaning yourself.

Apparently, it all boils down to the question, how much is the average housewife or househusband ready to pay for a cleaning robot and what do they expect and how much are they ready to pay for a gadget? Are

they ready to pay 3500 USD for a device which at least promises to systematically clean their living room or do they prefer to pay 100 USD for a toy which gets frequently trapped by cords and cables and breaks after a few month and create more noise than cleanliness?

Let us briefly look into professional cleaning and see whether the situation is different there. The professional cleaning of 1 m² floor costs on the order of 5–10 EUR cents if done manually with a mop (all figures are qualified estimates which are sufficient for a case study but do not claim to account for a specific application or business case). This includes the cost of labor and material. Now assume a 500 m² entry hall of a public building which is cleaned once a day, five days a week, 52 weeks a year. This totals approximately 6750 EUR per year.

Now assume that the cleaning is done by a robot which is deployed by a professional cleaner or housekeeper. Let us further assume that deploying and maintaining the cleaning robot takes the cleaner 20 min per day and that the cleaner has an hourly wage of 20 EUR. The labor for deploying and maintaining the cleaning robot accordingly costs approximately 1750 EUR per year.

What does this figure mean? Well it means that the cost for the cleaning robot must not exceed 5000 EUR per year, including consumables, repair, and purchase. Assuming a depreciation period of three years and assuming that consumables and repair make up 1000 EUR per year this means that the price for the robot must not exceed 12 000 EUR. Not a single one of the professional cleaning robot developed in the past 20 years has even gotten close to such a price. On average the price for a professional cleaning robot is around 50 000 EUR, four times the price that would satisfy our business case.

It should no longer be surprising that the number of professional cleaning robots installed over the past 20 years totals fewer than 500 units worldwide. What is even more disillusioning is the fact that, out of around 15 developments of robots for professional cleaning in the past 20 years, not a single one has survived and ever made it to a successful product [54.20].

What is the conclusion which we can draw from this? Well, launching a successful product does not only require a technology push but also a market pull. It is not the enthusiasm of the engineers which matters. It is the need of the customers and the business case.

54.6 Conclusions and Further Reading

In this chapter we have tried to give a survey of the state of the art in domestic robotics, smart appliances, and smart homes. We have tried to make this survey as comprehensive as possible, but do not claim that it is complete. In view of the huge market potential – we talk about hundreds of millions of customers – the field is developing rather dynamically. New products and new companies appear and disappear rather frequently.

We have discussed the technical challenges and open problems which have to be faced when developing a robot for a household task. Some of these challenges and problems require significantly more research to generate not only theoretical but also practical solutions; some are engineering problems, which are no less trivial. We have briefly looked into some new technologies which have the potential to boost the field and to make products more robust.

We have argued that whether or not a domestic robot makes its way onto the market is not only a matter of the engineers' ingenuity but also of the customers' needs and expectations and above all of the customers' wallet. There is a business case which needs to be met and not only technology to be developed.

We have given an overview of domestic cleaning robots for floors, windows, and pools and we have presented a selection of lawn-mowing robots. We have further looked into the latest developments in smart appliances such as ironing robots, intelligent refrigerators, and intelligent wardrobes. Some of these smart

appliances are intelligent networked devices but are not service robots with motors, wheels, and sensors. We have finally looked at smart homes, in which domestic robots are or can be embedded.

Concluding this chapter one can say: some of the robots which Karel Čapek and his brother Josef may have imagined in 1920 have become everyday reality 90 years later. Others, however, are still waiting to see the light of day. And some may never see.

The publication that blazed the trail for service robotics as a whole and for robots for *household tasks* in particular is Joe Engelberger's book *Robotics in Service* [54.21]. This book provides an amazing overview of potential applications of robotic technology for service tasks and, although it is nearly 20 years old, is still as inspiring as ever. A selective survey of the field of service robotics including domestic applications such as domestic cleaning and lawn mowing is given in [54.22]. A historical overview (until 2000) of the development of cleaning robotics from the very first prototypes to the very first products is presented in [54.23]. [54.24] reviews a selection of commercially available domestic robots and discusses open technical issues which have an impact on the development of domestic robots. The economic development of the field of service robotics as a whole branch and of domestic robots such as cleaning robots, robotic lawnmowers, entertainment robots, and assistive robots is documented in *World Robotics*, the annually published statistics of the Statistical Department of the International Federation of Robotics [54.18].

Robots for Education

David P. Miller, Illah R. Nourbakhsh, Roland Siegwart

This chapter provides an overview of the key ingredients that make successful education robots possible. Two very popular outlets for public interaction with robots are the robot tournament and the informal learning venue (e.g., the science museum). Section 55.2 provides a survey of the very popular world of robot-themed tournaments, which have already impacted tens of thousands of students across diverse geographic and age group boundaries [55.1–5]. Section 55.5 provides an overview of robotic installations in informal learning spaces. Robotic technology has now proven to have sufficient robustness and engagement to be a principal component of interactive exhibitory for a new generation of hands-on, active-learning museums [55.6].

To make interactive, educational robots successful, a new level of technology robustness and standardization is required, and significant progress has been made on this front in the past decade. Educational robot devices consist of both hardware (reassembled or as kits or components) and software (both as source code and programming environments). Section 55.3 discusses physical robot platforms that have achieved notable success, while Sect. 55.4 describes both low-level controllers that interface those platforms to high-level computation, as well as the top-level programming environments themselves.

Finally, an important class of tool in the study and execution of educational robotic systems is the ability to evaluate the efficacy of a robot system formally in an educational context. Numerous tools from human-computer interaction, cognitive psychology, and education have demonstrated their usefulness in this regard. Section 55.6 sum-

marizes the manner in which conventional analytical tools may be used to evaluate unconventional educational programs that tap robotic technologies as learning tools across a variety of ages and in both formal and informal learning venues.

In recent years robots have penetrated the education market, both as motivational tools for research programmes and as concrete, real-world deployments

that demonstrate the state of the art in robotic technologies. The newest education robots, and even entertainment robots to some degree, share the no-

table feature of human–robot interaction with the general public. In contrast to a space exploration robot or a nuclear cleanup robot, these newest, interactive robots do not function solely with the well-trained

specialist; they interact with individuals and groups with the goal of inspiring learning, providing engaging recreation, and even providing therapeutic value.

55.1 The Role of Robots in Education

Education is itself a broad area of application for robotics, with a rich history that started at least with notions of active learning disseminated by Seymour Papert and others [55.7]. Karel the Robot still serves as a metaphor for concrete activity in numerous introductory programming courses. Karel the Robot is merely an on-screen simulation of a two-dimensional robotic world. This first of three roles that robots can play in the educational setting is the *robot as a programming project*. The robotic system is a focus of problem set assignments, a black box to be programmed in order to create a concrete physical manifestation of the art of computer programming. Numerous studies have shown that poor engagement and retention statistics in courses such as Introduction to Programming (CS1) often stem from students' inability to see how the skills they learn can have a concrete impact on what they care about: their physical world, their friends, and family. Physical robot programming projects can cast coding problems into the real world, making those skills push back on one's world, and thereby achieve a level of significance and engagement that, for instance, computation of the Fibonacci sequence on a computer screen cannot inspire [55.8–16].

The second role for educational robotics is that of the *robot as a learning focus*. Mechatronics-style courses can focus on the creation and use of a physical robot as a goal in and of itself. Robots do this by stimulating general interest in science, technology, and engineering, and thereby show students that they can have an active role in shaping technology in their future. Such an application-oriented class has great benefits in cases where students learn best through integrative, project-oriented learning, and such classes have demonstrated significant lifelong-learning results in areas such as teamwork, problem-solving, and self-identification with technology-focused careers [55.7, 17–21]. In the United States, the National Academy of Engineering has identified trends reporting dropping technology literacy as troubling phenomena throughout the nation. Programs that reconnect students with complex mechatronic systems, providing the self-empowerment for lifelong, active relationships to technology artifacts, serve as one possible avenue to stem this dangerous trend away from

knowledge about the technology artifacts on which society depends so completely. Demonstrated learning themes in educational analyses include the following.

55.1.1 Interest in Science and Engineering

The study of robotics can be sufficiently rewarding, intellectually and emotionally, as to generate general enthusiasm for the follow-on study of science and engineering. Some educational robotics programs have shown promise in increasing retention rates among female students [55.22, 23], who are underrepresented in technology-focused fields.

55.1.2 Teamwork

An important result of team-based project-based robotic building experiences is that those with low self-esteem in their technology capability, teamwork skills, and communication skills can find measured improvement, leading to mitigation of fear towards working in teams on high-technology ventures [55.19, 21].

55.1.3 Problem Solving

The study of a systems engineering phenomena – a complex robot system – provides lessons in hierarchy, risk mitigation, planning and diagnosis that far outweighs the benefits of silo-driven, single-topic explorations of debugging and problem analysis. The resulting problem solving and decomposition skills have lifelong applicability to any complex system, see e.g., [55.7].

The third role for educational robots is that of the *robot as a learning collaborator*. In this case students are not designing robots, but rather conducting inquiry during which a high-functioning robot can serve as an all-season companion, aide, and even intellectual foil [55.24, 25]. Robots that have social capabilities are well suited in this regard, and this is an area where the potential for application greatly outweighs what has, so far, been achieved. There are two reasons why such a social role for robots in education holds particular promise. First, because of their novelty, robots can in-

spire dedication in learning, just as is possible in the case of the above two roles. Second, students have few preconceived expectations for the behavior of robots. In therapeutic cases, such as students with autism spectrum disorder (**ASD**), the robot can play an important role, as studies have shown that those students place dispro-

portionate interest in mechanical systems [55.24, 26]. In all cases the interaction can itself be a form of discovery and engagement quite different from traditional, more staid educational methods, and thus this can even border on the application area of entertainment robotics.

55.2 Educational Robot Tournaments

Competition catches people's attention and makes them want to get involved. This is true in almost all fields of endeavor. In education, competitions are commonplace from spelling bees to science fairs. Over the past 20 years robotic competitions have also come into their own; garnering the level of attention from students, teachers, and parents previously found almost exclusively in more traditional sports.

In this section we provide a brief history of robot tournaments, look at some of the popular current tournaments, and overview how they are being used to supplement standard educational curricula.

55.2.1 Origins

In 1970 professor H. H. Richardson adopted MIT's Introduction to Design Course (course 2.70), in the Mechanical Engineering (ME) department, and transformed it into a design contest. He had the students work in teams to design and create machines that would be operated by the students to compete against one another. As the course evolved over the years, and under new instructors, it became both popular and famous.

Several students in the Electrical Engineering and Computer Science department at MIT, envious of the ME course decided to create their own, more autonomous version of both the course and the contest. Since 1987, MIT students have held the 6.270 course during the intercession between the fall and spring semesters. While initially simulation, by 1991 the contest involved untethered autonomous robots in a head-to-head elimination tournament [55.27]. While only open to MIT students and, with the exception of the occasional documentary, poorly publicized, these two courses have become the models for many teleoperated machine contests and robot contests around the world.

55.2.2 A Taxonomy of Robot Tournaments

There are many possible ways to distinguish the multitude of activities often lumped together as robot contests.

For our purposes here we will us the following qualities.

Autonomy

The level of autonomous action that robots exhibit during a tournament varies widely. Some tournaments are completely radio controlled (e.g., *BEST*TM [55.28]) with no independent actions or decisions being undertaken by the 'robots' in the tournament. In other contests, the machines are teleoperated – still under real-time control by their operators, but doing some processing on the commands, and sometimes mixing in feedback from onboard sensors (e.g., *FIRST*[®] [55.5]). Autonomous robot contests have little or no interaction by the robot operators, but even in completely autonomous robot contests there is a spectrum. Some autonomous robots simply replay a canned set of actions – operating completely open loop. Others control all of their actions based on feedback from onboard sensors, and still others *learn* as they go, modifying not only their actions, but their internal programming as well. One generalization that can be made with regards to robot tournaments and education is that a contest that is more autonomous usually has more educational content in the areas of software/programming, while contests with little or no autonomy emphasize the mechanical design and physical implementation aspects of robotics.

Performance Versus Opposition

Some robotics tournaments are based on ranking the absolute performance of the robot against the course. Other tournaments have contestants ranked based on their triumph over a series of specific opponents. In the latter case, it does not matter how well the victorious robot performs in a given round, as long as it performs better than its opponent for that round. Trinity College's *Firefighting Robot Contest* [55.29] (TCFFHRC) ranks teams by how quickly they can carry out the task (locating and extinguishing a candle) and is an example of a performance-based tournament. The scoring in *RoboCup Junior Dance* [55.3] is more subjective, but is

still based on individual performance against an absolute scale. Sumo contests such as [55.30] are opposition-based tournaments sometimes known as head-to-head. Performance-based contests allow robot designers to implement more intricate strategies, since the environment is more predictable than if there were an opposing robot running amok through the course. In oppositional tournaments, robots must be designed to cope with the actions of their opponents. Both types of tournaments have their merits and each allows detailed problem solving. In theory, most people find head-to-head tournaments more exciting and entertaining. However, as with traditional human sumo, head-to-head tournaments often involve head-to-head collisions followed by lengthy, and less exciting, periods of robots trying to push or disentangle themselves from their opponents.

Heritage: Fixed Game Versus New Game Every Year

Is it more educational for students to examine how others have tried to solve a problem and then build on that to create their own incremental solution? Or is it better for students to tackle something new, without extensive examination of precedent? The educational community does not have a definitive answer, but different robot tournaments can be used to support the educational methodology of choice. Tournaments such as *Robocup* [55.32] are prime example of tournaments with a long heritage. In addition to the game and rules being well known (derived from soccer) and essentially remaining unchanged from year to year, there are a number of annual publications (e.g., [55.33]) that detail successful robots and techniques used in that year's contests. *Robocup* is a study in steady incremental improvement. Other contests, such as the *Botball*® robot tournament, use a different game every year. One of the motivations for doing this is so that established teams obtain the game rules at the same time as new teams – so whether experienced or not, everyone has to build

a new system for the new task, and has the same amount of time to do so [55.4]. As with all of these dimensions, there is no clear advantage of one methodology over the other. Some educators prefer to have a new activity every year to help keep themselves and their students engaged. Others prefer to have the same game every year, with the accompanying wealth of lessons learned and how-to guides that process makes available.

Table 55.1 presents a number of established robot tournaments using this taxonomy, although this is not a complete listing. Readers interested in finding out more information about a particular tournament should consult the cited website. All of the tournaments below are for students, though the age eligibility and level of adult involvement varies widely between the events.

55.2.3 The Entertainment Link

Tournaments are used (rather than a course assignment or demonstration) in part because of their entertainment value. A tournament is hopefully engaging to both the participants and the audience. However, the entertainment value of a tournament may not be linked to the technical sophistication of the robots. *Battlebots*® and its variations have been very successful as mass market entertainment. These robots are typically radio controlled, and while sometimes mechanically sophisticated, they are computationally simplistic. The Association for the Advancement of Artificial Intelligence (AAAI) mobile robot contest [55.34] usually has very computationally sophisticated robots – however that sophistication usually has an accompanying decrease in audience entertainment value. AAAI robots strive to do what everyday humans easily do – go to specific places, manipulate household objects, give talks, and answer questions, but the robots tend to be much slower than humans performing these activities. *Battlebots* do what humans are not allowed to do — use power tools and blunt instruments to demolish their op-

Table 55.1 Examples of different types of robot tournaments

| Tournament | Web | Autonomy | Contest type | Heritage | Notes |
|--------------|---------|---------------------|--------------------|----------|--------------------------------------|
| BEST | [55.28] | Radio control (R/C) | Head to Head (HtH) | New | |
| Botball | [55.1] | Autonomous | HtH + Points | New | Multiple robots per entry |
| FIRST | [55.5] | Teleop | HtH | New | Students teamed with engineers |
| Micro Maze | [55.31] | R/C to auton. | Time. | Fixed | Cubic cm robots |
| Sumo | [55.30] | R/C to auton. | HtH | Fixed | Divisions based on weight & autonomy |
| RoboCup | [55.32] | Autonomous | HtH | Fixed | Teams of robots |
| RC Jr. Dance | [55.3] | Autonomous | Points | N/A | Very free form |
| TCFFHRC | [55.29] | Autonomous | Time | Fixed | Random placement of fire |

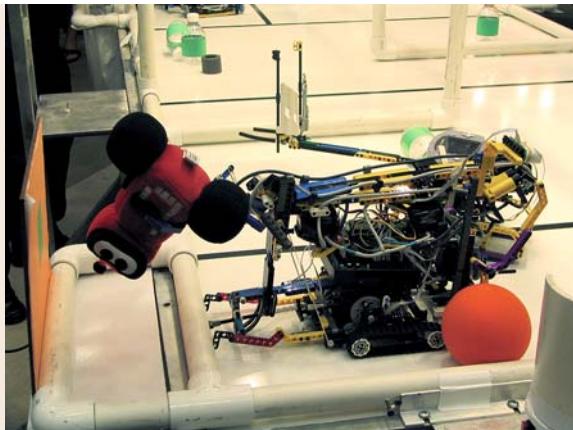

Fig. 55.1 Middle-school students present their paper at the National Conference on Educational Robotics (NCER)/Botball conference and then have their autonomous machine-vision-guided robots score points in the tournament

ponents. In robot tournaments, as in the movie business, violence is often more entertaining than demonstrations of intellectual ability and human activity.

55.2.4 Tournaments for Education

Professional organizations such as the [AAAI](#), Institute of Electrical and Electronics Engineers ([IEEE](#)), and others often hold tournaments for their student members at their major conferences. For these organizations, the purpose of the tournament is to attract students to attend the conference and become active in the organizations. The activity of building the robot also sharpens the students' skills and gets them excited about technologies and businesses linked to that organization and motivates them to pursue relevant degrees [55.35].

Many universities and colleges use robot tournaments as part of their curricula. Some create class tournaments (e.g., MIT 6.270) or use standard games such as *Beyond Botball* [55.36] that are distributed

for that purpose. Others use some of the tournaments mentioned in Table 55.1 as projects for their curricula [55.37].

However, the bulk of robot tournaments are aimed at middle- and high-school students. Here the motivation is not so much to teach detailed skills as to spark creativity while at the same time emphasizing basic concepts and an appreciation for the fundamentals of science, technology, education, and mathematics [55.38]. Some tournaments have added activities such as documentation, presentation, reports, and even tests [55.39] to reinforce and expand upon these fundamentals (Fig. 55.1). To assist educators in guiding the students, many tournaments have curriculum materials linked to their activities. National Aeronautics and Space Administration ([NASA](#)) has collected links to many of these materials and made them available on the Internet [55.40]. Evaluating the effectiveness of these materials and programs in meeting their educational goals is the subject of Sect. 55.6.

55.3 Education Robot Platforms

Education robot platforms fall into one of two main categories. The first is the research platform. These expensive, precision robot platforms were built to support research in robotics and related disciplines, or as research projects in their own right. Many of the humanoid robots discussed elsewhere in these volumes are examples of this. These robots, such as Honda's *Asimo*, are used for advanced research as well as for entertainment.

Other less sophisticated but still precise and expensive platforms are used as the basis for the museum robots discussed in Sect. 55.5.

A second class of education platforms (and the ones to be discussed in this section) are lower-cost robot platforms, or platform kits. These platforms are inexpensive, exist in large numbers, and are widely used in schools and by hobbyists.

Fig. 55.2 (a) Hero-1, (b) Hemisson, and (c) Amigobot

Education robots really got their start in the early 1980s with the introduction of the Heathkit *Hero-1* (Fig. 55.2a). Hero robots were sold as kits, both to keep the price down and to encourage users to learn how robots were made. However, while detailed assembly instructions were included, no information on the theory or principles behind the assembly were given; the kits, by themselves, did not provide a satisfactory educational experience. Unfortunately, neither the Hero robots, nor several other similarly sized and priced personal robots that came out in the 1980s, reached a level of capability and ease of use to attract an economically viable customer base. Heathkit and the other companies have since gone out of business.

In the intervening years several other companies have tried to make personal robot systems. Many of these companies started with more capable research robots. With few exceptions, these companies have faded away or gone into other markets. Most of the companies now mass marketing education robots do so as a side business. The primary business for most of these companies is consumer electronics, toys, and with one noticeable

exception consumer robots that were supposed to be neither educational nor entertaining.

K-Team [55.41] is one of the few companies making robot platforms specifically for the education market. The *Hemisson* (Fig. 55.2b) is a low-cost, less compact version of K-Team's Khepera research robot. It has reduced computational power and few sensors when compared to most research robots, but is priced and designed for robotics classes in secondary and university classes. Activimedia is the other research robot company that produces lower-cost educational robots. Their *Amigobot* platform is shown in Fig. 55.2c.

The LEGO® Mindstorms RCX was the first robotic platform from the LEGO company, and has had broad appeal across many demographics. The LEGO computation systems are discussed in Sect. 55.4. However the LEGO blocks themselves have been a mechanical prototyping system for robots long before LEGO ever introduced their own controllers. The LEGO bricks make RCX a good tool for early and fast robotic explorations. The newly released LEGO robot system, Mindstorms NXT (Fig. 55.3a) has a new processor and some new sen-

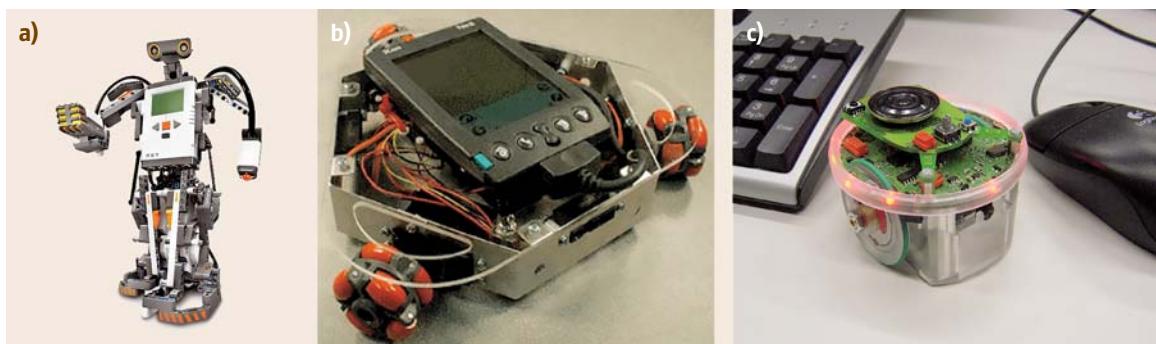

Fig. 55.3 (a) LEGO NXT, (b) PPRK, and (c) e-puck robots

Fig. 55.4 (a) Garcia, (b) ER1, and (c) KHR-1 robots

sors, but relies on the popular LEGO Technics building system for all of the mechanics.

The Palm Pilot Robot Kit (PPRK) platform [55.42] (Fig. 55.3b) is a low-cost kit combining a mobile base and a personal digital assistant (PDA), originally a PALM Pilot. The PALM provides computational power and a graphical user interface for robot control, and communicates with lower-level robot driver circuitry via the PALM's serial port. The result is a very compact omnidirectional platform with three distance sensors (in its basic configuration) that constitutes a starter kit for those who want to begin by building their own robot from kit parts.

E-puck [55.43] (Fig. 55.3c) is the first desktop robot (70 mm in diameter) based on an open-hardware concept. Equipped in its basic version with a diverse sensor package (three-dimensional accelerometer, proximity sensors, three microphones, color camera), several actuators (stepper motors, speakers and numerous LEDs), Bluetooth® communication and a good processor capable of signal processing (dsPIC family), it is relatively inexpensive due to its simple mechanics. It is a desirable

tool for education in technical schools and universities.

The Garcia robot from Acroname [55.44] (Fig. 55.4a) is a small-size platform (25 cm × 18 cm × 10 cm) that can be extended with a XScale-based board. It is sufficiently small to develop experiments in small environments and yet this robot is sufficiently large for diverse payloads, including a small manipulator mechanism and an array of sensors.

The ER1 robot from Evolution Robotics [55.45] (Fig. 55.4b) constitutes a simple extruded aluminum frame kit supporting a laptop and equipped with stepper motors and wheels. This robot focuses interaction on the onboard laptop, enabling onboard computation as well as onboard vision via a universal serial bus (USB)-based camera. This robot system, which is going out of production, comes with a sophisticated software environment for navigation and visual recognition of artifacts in the robot's field of view.

The KHR-1 [55.46] (Fig. 55.4a) is an initial humanoid robot at an affordable price, based on a set of 17 servomotors. The growing family of humanoid robots

Fig. 55.5 (a) Robosapien, (b) Roomba, and (c) Create robots

still depends upon large numbers of servo actuators and very few sensors; however, due to the draw of humanoid robots, these kits are nonetheless excellent motivational tools.

Robosapien [55.47] is a popular toy humanoid robot (Fig. 55.5b). Because this is an infrared (IR)-controlled toy, using the IR link from a computer or PDA is relatively straightforward. Some hobbyists have hacked deeper into the system so that the Robosapien can be used as a fully fledged computer controllable robot platform.

The iRobot® *Roomba*® [55.48] (Fig. 55.5c) is a mass-produced, inexpensive household vacuum robot ($33\text{ cm} \times 33\text{ cm} \times 7\text{ cm}$). With millions sold, the Roomba is currently the most common robot in the world. The Roomba was not initially meant to be an education robot – but rather a service robot doing dirty and dull work. However, much like the Robosapien, the robot hobbyists quickly started using the Roomba

as a platform, and starting in 2005, iRobot responded to requests and included an exposed serial port and released an application programming interface (API) for controlling the Roomba and reading its sensors from an external computer [55.49]. A community of Roomba hackers has come into existence using Roombas for everything from musical instrument digital interface (MIDI) devices to security robots [55.50]. Many schools are adopting the Roomba, combined with one of the controllers described in Sect. 55.4.1, as a platform for classes and experimentation. A new product, the iRobot *Create*™ was released in 2007. This product is a Roomba without the vacuum or brushes, but with additional interfaces to encourage experimentation. The iRobot Create can be purchased with a processor of its own or easily interfaced with robot processors such as the XBC [55.51] or small low-power general-purpose processors such as the *Gumstix*™ [55.52, 53].

55.4 Education Robot Controllers and Programming Environments

Education and entertainment activities in robotics sometimes run at cross purposes. For entertainment we want robots that are active and very easy to use and to control. Products like the LEGO Mindstorms provide both a robot controller and a programming environment that meets those criteria.

However, when it comes to robot education, it is important to remember that in most cases we are using robots to inspire and motivate students to learn many things, of which robotics is just one. Robotics educators, especially at the K-12 (students aged approximately 5–18 years level), are hoping to teach students general science, programming, math, and engineering techniques. The toy programming environments used in some products such as Mindstorms may be inappropriate for this mission.

This section overviews some of the popular robot controllers and programming environments. Usually the two are linked, but there are some environments that work with several different controllers and vice versa.

As with the robot tournaments described in Sect. 55.2, many of the robot controllers and their programming environments in use for tournaments and by hobbyists can trace their origins back to the MIT 6.270 course [55.27]. At an even more fundamental level, the origin of most robot controller starts with the Motorola 68HC11 processor.

55.4.1 Robot Controllers

The venerable HC11 is a single-chip processor with small amounts of onboard flash and random-access memory (RAM) memory. It also has a number of input/outputs (I/O) and timing ports that make it relatively easy to interface to sensors and external devices. The 8-bit HC11 uses the same instruction set as the Motorola 6800 series of processors, which have been in existence in one form or another for more than three decades.

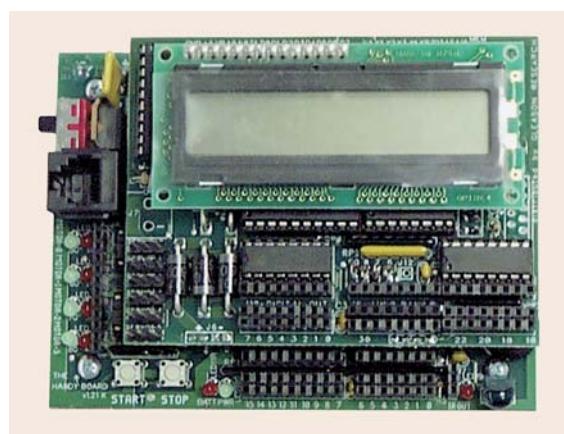

Fig. 55.6 The HandyBoard with its expansion board

The HC11 was used by Anita Flynn and Joe Jones in a board for the MIT robot talent show in 1991, which spawned the Book Board [55.54], the MIT 6.270 board, and Fred Martin's Handyboard. The last of these became the de facto high-end robot controller for hobbyists and autonomous robot contests for most of the 1990s.

The Handyboard (Fig. 55.6) can provide pulse-width modulation (PWM) control for four direct-current (DC) motors, read eight digital and eight analog sensors, control a couple of light-emitting diodes (LEDs) and has a 32-character display. With the expansion board, eight lines of digital input-output (DIO) and control for six R/C servos is also added. The Handyboard can be programmed using 6811 assembly language and several other languages including Java and C.

The other low-cost commercial robot controller in widespread use throughout the 1990s was the BASIC Stamp [55.55] (Fig. 55.7). This programmable interrupt controller computer (PIC)-based controller could be programmed in a special (often assembly language-like) version of the BASIC language. While very small in memory, and usually requiring supplementary electronics for most sensors and actuators, the Stamp was very popular because of its low cost and flexibility.

In the late 1990s, spurred on in large part by the growing interest in robot tournaments, a renaissance in robot controller hardware started making available a number of controllers ranging from advanced PICs to full-blown personal computers (PCs). A sampling of some of the controllers now available is presented in Fig. 55.8

The RCX (Fig. 55.7) and its successor, the soon to be released NXT (Fig. 55.3a), are widely available controllers from LEGO. These are very easy to interface to the special sensors and motors produced by LEGO, using variations of LEGO's brick interface. However, this simplicity of use makes it more difficult to connect to other sensors and motors. These foolproof interfaces also take up a lot of physical space, limiting the controllers to just a few sensors and actuators. While the central processing units (CPUs) are relatively powerful, most of this horsepower remains unused because of the limitations of the interface. However, these controllers are not very expensive, are mass produced, and require absolutely no knowledge of electronics, mechanics (or when using LEGO's software) programming in order to get them to control simple robots.

For the more technically inclined hobbyist or student, but one on a stricter budget, there are the PIC-based controllers. The OOPic system [55.56] (Fig. 55.8), uses an object-oriented programming system, and includes

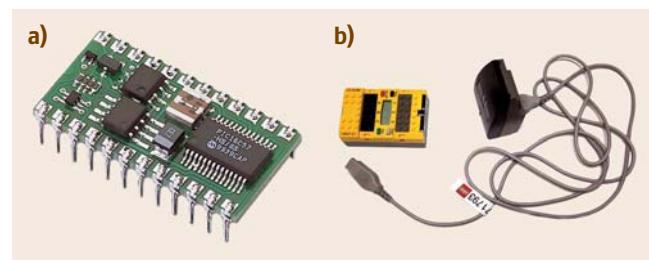

Fig. 55.7 (a) The BASIC Stamp 2 and (b) the LEGO RCX

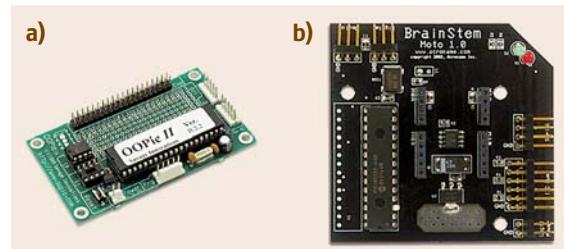

Fig. 55.8 (a) The OOPic Controller and (b) the Brainstem MotoBoard

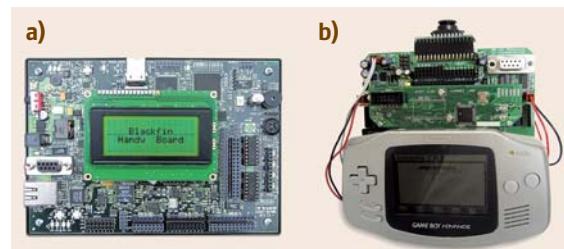

Fig. 55.9 (a) The Black Fin Handy board and (b) the Xport Botball Controller (XBC) with camera

much, but not all, of the interface electronics needed to get a robot up and going.

Acroname's Brainstem system [55.57] (Fig. 55.8) uses a small reduced-instruction-set computer (RISC) processor to create a low-cost modular controller. Modules are linked over an inter-integrated-circuit (IIC) bus. The Brainstem is programmed in the tiny embedded application (TEA) language, a variant subset of the C language.

For more capability including proportional–integral–derivative (PID) motor control and vision processing there are controllers such as KIPR and Charmed Labs, XBC [55.58] (Fig. 55.9), and the Black-fin Handy Board [55.59] (Fig. 55.9). Both of these boards share the same basic architecture of a RISC processor combined with a field-programmable gate array (FPGA). The FPGA comes preprogrammed with a va-

riety of useful functions (e.g., motor control) but can be reconfigured if desired. The processor runs user code and uses the FPGA to handle hardware-related library calls. Both of these boards contain ports for connecting with complementary metal–oxide–semiconductor (CMOS) cameras.

The XBC uses a Nintendo GameBoy Advance as part of its architecture to provide processor, display, and user buttons. This provides the user with a color graphics screen on the robot that can be used for displaying text and images and for setting parameters. This is especially useful for tuning vision parameters, as the camera output (processed or raw) can be redirected to the screen.

55.4.2 Edutainment Programming Environments

Many of the lower-priced controllers (e.g., BASIC Stamp) have limited options for programming environments, while the higher-end controllers such as the XBC can accept cross-compiled programs in most languages.

The LEGO processors are shipped with a graphical programming environment. While sometimes limiting in what can be programmed, the environment is highly intuitive. A more capable (and not quite as intuitive) graphical programming environment based on LabVIEW has been created for the LEGO processors and has been used in a number of schools [55.60].

For educational environments where the robotics experience is serving as an introduction to programming, there are a few good choices. There are Java, C, and

other language implementations specific to one or more of the processors above.

One the most popular (because it runs on many of the processors and under all major operating systems and is free) is Interactive C or IC [55.61]. IC provides a fully integrated development environment (IDE) including an editor, compiler/interpreter and controller simulator. IC implements a subset of American National Standards Institute (ANSI) C, the primary missing functionality being in pointer arithmetic. Other differences between IC and standard C are there to protect the novice user (e.g., IC performs array bounds checking during runtime).

IC also has an interpreted interaction window which allows the user to try out C expressions or function calls, query global variables, etc. either to the actual hardware or to the hardware simulator. The IC environment also provides utilities such as uploading global array data from the robot hardware to the PC, providing memory maps of the program on the controller, colorization, block-level indentation, and interactive documentation from the editor. The IC runtime environment provides library functionality for multithreading.

IC is used regularly in a number of the robotics tournaments described in Sect. 55.1. It is also being widely used in introductory programming courses [55.62] robotics courses [55.63] and for more advanced courses such as in the teaching of neural nets and control [55.64].

IC uses a virtual machine model that runs on the processor, allowing it to be ported to new robot controllers with relative ease.

55.5 Robots and Informal Learning Venues (Museums)

Robots are objects of great attraction and can have a large number of modalities for establishing a strong interaction with humans. It is therefore not surprising that one of the first applications of mobile robots have been robot guides in research labs and later in museums and exhibitions. SHAKEY (Fig. 55.10a), developed at SRI in the early 1980s is often considered the first mobile robot [55.65]. It was able to move wooden blocks according to verbal commands given via a keyboard. Probably the first robot exposed to untrained visitors was POLLY, developed to give simple lab tours at MIT's artificial intelligence (AI) laboratory in the early 1990s [55.66]. The only communication input was vision; visitors waved their feet if they wanted a lab tour. Whereas these early solutions were landmarks in

their time, more recent tour robots offer a much richer interaction and are able to navigate in the somewhat more complex and dynamic environment of museums and exhibitions. One of the first examples of these next-generation tour-guide robot prototypes is Jijo-2, demonstrated in the late 1990s [55.67] (Fig. 55.10c). However, it was operated under laboratory conditions and only by people that were more or less familiar with the robot.

55.5.1 Tour-Guide Robot Examples

The first real tour-guide robot, called Rhino, was deployed for six days in the Deutsches Museum in Bonn during the summer of 1997. It was freely navigating

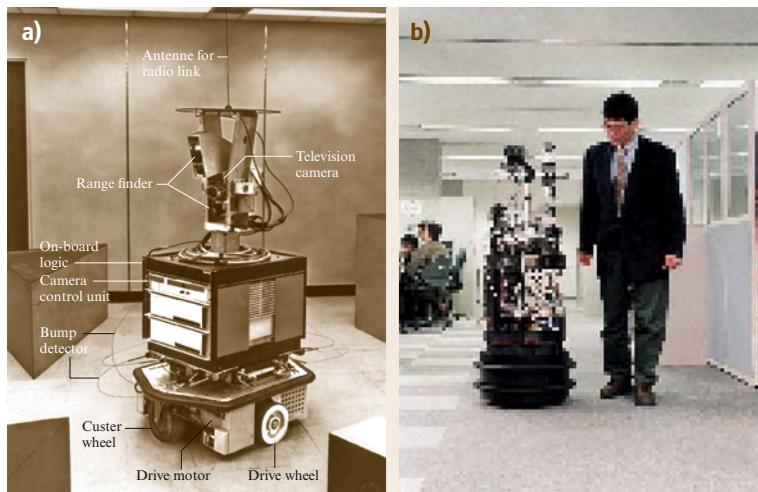

Fig. 55.10a,b The SHAKEY Robot developed in the 60-ties at SRI (a) and the Jijo-2 Robot giving a tour at the National Institute of Advanced Industrial Science and Technology (AIST) (b)

and equipped with speech synthesis (output) and buttons for user input. The robot's main tasks were to get people involved and to support them in navigating through the environment. The experience gained in this short-term installation showed a strong need for enhanced human–robot interaction [55.68] (Fig. 55.11a).

A first step towards a more appealing interaction was realized with Minerva, which was operated for two weeks in late summer 1998 in the Smithsonian's National Museum of History, Washington DC, USA [55.69] (Fig. 55.11b). One version of Minerva was equipped with a caricature face (eyes, eyebrows, mouth), enabling it to appear to express its feelings and entertain the visitors. In addition to on-site interaction, Minerva was accessible for tours via the

Internet from remote sites. According to a study, people perceived the robot's intelligence similar to that of a dog. This basic experience was further expanded in a European project towards two installations of tour-guide robots enabling telepresence in museums and fairs [55.70]. The robot Albert, developed in this project, was equipped with a commercially available speech recognition system that enabled on-site visitors to give spoken commands.

Hermes is a robot from the Universität der Bundeswehr München that was demonstrated at various fairs and exhibitions in 2001 and 2002 [55.71] (Fig. 55.12a). Equipped with two arms, Hermes is able to conduct simple fetch and carry tasks. However, his mobility was typically limited to a very small and well-structured area.

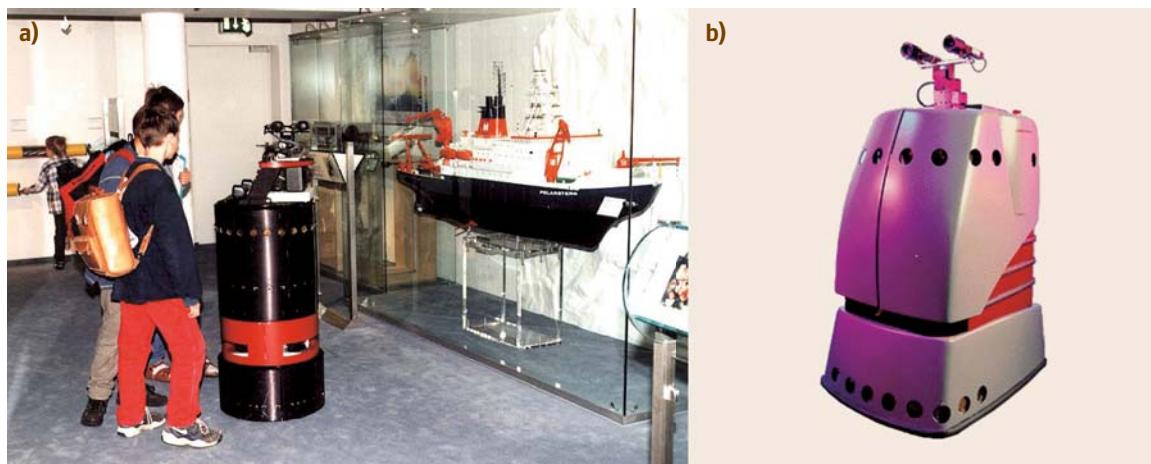

Fig. 55.11a,b Rhino (a), (University of Bonn) and Minerva (b), (Carnegie Mellon University, University of Bonn)

Fig. 55.12a,b Chips developed at Carnegie Mellon University (a) and Hermes, a humanoid interaction robot developed at Universität der Bundeswehr München (b)

Using an off-board microphone, Hermes was able to get simple spoken commands based on keywords.

The first robots deployed in a museum for a long period were Chips (Fig. 55.12b) and its successors SWEETLIPS and JOE, developed by Carnegie Mellon University and Mobot Robotics [55.72, 73]. Installed in 1998, they were operated for several years in the Carnegie Museum of National History, the Hall of North America Wildlife, and the Heinz History Center, respectively. All robots used specially deployed color landmarks for localization, and a touch screen for en-

hanced audiovisual interface. The robots primary goal was to attract visitors to less frequented areas and to enhance the learning rate during the visit. They were conceived as educators offering background information about the exhibition through their audiovisual touch screen. A study done along with the installation of Chips showed that the learning success rate increased by more than 50% when visitors (children and adults) were guided by the robot through the exhibition [55.72].

The Inciting, the Instructive, and the Twiddling robots were developed by the Fraunhofer Institute for Manufacturing Engineering and Automation (IPA) in Stuttgart (Fig. 55.13) [55.74]. These very appealing robots use old-fashioned technology elements such as a mechanical scale, as design elements, and have been running in the Communication Museum of Berlin since 2000. They attract and greet visitors (The Inciting), offer introductions to the museum (The Instructive), and play with a big ball (The Twiddling). They have no input device to give commands, but are very expressive and playful through their appearance and body motions.

The largest installation of tour-guide robots, in terms of number of robots and accumulated operation hours, was realized with a fleet of 11 RoboX robots at the Swiss National Exhibition Expo 02 in 2002 [55.75, 76] (Fig. 55.14). The robots presented the robotics exhibition and themselves through synthesized speech in four languages. A special programming interface enabled easy implementation of different scenarios using speech and sounds, facial expressions (two independent pan-tilt eyes, eyebrows), display of icons in one eye, body motion, and navigation as output modality, and the buttons, face tracking, people tracking and an analysis of the global visitor distribution in the exhibition as input modality. Two robots were equipped with speech recognition enabling simple spoken commands like yes/no in four languages [55.77]. After finishing their job at Expo 02, the RoboX robots found a second life as research platforms and were installed in other exhibitions and as TV moderators by BlueBotics.

Rackham is a tour-guide robot deployed in 2004 at the Mission Biospace Exhibition in Toulouse, France [55.78, 79] (Fig. 55.15a). This robot, developed by the Laboratoire d'Architecture et d'Analyse des Systèmes (LAAS) in Toulouse, has an enhanced audiovisual output system and obtains user commands via a touch screen. The animated helmet together with the touch screen are used as a focal point of attraction to this very futuristic robot. Once a visitor is detected by the pan-tilt camera in the helmet, the robot explains its utilization

Fig. 55.13 The Inciting, the Instructive, and the Twiddling robot amusing and informing peoples at the Communication Museum, Berlin. These very attractive robots have been developed at Fraunhofer Institute for Manufacturing Engineering and Automation (IPA)

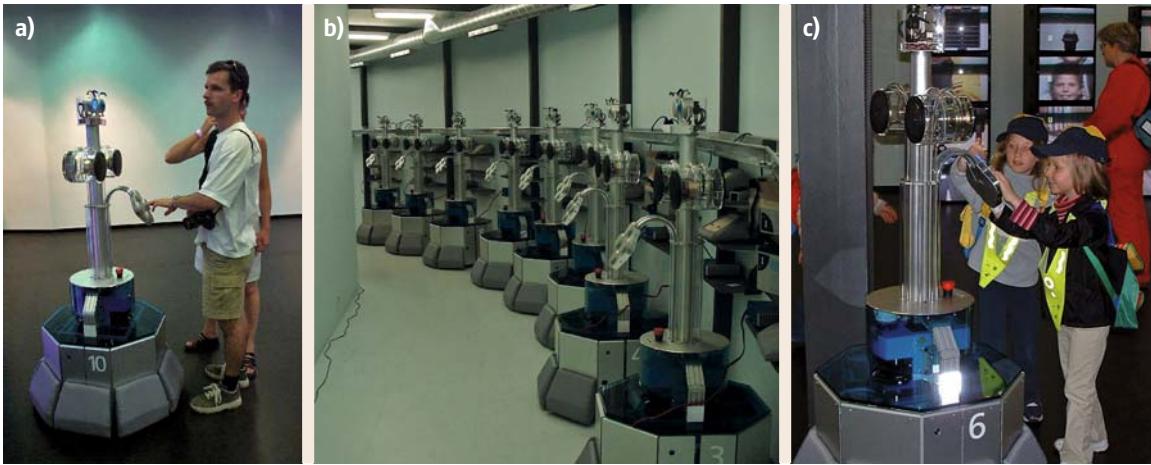

Fig. 55.14a–c The family of 11 RoboX tour guide developed by the EPFL gave tours during five months to over 650,000 visitors at the Swiss National exhibition Expo 02

and offers its services. This installation is also used as an experimental environment for further research.

More recent tour-guide robot platform developments are focusing on enhanced human–robot interaction and more humanoid appearance. One illustration is Brion, which learns the environmental setting from humans through an enhanced dialog system [55.80]. Voice and gesture recognition are the main inputs for driving the dialogue with the human that is based on a finite state machine (FSM). The humanoid exhibition robot Repliee Q1 has been developed at Osaka University. It consists of an artificial human upper body with a very realistic appearance (Fig. 55.15b). Repliee Q1 communicates through speech, enhanced facial expressions and body language. It has a tactile skin over the entire body, able to sense being touched and react to it. During the 2005 World Expo in Japan, Repliee Q1 was offering its services at an information desk. The next generation of Repliee is intended to have actuated legs for full motion abilities.

More sophisticated robots will be deployed in informal learning venues as tour guides and teachers soon. They have the potential to offer a more appealing and lasting learning experience. However, there is still important research and technological advancement required. Until then, robots can only partially compete with a human guide.

55.5.2 Lessons Learned

Through the various installations presented above, new insights on the design of tour-guide robots and the user's

Fig. 55.15a,b Rackham is a tour-guide robot deployed at the Mission Biospace Exhibition in Toulouse, France (a). The Repliee Q1 humanoid robot (b) was at the information counter at the 2005 World Expo in Japan. It was developed by Osaka University

behaviors were gained. Various details can be found in [55.69, 72] and [55.76]. At informal learning venues it is nearly impossible to instruct the visitors on how to operate the robots. Thus the robot's interactivity has to be plug-and-play. This is only possible if design and functionality are harmonically integrated and the robot's intention and internal states are transparent and understandable for the visitor. Design creates expectations, e.g., a humanoid appearance makes visitors believe that the robot has similar competence as a human. A robot that speaks is also expected to understand spoken dialog. In general, the public has the tendency to overestimate the robot's competence because most people only know

robots from science-fiction movies or futuristic research documentaries.

Visitors are curious, but also impatient and rude. Therefore tour-guide robots have to allow visitors to discover new elements in a fast rhythm, have to be very dynamic and fast responding, and should be robust against harsh treatment. If possible, visitors will sit and hang on the robot or hit the bumpers. On the other hand, visitors are respectful with elements that look fragile, e.g., they will not touch the eyes of the robot. The most appealing interactions are often elements such as

obstacle avoidance or even security buttons because the feedback is immediate and easy to understand. It is therefore of crucial importance that the actions of the robot are immediately responsive to users' needs and wishes. A delay of only one second to a pushed button is often too much and will often incite inappropriate reactions from the visitors, such as hammering on the button.

A successful installation of robots in informal learning venues must be carefully designed according to the functionalities and services they are intended to offer. Form has to follow function.

55.6 Educational Evaluation of Robot Programs

An important aspect of assessment, beyond technical evaluation, is educational evaluation: how does human–robot interaction change models of learning and identities with respect to technology; and how is this done in educationally appropriate ways? We find several techniques to be applicable during each of the following phases of an educational project:

- design-time assessment: the creation phase of an educational robot system
- formative evaluation: during execution of an educational robot program
- summative evaluation: following completion of an educational program

This section will identify relevant tools for design, formative, and summative evaluation that we borrow from the human–computer interaction community and the cognitive-educational analysis community. These tools are well suited to helping researchers understand and quantify how educational robots can impact learning in the classroom and, beyond the classroom, in informal learning venues such as museums and after-school workshops.

55.6.1 Design-Time Assessment

The field of human–computer interaction (**HCI**) offers formal and heuristic techniques for addressing interfaces between humans and technology [55.81, 82]. Current **HCI** practice often focuses on user-centered design, which suggests that understanding the user and the entire task can help us be better designers. One specific **HCI** technique, contextual inquiry and design, is especially useful for both informal and formal learning venues where robots will interact directly with students

as users. Contextual inquiry guides the collection of background data concerning interactions taking place before inclusion of the new, to-be-designed robotic technology, and is often achieved through the collection and analysis of direct interviews and observations. The process includes identifying and polling various stakeholders in the educational environment, from the classroom as a whole to individual educators and mentors.

A second **HCI** activity, modeling, guides the creation of pictorial flow diagrams that identify the most important features of the environment in which the robotic educational technology is to be used. *Workflow* describes the communication necessary for the classroom activities. *Sequence* identifies actual sequences of action required for various activities in the classroom (or museum). *Artifact* captures the relationship of existing tools required for activities to be performed successfully. Finally the *physical model* identifies how space is used, which can be notable in the case of the design and potential inclusion of mobile robots in spaces that were generally not designed for them in the first place, such as conventional laboratories and, even worse, regular lecture halls.

Why do all the above? Because it is a principled way of understanding existing environments. This in turn facilitates design-time judgments in regards to the best manner in which to add a new technology, such as interactive robots, while maximizing the chances that the technology is a real success. However, it is the continual cycle of evaluations during the implementation phase that is critical to a positive outcome. So in summary design-time data collection and assessment helps set the stage and control expectations. Formative evaluations and feedback into the continuing design process,

as described below, help keep the engineering on a path to success.

55.6.2 Formative and Summative Evaluation

Traditional school-based assessments of learning, for instance course surveys or exam grades, are useful as coarse-resolution data collection devices. However, these do not provide sufficient detail to build models of how learning is proceeding with or despite of technology changes, nor how further technology changes may improve learning. Furthermore, especially in informal settings such as museums, school-based assessments are even more inappropriate. In such settings significant learning results from communication. As groups of visitors or teams of students use and talk about a museum exhibit or project challenge, they construct a shared understanding of the content and context of the challenge. There is an outstanding body of work in the education community that focuses on this form of conversation and learning. The following references are excellent starting points [55.83–87]. Applying this education learning strategy to educational robotics yields wonderfully rich analyses in terms of how the robots change conversations in the classroom [55.88].

In education learning, tools include broad evaluation tools for qualitatively and quantitatively constructing a model of learning across the classroom and deep, focused tools for studying the specific communication-oriented mechanisms of learning that may inform patterns of change and exploration at the student and team level. In terms of broad tools, written student surveys are one useful data collection tool. A combination of linear, quantitative queries (called Likert scales) coupled with open-ended essay questions such as *What is the most important concept you learned this week?* invite both statistical analysis of raw results and thematic analysis of self-reported challenges and successes by the students themselves. Recorded interviews with students, individually or in teams, provides even richer information due to the ability to ask complex *What have you learned?* questions appropriate for open-ended analysis, again in terms of thematic content. A deep, focused tool that is expensive in terms of analyst resources but generates very useful information is the ethnography, whereby a trained observer spends, for instance, one week tracking all the activities of two teams in the classroom, including conversations within the team, among team members and other pupils, and between the team and the course instructors and teaching as-

sistants [55.89–91]. Ethnography is intended to detail the learning and problem-solving process that occurs in class on a minute-by-minute basis.

Taken as a whole, the above collected data can then be analyzed by thematic content, for themes such as those listed in Sect. 55.1. Statistical significance and correlation tests can be applied to the quantitatively derived results of coding all such information to yield information on how the frequency of learning themes appearing in conversation increases or decreases, and how specific themes become more refined or specific in students' speech over the duration of the course.

However, assessment of the educational value of robotics programs such as those described in Table 55.1 is often more difficult than evaluating programs in more traditional disciplines. There are widely accepted textbooks and curricula for many disciplines, but not yet for robotics. Additionally, the different educational robotics programs described earlier take a variety of approaches towards education.

Many programs (e.g., FIRST LEGO League and RoboCup Jr) are large but are implemented at the local level, so the experience for students can vary tremendously from one locale to another. The more standardized programs (e.g., Botball and FIRST) have different educational models. FIRST uses an inspirational model where students work with professional engineers. Botball follows a more traditional high-school model of education where the teachers are trained in the techniques and principles, so that they may guide the students at a high level, but all of the work (both design and implementation) is done by the students.

Because robotics can serve as an unfamiliar tool for many students in such courses and programs, evaluation of how this unfamiliar, potentially rich interactive tool impacts student learning and perceived interest levels in science and technology is a common focus of educational robotics assessment. This trend is exacerbated because these programs, which involve tens or even hundreds of thousands of students, are implemented by nonprofit companies and volunteers that lack specific funds and training for formal assessment. For these reasons, formal assessment of the programs tends to be based on student and/or teacher surveys rather than rigorous testing, and the assessment usually focuses on specific issues (e.g., gender issues in technology education) where assessment-specific funding may be available.

As educational robotics becomes more mainstream, we can expect that evaluation will shift from general enthusiasm about science, technology, engineering, and

mathematics (STEM) learning to specific learning advantages derived from such robot-inclusive coursework

for follow-on coursework in diverse disciplines such as biology, physics, and computer science.

55.7 Conclusions and Further Reading

This chapter has given an overview of many, but by no means all, of the educational robot hardware and programs currently available. Websites such as robots.net and robotevents.com attempt to maintain lists of the rapidly evolving field of educational robot tournaments. Keeping track of the latest hardware and software tools are more problematic. Some additional sources for these topics, and others covered in this

chapter include: *Robots for Kids, Exploring new technologies for learning*, edited by Druin and Hendler; *Robotic Explorations: A Hands-On Introduction to Engineering* [55.92], by Martin; *Where the Action Is, Foundations of embodied interaction*, by Dourish; *Piaget's theory of cognitive development* [55.93], by Wadsworth; and *Computer as Theater* [55.94], by Laurel.

64 Roboethics: Social and Ethical Implications of Robotics

Gianmarco Veruggio, Genova, Italy
 Fiorella Operato, Sampierdarena, Genova, Italy

Part G Human-Centered and Life-Like Robotics, covers some of the most recent advances concerned with human–robot interaction, ranging from designing biologically inspired robots, to programming and safety issues for human–robot interaction, and ethical issue brought forth by robotics. Our field’s future vision for technology is the leap from personal computers to personal robots, in a world where robots exist pervasively and work side by side with humans. Over the past 50 years we have made great strides in robotics, as the previous parts of this Handbook show. However, there are still new capabilities that need to be developed and existing capabilities that need to be improved to create a world in which robots and humans work together. Robot bodies should be easily integrated into our living environments. Robots should be safe to be around. Robots should take commands from human users easily. Robots should be functionally capable. Robots should engage humans to help mitigate error states and task uncertainties. Meeting these challenges will bring robots closer to our vision of pervasive robotics.

The topics in Part G are essential for creating robots that operate in human-centered environments. The chapters cover organically human-centered and life-like robots and include hardware design, control (of locomotion, manipulation, and interaction), perception, user interfaces, and social and ethical implications for robotics. As such, Part G builds on all of the Handbook’s previous parts. The connection with the chapters in Robot Foundations (Part A) and Robot Structures (Part B), particularly Mechanisms and Actuation (Chap. 3), Sensing and Estimation (Chap. 4), Motion Planning (Chap. 5), Robot Systems Architectures and Programming (Chap. 8), AI Reasoning Methods for Robotics (Chap. 9), Robot Hands (Chap. 15), Legged Robots (Chap. 16), and Wheeled Robots (Chap. 17) are essential. There is also an important dependency on Sensing and Perception (Part C), Manipulation and Interfaces (Part D), and Mobile and Distributed Robotics (Part E) as these chapters cover some of the basic algorithms and technologies required by robots operating in human-centered environments.

Today’s approach to computation has progressed naturally from desktop computing, to mobile computing, to pervasive computing, ultimately leading to computation for interaction with the physical world, in other words, robotics. Part G presents a snapshot of the field’s advances for creating machines in our own image that are smart and obedient.

With this overview of Part G, we now provide a brief synopsis of each chapter.

Chapter 56, Humanoids, provides a concise overview of the state of the art in creating human-like machines, starting with a historical and philosophical discussion on the human example and understanding intelligence. These machines are capable of bipedal locomotion and manipulation. In addition, humanoid robots can take advantage of their entire body (e.g., lifting objects while moving the body to compensate for the load). Control issues specific to humanoids include static and dynamic stability during a mobile manipulation action. Humanoid robots interact with humans via perception systems which should be capable of interpreting behavior and mood as well as via speech systems for interpreting human language.

Chapter 57, Safety for Physical Human–Robot Interaction, discusses what happens when humans and robots share the same workspace and come into contact with one another. Safety can be jeopardized by mechanical failures, operator errors, or software problems. Designing and controlling robots with safety guarantees is a very important precondition for physical human–robot interaction (**pHRI**). The chapter discusses safety standards for **pHRI** and surveys several approaches to safety.

Chapter 58, Social Robots that Interact with People, discusses the creation of robots designed to interact with people in a social and emotional way for applications in education, entertainment, health care, etc. These robots’ embodiment is life-like and they are capable of multimodal communication. The chapter uses a case study of the Kismet robot to illustrate the idea of a machine capable of projecting emotion. The chapter surveys some basic approaches to giving robots sociocognitive skills such as shared attention, emotional empathy, and mental perspective tasking.

Chapter 59, Robot Programming by Demonstration, is an important approach to teaching robots what to do by providing either good or bad examples. This is an intuitive approach to robot control and learning of tasks with the potential of opening robot applications to nonexpert users. The chapter starts by discussing what it means for a robot to learn a new skill and surveys several learning approaches for this. Biologically oriented learning approaches such as conceptual models of imitation learning and neural models of imitation learning are also introduced. The chapter concludes with several open issues in robot programming by demonstration.

Chapter 60, Biologically Inspired Robots, starts with a discussion of the difference between bio-inspired and biomimetic robots. Bio-inspired robots seek to re-

produce a natural phenomenon but not necessarily the underlying means. Biomimetic robots reproduce both the natural phenomenon and the means. The chapter starts with a survey of bio-inspired morphologies. A survey of bio-inspired sensors from vision to audio, touch, smell, and taste is then presented. Bio-inspired actuators include locomotion topics such as crawling, legged locomotion, climbing swimming, flying, and manipulation. The chapter also examines bio-inspiration in the context of control and planning. This includes behavior-based architectures, learning robots, evolving robots, and developing robots. Finally, the chapter examines how to make machines self-sustaining from an energy point of view.

Chapter 61, Evolutionary Robotics, discusses a method for creating robots that is inspired by the Darwinian principle of selective reproduction of the fittest captured by evolutionary algorithms. The chapter describes the basic method and presents several case studies. Because the evolutionary method requires intensive computation, it is often run in simulation and the final result is transferred to the robot platform. However, in the recent past there were several successes with running evolutionary algorithms in real time on physical platforms to achieve complex behaviors such as learning to walk.

Chapter 62, Neurorobotics: From Vision to Action, looks at how neuroethology, the study of brain mechanisms for animal behavior, inspires the creation of a central nervous system for a machine. The chapter presents several case studies that sample this bio-inspired design of robot controllers structurally and functionally: the optic flow in bees and robots, visually

guided behaviors in frogs and robots, and navigation in rats and robots. The chapter then examines the role of the cerebellum in motion control and the role of mirror systems. The chapter concludes by observing the the brain has evolved to serve as action-oriented perception, which is a useful guiding principle for building robot controllers.

Chapter 63, Perceptual Robotics, discusses principles derived from high-level cognitive processing in vision in the human brain that have led to results in robotics and computer vision. The chapter is focused on the technical realization of perceptual functions in robots by examining relationships between biological perception and robotics systems. Object recognition is used as an exemplary task and issues such as representation, structural description models, neural representations, as well as recognition and learning algorithms are discussed. Next, example-based movement representations are examined to establish the connection between the functionality of the visual cortex and a class of computer vision algorithms.

Chapter 64, Roboethics: Social and Ethical Implications of Robotics, discusses the social and ethical implications in a society where robots coexist with humans. Starting with a philosophical introspection into the dangers of unlimited use of technology, the chapter argues for the need for a new ethics of robots. Many other factors, including the cultural differences in societies ready to accept robots, define this need. The chapter surveys the code of ethics, privacy, accuracy, intellectual property, and access which could be adopted by robotics. A taxonomy of robots, along with socio-ethical issues for each robot type is then presented.

Humanoids

Charles C. Kemp, Paul Fitzpatrick, Hirohisa Hirukawa, Kazuhito Yokoi, Kensuke Harada, Yoshio Matsumoto

Humanoid robots selectively emulate aspects of human form and behavior. Humanoids come in a variety of shapes and sizes, from complete human-size legged robots to isolated robotic heads with human-like sensing and expression. This chapter highlights significant humanoid platforms and achievements, and discusses some of the underlying goals behind this area of robotics. Humanoids tend to require the integration of many of the methods covered in detail within other chapters of this handbook, so this chapter focuses on distinctive aspects of humanoid robotics with liberal cross-referencing.

This chapter examines what motivates researchers to pursue humanoid robotics, and provides a taste of the evolution of this field over time. It summarizes work on legged humanoid locomotion, humanoid manipulation, whole-body activities, and approaches to human–robot communication. It concludes with a brief discussion of factors that may influence the future of humanoid robots.

56.1 Why Humanoids?

Throughout history, the human body and mind have inspired artists, engineers, and scientists. The field of humanoid robotics focuses on the creation of robots that are directly inspired by human capabilities (see

Chap. 60, *Biologically Inspired Robots*). These robots usually share similar kinematics to humans, as well as similar sensing and behavior. The motivations that have driven the development of humanoid robots vary widely.

For example, humanoid robots have been developed as general-purpose mechanical workers, as entertainers, and as test-beds for theories from neuroscience and experimental psychology [56.1–3].

56.1.1 The Human Example

On a daily basis, humans perform important tasks that are well beyond the capabilities of current robots. Moreover, humans are generalists with the ability to perform a wide variety of distinct tasks. Roboticists would like to create robots with comparable versatility and skill. When automating a task that people perform, it is natural to consider the physical and intellectual mechanisms that enable a person to perform the task. Exactly what to borrow from the human example is controversial. The literal-minded approach of creating humanoid robots may not be the best way to achieve some human-like capabilities (see Chap. 54, *Domestic Robots*). For example, dishwashing machines bear little similarity to the manual dishwashing they replace.

56.1.2 The Pleasing Mirror

Humans are humanity's favorite subject. A quick look at popular magazines, videos, and books should be enough to convince any alien observer that humanity is obsessed with itself. The nature of this obsession is not fully understood, but aspects of it have influenced the field of humanoid robotics.

Humans are social animals that generally like to observe and interact with one another [56.4]. Moreover, people are highly attuned to human characteristics, such as the sound of human voices and the appearance of human faces and body motion [56.5–7]. Infants show preferences for these types of stimuli at a very young age, and adults appear to use specialized mental resources when interpreting these stimuli. By mimicking human characteristics, humanoid robots can engage these same preferences and mental resources.

Humanity's narcissism has been reflected in media as diverse as cave paintings, sculpture, mechanical toys, photographs, and computer animation. Artists have consistently attempted to portray people with the latest tools at their disposal. Robotics serves as a powerful new medium that enables the creation of artifacts that operate within the real world and exhibit both human form and behavior [56.8].

Popular works of fiction have frequently included influential portrayals of humanoid robots and manmade humanoid creatures. For example, Karel Čapek's sci-

ence fiction play Rossum's Universal Robots (R.U.R.) is centered around the story of artificial people created in a factory [56.9]. This play from 1920 is widely believed to have popularized the term robot. Many other works have included explicit representations of humanoid robots, such as the robot Maria in Fritz Lang's 1927 film *Metropolis* [56.10], and the thoughtful portrayal of humanoid robotics by Isaac Asimov in works such as *The Caves of Steel* from 1954 [56.11]. The long history of humanoid robots in science fiction has influenced generations of researchers, as well as the general public, and serves as further evidence that people are drawn to the idea of humanoid robots.

56.1.3 Understanding Intelligence

Many researchers in the humanoid robotics community see humanoid robots as a tool with which to better understand humans [56.3, 12]. Humanoid robots offer an avenue to test understanding through construction (*synthesis*), and thereby complement the careful *analysis* provided by researchers in disciplines such as cognitive science.

Researchers have sought to better emulate human intelligence using humanoid robotics [56.13]. Scientists, developmental psychologists, and linguists have found strong links between the human body and human cognition [56.14]. By being embodied in a manner similar to humans, and situated within human environments, humanoid robots may be able to exploit similar mechanisms for artificial intelligence (AI). Researchers are also attempting to find methods that will enable robots to develop autonomously in a manner akin to human infants [56.15]. Some of these researchers use humanoid robots that can physically explore the world in a manner similar to humans [56.16].

56.1.4 Interfacing with the Human World

Environments built for humans have been designed to accommodate human form and behavior [56.17, 18]. Many important everyday objects fit in a person's hand and are light enough to be transported conveniently by a person. Human tools match human dexterity. Doors tend to be a convenient size for people to walk through. Tables and desks are at a height that is well matched to the human body and senses. Humanoid robots can potentially take advantage of these same accommodations, thereby simplifying tasks and avoiding the need to alter the environment for the robot [56.19]. For example, humanoid robots and people could potentially collaborate with one another in the same space using the same

Fig. 56.1 The humanoid robot HRP-1S driving a backhoe (Courtesy of Kawasaki Heavy Industries, Tokyu Construction and AIST). The robot can be teleoperated by a human operator to control the backhoe remotely. The same robot could potentially interface with many different unmodified machines

tools [56.20]. Humanoid robots can also interface with machinery that does not include drive-by-wire controls, as shown by the teleoperated robot in the cockpit of a backhoe in Fig. 56.1 [56.21].

Mobility serves as another example. It is very difficult to create a tall wheeled robot with a small footprint that is capable of traversing stairs and moving over rough terrain. Robots with legs and human-like behavior could potentially traverse the same environments that humans traverse, such as the industrial plant shown in Fig. 56.2, which has stairs and handrails designed for human use [56.23]. In addition to mobility advantages, legs have the potential to help in other ways. For example, legs could enable a humanoid robot to

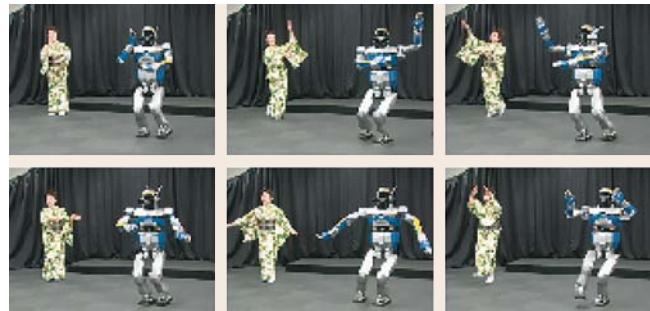

Fig. 56.3 The humanoid robot HRP-2 dancing with a human [56.22]. The human is a master of a traditional Japanese dance whose dancing was recorded by a motion-capture system, and transformed for use by the robot

change its posture in order to lean into something, pull with the weight of its body, or crawl under an obstacle [56.24, 25].

56.1.5 Interfacing with People

People are accustomed to working with other people. Many types of communication rely on human form and behavior. Some types of natural gestures and expression involve subtle movements in the hands and face (Chap. 58, *Social Robots that Interact with People*). People can interpret eye gaze and facial expressions without training. Humanoid robots can potentially simplify and enhance human–robot interaction by taking advantage of the communications channels that already exist between people.

Similarly, people already have the ability to perform many desirable tasks. This task knowledge may

Fig. 56.2 HRP-1 operating in a mockup of an industrial plant (Courtesy of Mitsubishi Heavy Industries)

Fig. 56.4 Actroid (Courtesy of Kokoro), an android designed for entertainment, telepresence, and media roles

be more readily transferred to humanoid robots than to a robot with a drastically different body. This is especially true of cultural actions centered around the human form (Fig. 56.3).

56.1.6 Entertainment, Culture, and Surrogates

Humanoid robots are inherently appropriate for some applications. For example, many potential forms of entertainment, such as theater, theme parks, and adult companionship, would rely on a robot that closely re-

sembles a human, see Fig. 56.4. For a humanoid robot to be an improvement over a wax figure or an animatronic historical character, it must be realistic in form and function.

People may one day wish to have robots that can serve as an avatar for telepresence, model clothing, test ergonomics, or serve other surrogate roles that fundamentally depend on the robot's similarity to a person. Along these lines, robotic prosthetics have a close relationship to humanoid robotics, since they seek to directly replace parts of the human body in form and function (Chap. 53, *Health Care and Rehabilitation Robotics*).

56.2 History and Overview

There is a long history of mechanical systems with human form that perform human-like movements. For example, Al-Jazari designed a humanoid automaton in the 13th century [56.27], Leonardo da Vinci designed a humanoid automaton in the late 15th century [56.28],

Fig. 56.5 WABOT-1 (1973) and WABOT-2 (1984) (Courtesy of Humanoid Robotics Institute, Waseda University)

and in Japan there is a tradition of creating mechanical dolls called Karakuri ningyo that dates back to at least the 18th century [56.29]. In the 20th century, animatronics became an attraction at theme parks. For example, in 1967 Disneyland opened its Pirate's of the Caribbean ride [56.30], which featured animatronic pirates that play back human-like movements synchronized with audio. Although programmable, these humanoid animatronic systems moved in a fixed open-loop fashion without sensing their environment.

In the second half of the 20th century, advances in digital computing enabled researchers to incorporate significant computation into their robots for sensing, control, and actuation. Many roboticists developed isolated systems for sensing, locomotion, and manipulation that were inspired by human capabilities. However, the first humanoid robot to integrate all of these functions and capture widespread attention was WABOT-1, developed by Ichiro Kato et al. at Waseda University in Japan in 1973 (Fig. 56.5).

The WABOT robots integrated functions that have been under constant elaboration since: visual object recognition, speech generation, speech recognition, bimanual object manipulation, and bipedal walking. WABOT-2's ability to play a piano, publicized at the Tsukuba Science Expo in 1985, stimulated significant public interest.

In 1986, Honda began a confidential project to create a humanoid biped. Honda grew interested in humanoids, perhaps seeing in them devices of complexity comparable to cars with the potential to become high-volume consumer products one day. In 1996, Honda unveiled the Honda Humanoid P2, the result of this confidential project. P2 was the first full-scale humanoid capable of

Fig. 56.6 Honda P2 (180 cm tall, 210 kg), P3 (160 cm, 130 kg), and Asimo (120 cm, 43 kg) [56.26]. (Images courtesy of Honda)

stable bipedal walking with onboard power and processing. Successive designs reduced its weight and improved performance (see Fig. 56.6). Compared to humanoids built by academic laboratories and small manufacturers, the Honda humanoids were a leap forward in sturdiness, using specially cast lightweight high-rigidity mechanical links, and harmonic drives with high torque capacity.

In parallel with these developments, the decade-long *Cog* project began in 1993 at the MIT Artificial Intelligence laboratory in the USA with the intention of creating a humanoid robot that would, *learn to ‘think’ by building on its bodily experiences to accomplish progressively more abstract tasks* [56.13]. This project gave rise to an upper-body humanoid robot whose design was heavily inspired by the biological and cognitive sciences. Since the inception of the Cog project, many humanoid robotics projects with similar objectives have been initiated, and communities focused on developmental robotics, autonomous mental development (AMD [56.31]), and epigenetic robotics have emerged [56.32].

As of the early 21st century, many companies and academic researchers have become involved with humanoid robots, and there are numerous humanoid robots across the world with distinctive features.

56.2.1 Different Forms

Today, humanoid robots come in a variety of shapes and sizes that emulate different aspects of human form and behavior (Fig. 56.7). As discussed, the motivations that have driven the development of humanoid robots vary widely. These diverse motivations have lead to a vari-

Fig. 56.7 Kismet is an example of a humanoid head for social interaction

Fig. 56.8 The NASA Robonaut consists of an upper body placed on a wheeled mobile base

ety of humanoid robots that selectively emphasize some human characteristics, while deviating from others.

One of the most noticeable axes of variation in humanoid robots is the presence or absence of body parts. Some humanoid robots have focused solely on the head and face, others have a head with two arms mounted to a stationary torso, or a torso with wheels (see, for example, Fig. 56.8), and still others have an articulate and expressive face with arms, legs, and a torso. Clearly, this variation in form impacts the ways in which the robot can be used, especially in terms of mobility, manipulation, whole-body activities, and human–robot interaction.

56.2.2 Different Degrees of Freedom

Humanoid robots also tend to emulate some degrees of freedom in the human body, while ignoring others. Humanoid robots focusing on facial expressivity often incorporate actuated degrees of freedom in the face to generate facial expressions akin to those that humans can generate with their facial muscles. Likewise, the upper body of humanoid robots usually includes two arms, each with a one-degree-of-freedom (one-DOF) rotary joint at the elbow and a three-DOF rotary joint for the shoulder, but rarely attempt to emulate the human shoulder’s ability to translate or the flexibility of the human spine [56.33, 34].

In general, humanoid robots tend to have a large number of degrees of freedom and a kinematic structure that may not be amenable to closed-form analysis due to redundancy and the lack of a closed-form inverse. This is in contrast to traditional industrial manipulators that are often engineered to have minimal redundancy (six DOFs) and more easily analyzed kinematic structures.

56.2.3 Different Sensors

Humanoid robots have made use of a variety of sensors including cameras, laser range finders, microphone arrays, lavalier microphones, and pressure sensors. Some researchers choose to emulate human sensing by selecting sensors with clear human analogs and mounting these sensors on the humanoid robot in a manner that mimics the placement of human sensory organs. As discussed in Sect. 56.6, this is perhaps most evident in the use of cameras. Two to four cameras are often mounted within the head of a humanoid robot with a configuration similar to human eyes.

The justifications for this bias towards human-like sensing include the impact of sensing on natural human–robot interaction, the proven ability of the human senses to support human behavior, and aesthetics. For example, with respect to human–robot interaction, nonexperts can sometimes interpret the functioning and implications of a human-like sensor, such as a camera, more easily. Similarly, if a robot senses infrared or ultraviolet radiation,

the robot will see a different world than the human. With respect to behavior, placement of sensors on the head of the robot allows the robot to sense the world from a vantage point that is similar to that of a human, which can be important for finding objects that are sitting on a desk or table.

Prominent humanoid robots have added additional sensors without human analogs. For example, Kismet used a camera mounted in its forehead to augment the two cameras in its servoed eyes, which simplified common tasks such as tracking faces. Similarly, versions of Asimo have used a camera mounted on its lower torso that looks down at the floor in order to simplify obstacle detection and navigation during locomotion.

56.2.4 Other Dimensions of Variation

Other significant forms of variation include the size of the robot, the method of actuation, the extent to which the robot attempts to appear like a human, and the activities the robot performs.

56.3 Locomotion

Bipedal walking is a key research topic in humanoid robotics (see also Chap. 16, *Legged Robots*, for a review of this topic in the context of locomotion in general). Legged locomotion is a challenging area of robotics research, and bipedal humanoid locomotion is especially challenging. Some small humanoid robots are able to achieve statically stable gaits by having large feet and a low center of mass, but large humanoids with a human-like weight distribution and body dimensions

typically need to balance dynamically when walking bipedally.

56.3.1 Bipedal Locomotion

Currently the dominant methods for bipedal legged locomotion with humanoids make use of the zero-moment point (**ZMP**) criterion to ensure that the robot does not fall over [56.35]. As discussed in detail in Chap. 16, con-

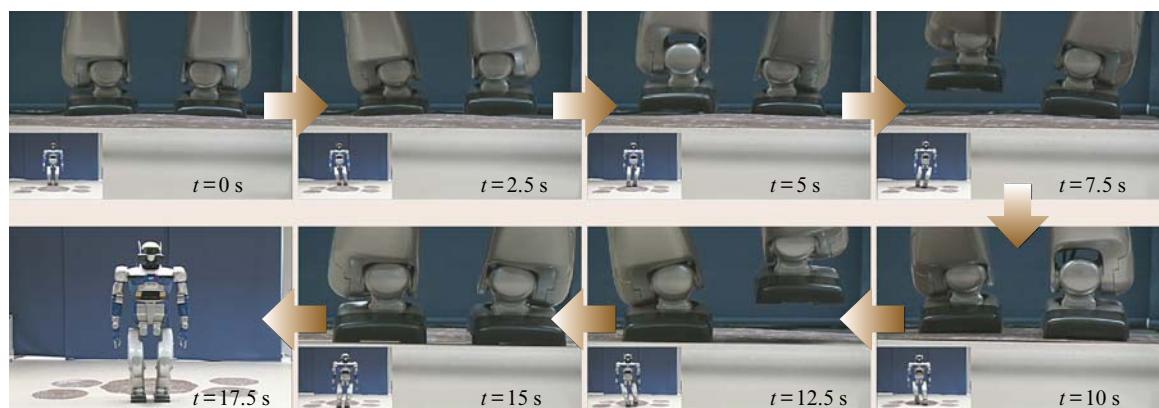

Fig. 56.9 HRP-2 walks on a slightly uneven surface

Fig. 56.10 These robots from Delft, MIT and Cornell (*left to right*) are designed to exploit their natural dynamics when walking [56.36]. (Image courtesy of Steven H. Collins)

trol of the robot's body such that the **ZMP** sits within the support polygon of the robot's foot ensures that the foot remains planted on the ground, assuming that friction is high enough to avoid slipping. The **ZMP** can be used to plan motion patterns that make the robot dynamically stable while walking.

Controllers based on the **ZMP** criterion try to follow a planned sequence of contact states and are often unable to change the landing positions in real time in response to lost contact. Current **ZMP**-based bipedal walking algorithms have difficulty handling unexpected perturbations, such as might be encountered with uneven natural terrain (Fig. 56.9). Robots using **ZMP** differ from human locomotion in significant ways. For example, unlike people, robots using **ZMP** typically do not exploit the natural dynamics of their legs, or control the impedance of their joints.

Augmenting **ZMP**-based control is currently an active area of research. As will be discussed in Sect. 56.5 on whole-body activities researchers are working to integrate manipulation and bipedal locomotion. For example, when a robot walks while grasping a handrail, the contact could potentially increase the stability of the robot, but the **ZMP** criterion does not easily generalize

Fig. 56.12 The humanoid robot HRP-2P getting up from a lying-down position

to this task. So far, a generic and rigorous new criterion has not been established.

As an example of an alternative mode of bipedal locomotion, some running robots have used controllers based on an inverted pendulum model to achieve stable gaits. These methods change the landing positions to keep the robot dynamically stable [56.37]. More recently, researchers have begun to use the principles of bipedal passive-dynamic walkers to develop powered bipedal walkers that walk with high efficiency in a human-like way by exploiting natural dynamics (Fig. 56.10 [56.36]).

56.3.2 Falling Down

A human-scale robot should expect to fall from time to time in realistic conditions. A humanoid robot may fall down due to a large disturbance even if the motion is planned carefully and a sophisticated feedback controller is applied to the robot. In this event, the robot could be damaged significantly during a fall, and could also damage the environment or injure people who are nearby. An important area of research is how to control the robot's fall in order to gracefully recover or minimize damage. The Sony **QRI**O can control its falling motions in order to reduce the impact of touch down [56.38], al-

Fig. 56.11 Example of controlled falling-down motion

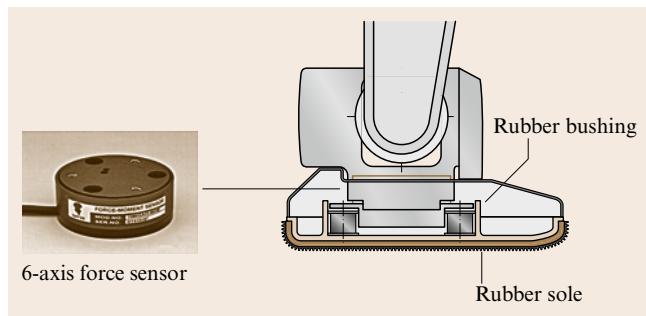

Fig. 56.13 Example of a humanoid foot structure for legged locomotion that uses compliance and force/torque sensing

Fig. 56.14 Asimo and artificial landmarks on the floor

though it is of a relatively small size (which simplifies the problem). Fujiwara et al. developed a falling motion controller for a human-size humanoid robot that is falling backwards [56.39]. Figure 56.11 shows an example of a controlled falling motion. The general problem is still very much an active area of research. Similarly,

there is also the issue of getting back up again [56.40] (Fig. 56.12).

56.3.3 Sensing for Balance

Bipedal walking needs to be robust to unexpected disturbances encountered during the execution of planned walking patterns. In these situations, walking can sometimes be stabilized with feedback control and appropriate sensing. Many humanoid robots, such as Honda's Asimo, make use of accelerometers, gyroscopes, and six-axis force/torque sensors to provide feedback to the robot during locomotion.

Force/torque sensors have long been applied to manipulators for the implementation of force control, but force/torque sensors with sufficient robustness to handle foot impact for a full-size humanoid robot are relatively new. When the foot of the robot touches down, the foot receives an impact which can disturb its walking. This impact can be rather large, especially when the robot is walking quickly. Some feet now incorporate a spring and damper mechanism as shown in Fig. 56.13 in order to mitigate these problems. As with many other aspects of bipedal humanoid locomotion, foot design is currently an open problem.

56.3.4 Localization and Obstacle Detection

In order for a humanoid robot to walk in unmodeled environments, localization and obstacle detection are essential. Wheeled robots encounter similar issues while navigating, but full bipedal humanoids have more-specialized requirements. For example, bipedal humanoids have the ability to control contact with the world through their highly articulate legs.

Artificial landmarks can simplify localization. As shown in Fig. 56.14, Honda's Asimo uses a camera mounted on its lower torso that looks down at the floor to find artificial markers for position correction [56.41]. Accurate positioning is important for long-distance navigation and stair climbing, since slippage usually occurs while walking and accumulated positional and directional errors can lead to severe failures.

Obstacle avoidance is also an important function for locomotion. Disparity images generated by stereo vision have been utilized for this purpose. For example, the plane segment finder [56.42] developed by Okada et al. helps detect traversable areas. Figure 56.15 shows the result of detecting clear areas of the floor plane appropriate for gait generation.

Humanoids require a great deal of computation due to the need for sophisticated sensing and con-

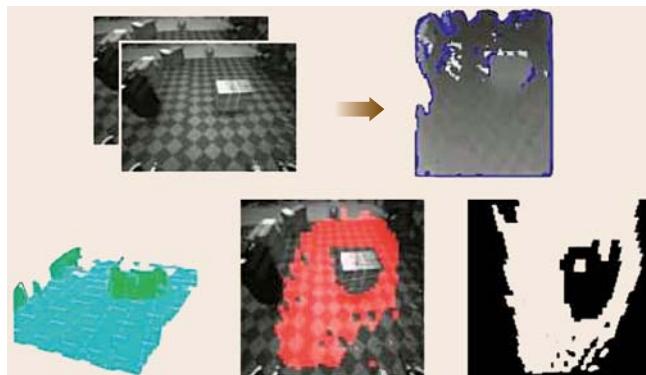

Fig. 56.15 Plane segment finder for detecting traversable floor area

trol. Customized computational hardware may help mitigate this problem. For example, Sony's humanoid robot **QRIQ** is equipped with a field-programmable gate array (FPGA) to generate disparity maps in

real time from the stereo cameras. This real-time vision system has been used to detect floor areas, stair steps, and obstacles for navigation [56.43, 44].

56.4 Manipulation

Hands and arms are the main interfaces with which humans act on the world around them. Manipulation research within humanoid robotics typically focuses on the use of anthropomorphic arms, hands, and sensors to perform tasks that are commonly performed by people. Several chapters of the handbook relate to these goals, including Chap. 24 (*Visual Servoing and Visual Tracking*), Chap. 26 (*Motion for Manipulation Tasks*), and Chap. 28 (*Grasping*).

56.4.1 The Arm and Hand

The kinematics of humanoid robot arms emulate the human arm, which can be approximated by seven degrees of freedom (DOFs), with three at the shoulder,

one at the elbow, and three at the wrist. The use of seven DOFs results in a redundant degree of freedom with respect to the six-DOF pose of the hand. To reduce mechanical complexity, humanoid robot arms sometimes have fewer than seven DOFs, for example, ARMAR-III and Justin have seven-DOF arms, Cog and Domo have six-DOF arms, and Asimo has five-DOF arms (Fig. 56.16) [56.45, 46].

Humanoid robot hands tend to vary more in their design (see Chap. 15, *Robot Hands*). The human hand is highly complex with over 20 DOFs (i.e., approximately four DOFs per finger and a five-DOF thumb) in a very compact space with a compliant exterior, dense tactile sensing, and muscular control. If a robot hand is to be mounted on a robot arm, there are additional constraints in terms of the mass of the robot hand, since the hand sits at the end of the arm and must be efficiently moved in

Fig. 56.16 The humanoid robot Justin has two seven-DOF torque-controlled arms (DLR-Lightweight-Robot-III), and two 12-DOF hands (DLR-Hand-II). Justin's body is larger than a human's

Fig. 56.17 3-D object recognition by HRP-2 using versatile volumetric vision

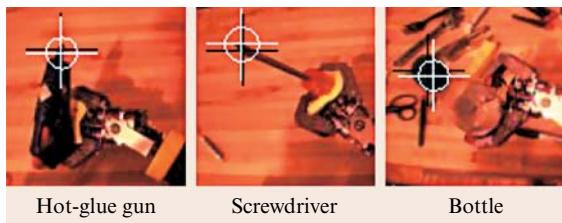

Fig. 56.18 Using visual motion, Domo detects (white cross) the tips of tool-like objects it is rigidly grasping with error (white circle) comparable to the error achieved with hand labels (black cross)

space. Researchers have approximated the human hand with varying levels of accuracy, including the ACT hand, the 20-DOF Shadow Hand, the 12-DOF DLR-Hand-II, the 11-DOF Robonaut hand, the two-DOF Cog hand, and the one-DOF Asimo hand [56.47–50].

The ACT hand is an excellent representative of the high-fidelity end of the spectrum, since it emulates the bone structure, inertial properties, and actuation of the human hand in addition to the kinematics. Humanoid robot hands often include passive degrees of freedom. For example, one DOF of the two-DOF Cog hand controlled a multijointed power grasp, while the other controlled a multijointed two-fingered precision grasp. Studies indicate that many human grasps can be approximated with two degrees of freedom [56.53], so simplified hands may be sufficient to emulate a variety of human manipulation activities.

56.4.2 Sensing for Manipulation

Model-Based Vision

A common approach to visual perception for humanoid robots is real-time three-dimensional (3-D) object recognition and six-DOF pose estimation using models of the objects to be manipulated (see Chap. 23, *3-D Vision and Recognition*).

An example of this approach is provided by the versatile volumetric vision (**VVV**) system, which is an edge-based 3-D vision system developed by Tomita et al. [56.54]. The **VVV** system has been utilized to find and grasp objects during everyday manipulation tasks. Figure 56.17 shows a demonstration of the HRP-2 recognizing a beverage can on a table so that it can pick up the can and throw it into a trash can. This integrated system was demonstrated at Aichi EXPO 2005, where it enabled a human operator to control the HRP-2 humanoid robot in a semi-autonomous fashion with reduced effort [56.55]. The **VVV** system has also helped HRP-2 carry a table in cooperation with a human [56.56].

Other robots have used similar approaches. For example, Robonaut from the National Aeronautics and Space Administration (**NASA**) Johnson Space Center (JSC) has used model-based vision to perform everyday manipulation tasks, such as tightening lug nuts on a wheel [56.57].

Feature-Based Vision

Another approach to visual perception for humanoid robots is feature-based vision. Encoding tasks in terms of task-relevant features, such as the tip of a tool or the contact surface of a hand, offers an alternative to approaches that use detailed 3-D models of objects. In order to generalize a task across different objects, only the task-relevant features need to be detected and mapped.

An example of this approach is provided by the humanoid robot Domo, which uses task-relevant features to perform everyday tasks such as pouring, stirring, and brushing. Domo detects features such as the opening of a container or the tip of a tool (Fig. 56.18) and then visually servo these features with respect to one another in order to perform a task. Once the objects are in contact with one another, Domo uses force sensing and compliance to simplify tasks such as regrasping, inserting, and placing objects [56.52, 58].

Active Perception

Through action, robots can simplify perception. Humanoid robots have used this approach in ways that are reminiscent of human behavior. For example, a humanoid robot can reach out into the world to physically sense its surroundings (Fig. 56.19), or induce visual motion through physical contact so as to better estimate the extent of manipulable objects [56.59]. Similarly, a hu-

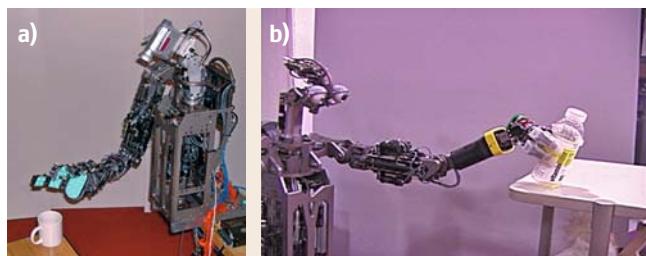

Fig. 56.19a,b The humanoid robots Obrero (a) and Domo (b) use passive compliance and force control to safely reach out into the world. Obrero haptically grasps an object [56.51]. Domo physically finds the shelf, and uses force control to let objects settle into place [56.52]

manoid robot can select postures that enable it to more easily view visual features that are relevant to the current task.

Force, Torque, and Tactile Sensing

When in contact with the world, force, torque, and tactile sensing are especially valuable (see Chap. 19, *Force and Tactile Sensors*), for example, as shown in the section on whole-body activities, force/torque sensing in the arms can be used to help a humanoid robot stay balanced while lifting or pushing an object for which an accurate model with friction coefficients and mass does not exist (Figs. 56.36 and 56.23). Likewise, many of the capabilities of the humanoid robots Cog, Domo, and Obrero depend on force, torque, and tactile sensing. As another example, the humanoid robot Justin from DLR uses torque sensing at all of its joints to perform Cartesian impedance control, which can implement virtual springs to coordinate bimanual manipulation of large objects (Fig. 56.16) [56.46].

The extent to which passive compliance and torque control should be integrated into humanoid robots is still an open issue (see Chap. 7, *Force Control*). Many humanoid robots have stiff joints that are well suited to position control, or perform force control using feedback from a force/torque sensor near the point of contact, such as the wrist or foot. However, even when a human attempts to maintain the position of her hand, the joints of her arm continue to exhibit significant compliance [56.60, 61] (Chap. 13, *Robots with Flexible Elements*).

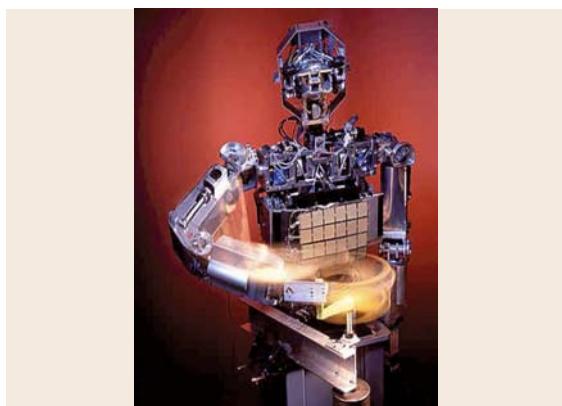

Fig. 56.20 The humanoid robot Cog used neural oscillators in conjunction with compliant force-controlled arms to perform a variety of everyday tasks with human tools, such as crank turning, hammering, and sawing. Photo by Sam Ogden

56.4.3 Rhythmic Manipulation

Many everyday tasks performed by humans involve rhythmic motions rather than discrete motions [56.62].

A good example of rhythmic humanoid manipulation was provided by Williamson, who demonstrated that central pattern generators (CPGs) in conjunction with compliant force-controlled arms can enable a humanoid robot to perform many everyday rhythmic manipulation tasks in a manner similar to humans (Fig. 56.20). His approach enabled the humanoid robot Cog to perform a variety of tasks without motion planning or model-based control. These tasks included hammering nails, sawing through wood, turning a crank at various orientations, turning cranks bimanually, playing with a slinky toy bimanually, and playing a snare drum [56.63]. The CPGs entrained on the natural dynamics of the robot's arm coupled to the environment. The output of the CPGs were used to control the set point of virtual springs in the joints, which were actuated with series elastic actuators (SEAs) [56.64].

Rhythmic motion can also be used as a basis for learning human-like manipulation tasks. For example, The humanoid robot DB has learned to perform rhythmic manipulation tasks, such as drumming, from human demonstration [56.65].

56.4.4 Cooperative Manipulation

Humanoid robots have potential advantages when working with humans to perform tasks cooperatively [56.20] (see Chap. 57, *Safety for Physical Human–Robot Interaction*). Humans typically have extensive experience cooperating with other humans to perform manual tasks. Humanoid robots have the potential to simplify this

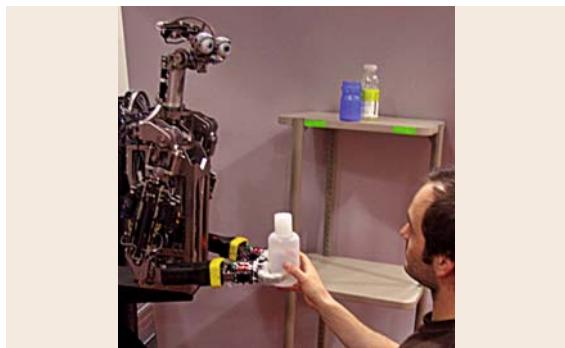

Fig. 56.21 Domo works with a human to place objects on a shelf [56.52]

form of human–robot interaction by closely matching a human counterpart during cooperative activities. For example, this can reduce the need for a human cooperator to learn how to interact with novel kinematic structures and sensing, and enable the robot and the human to use the same tools. Robonaut has been teleoperated to perform an insertion task in cooperation with a human [56.66]. Work with Domo has shown that people without prior experience readily interpret reaching cues and place an object in Domo’s hand in a favorable pose (Fig. 56.21) [56.52, 67]. Likewise, as shown in the section on whole-body activities (Sect. 56.6), humanoid robots have the potential to help a person move large objects (Fig. 56.36).

56.4.5 Learning and Development

Humans are very successful at learning new manipulation tasks, and human infants progressively develop sophisticated manipulation abilities over the course of several years. Researchers within humanoid robotics have attempted to emulate these aspects of human intelligence.

Learning by demonstration is a common way for people to learn from one another. Since humanoid robots have a similar form to humans, and have been designed to perform similar tasks, learning by demonstration may have advantages for skill acquisition [56.68, 69] (see Chap. 59, *Robot Programming by Demonstration*). The humanoid robot ARMAR has a framework for learning bimanual tasks from demonstration, which has enabled ARMAR to open a container with a screw-on lid [56.70]. Researchers have also sought to integrate learning by

Fig. 56.22 The humanoid robot DB learns to play air hockey against a human opponent through observation and practice. ©JST, ATR; Robot developed by SARCOS

demonstration with learning from exploration and motor primitives. For example, Bentivegna et al. have demonstrated methods that enable the humanoid robot DB to learn to play air hockey by observing a human opponent and practicing (Fig. 56.22) [56.71].

Biologically inspired approaches to humanoid manipulation are also common (see Chap. 62, *Neuro-robotics: From Vision to Action*). Before contact, the hand must move through free space to a target. Researchers have worked to enable robots to develop reaching behaviors using methods inspired from infant development [56.15]. Likewise, researchers such as Platt et al. have created methods that enable a humanoid robot to learn to grasp everyday objects in order to perform common tasks, such as grasping grocery items and placing them in a bag [56.72].

56.5 Whole-Body Activities

The two previous sections have focused on humanoid locomotion and humanoid manipulation independently. This section looks at mobile manipulation using a full humanoid robot with both arms and legs. Researchers wish to enable these humanoids to perform tasks such as lifting and carrying a box (as shown in Fig. 56.23), climbing a ladder, or even playing a sport. This section provides a brief glimpse into several approaches to this challenging problem.

Unlike the industrial manipulators described in Chap. 42 (*Industrial Robotics*), or a humanoid that is rigidly fixed in place, a bipedal humanoid must be controlled so as to remain balanced while manipulating an

object. Without actively maintaining stability, the robot could tip over and fall to the ground.

Moreover, a humanoid robot usually has many joints compared to a standard industrial manipulator. Humanoids are a kind of redundant robot as described in Chap. 11 (*Redundant Manipulators*). Consequently, there are many postures that can achieve a given pose of the robot’s hand. Out of the possible configurations of the robot’s body, many will result in the robot falling over.

Figure 56.24 shows an overview of several approaches to whole-body motion generation for humanoid robots. These methods decouple the problem

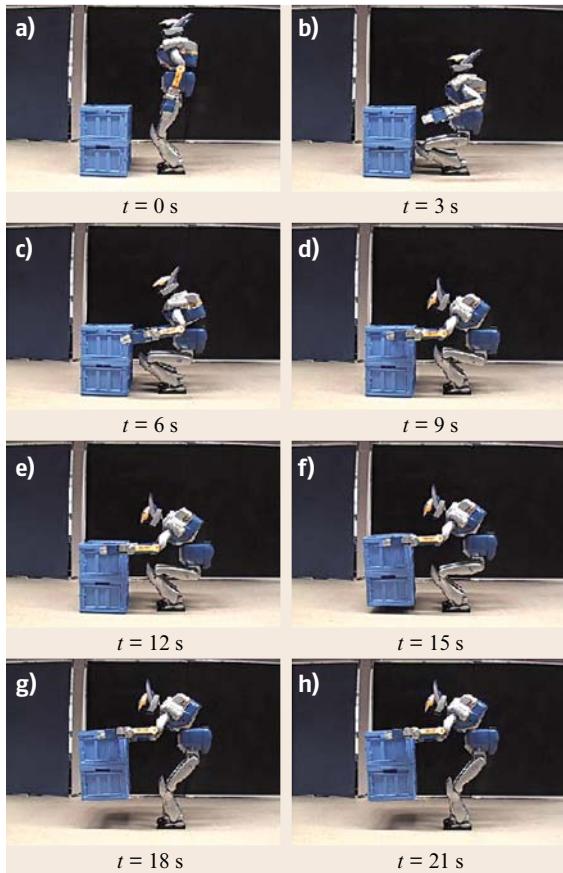

Fig. 56.23 Lifting an object while moving the waist to compensate for the load [56.73]

by computing a coarse movement and transforming it into a dynamically balanced movement. Then, during the whole-body activity, the humanoid uses a sensory

feedback control system to stabilize its motion. If the generated motion pattern were perfect and the state of the world could be exactly anticipated in advance, this feedback might be unnecessary. However, it is very difficult, if not impossible, to make a perfect motion pattern during real-world situations, since models of the robot and the environment inevitably have errors, for example, surface conditions, such as friction and compliance, can be very important, yet difficult to anticipate (Chap. 27, *Contact Modeling and Sliding Manipulation*).

This section focuses on the first two parts of the process shown in Fig. 56.24: coarse motion generation and the conversion of coarse motions into detailed motions that enable whole-body activities.

56.5.1 Coarse Whole-Body Motion

There are currently four prevalent ways to generate coarse whole-body motion:

1. Using a motion capture system
2. using a graphical user interface (GUI) offline
3. using a teleoperation interface in real time
4. using automatic motion planning

Using a Motion Capture System

Humanoid robots have a human-like shape and many researchers would like humanoid robots to perform tasks in a human-like way. Consequently, human motion is often used when generating the motion of a humanoid robot. Motion capture systems, such as those used by movie studios for special effects, are commonly used for recording human motion. Typically a human subject

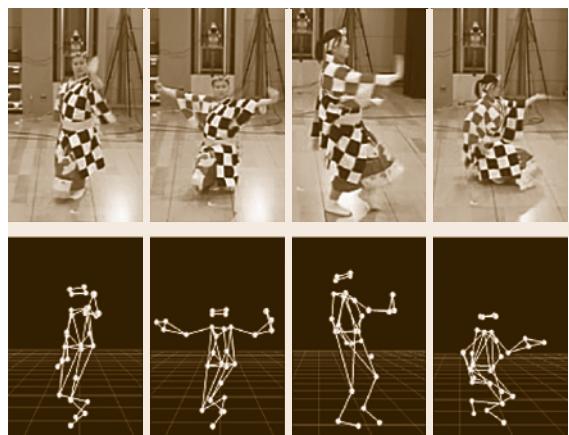

Fig. 56.25 An example of captured motion data for a Japanese folk dance [56.22]

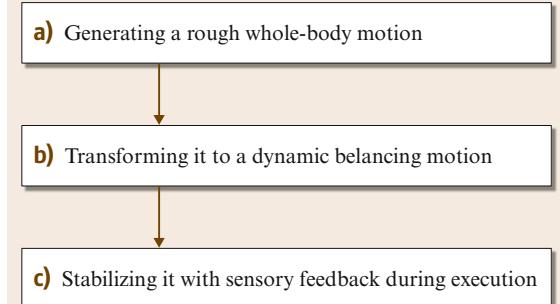

Fig. 56.24 Overview of motion-generation stages for a balancing robot

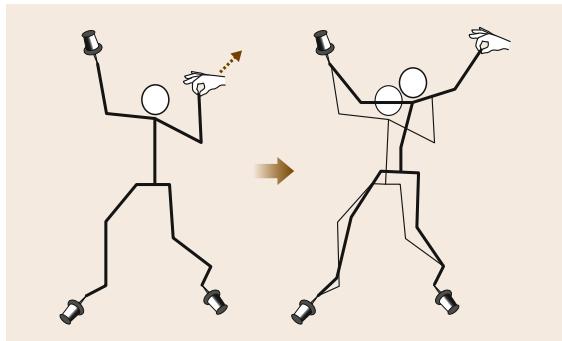

Fig. 56.26 The *pin-and-drag* interface for generating coarse movements [56.74]

performs actions while wearing easily detected markers on his or her body. The motion of these markers are recorded by cameras placed in the room, and software then infers the 3-D positions of these markers over time. Figure 56.25 shows an example: the captured motions of a woman performing a Japanese folk dance [56.22].

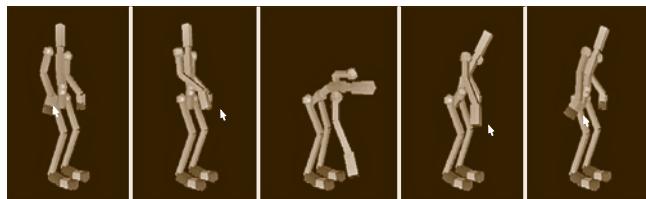

Fig. 56.27 An example of a whole-body motion generated using the pin-and-drag interface [56.74]

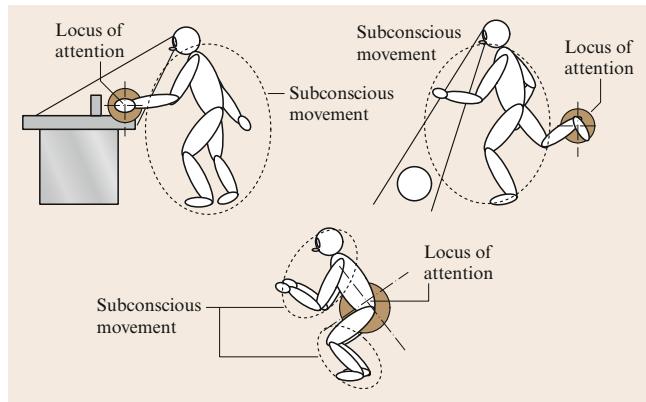

Fig. 56.28 While teleoperating a robot, the human operator can focus his or her attention on a small part of the humanoid robot. Automatic techniques can then take this coarse motion specification and automatically generate full motion specifications that meet important constraints, such as maintaining the robot's balance

This is a mature technology, so motions such as those shown in Fig. 56.25 can easily be obtained and then used as a reference for a humanoid's whole-body motion. Due to kinematic similarities, coarse kinematic motions can be transferred to a humanoid robot. However, due to dynamic differences, such as mass distributions and torque generation, captured motions may not be stable or feasible. Moreover, the task constraints and sensory feedback involved in a motion-captured activity may not be easily inferred, which can lead to robot motion that is similar in appearance, yet fails to achieve the goals of a motion.

Using a GUI Offline

Tools such as those used in character animation for computer graphics can also be used to design movements for humanoid robots. If the designer were forced to control each of the many degrees of freedom independently, the process would be tedious and inefficient. One approach to overcoming this issue is a *pin-and-drag* GUI interface, which can help the designer more efficiently control the motion of all the joints of a high degree of freedom humanoid [56.74]. Figure 56.26 outlines this interface. The user can pin links of the humanoid to desired locations. Then the software automatically generates natural movements of the humanoid's joints subject to these constraints, while the user drags other links. Figure 56.27 shows a whole-body movement generated by dragging the right hand up and down for four seconds while pinning the left hand, the toes, and the heels. This results in natural-looking movements for picking up an object. As with the motion capture system, this generated whole-body motion may not be directly applicable to a humanoid robot due to dynamics and modeling errors.

Using a Teleoperation Interface in Real Time

Given the complexity and potential instability of humanoid robots, every detail of a whole-body activity cannot be efficiently controlled by a human in real time. The teleoperation (Chap. 31, *Telerobotics*) of humanoid robots combines coarse motion control provided by a user with methods that generate effective full-body motions. Since teleoperation occurs in real time, the methods used to perform this transformation cannot rely on knowledge of future motion commands, and must be computationally efficient. This rules out the use of methods such as the autobalancer (described later), which requires an entire motion trajectory in order to globally optimize the conversion.

Fig. 56.29 An example whole-body motion generated by the RRT motion planning system [56.77]

Human motions are generated with a mixture of two kinds of motion: motions that require careful attention and motions that require little cognitive effort (Fig. 56.28). A similar division can be used when designing a teleoperation system for whole-body activities [56.75]. For example, in a manner similar to the previously discussed GUI interface, a human operator can control specific points on a humanoid robot's body in order to generate coarse motions. By reducing the aspects of the motion that the human operator must specify, he or she can control a humanoid robot to perform complex motions in real time using simple interfaces, such as joysticks or high-level commands [56.76].

Using Automatic Motion Planning

Motion capture, teleoperation, and GUI-based motion editing tools give the user interactive control over the robot's motions, but they can be time consuming

to use. Fast path-planning techniques such as rapidly exploring random trees (RRT) [56.79] can compute collision-free full-body motions for humanoid robots automatically [56.77] (see Chap. 5, *Motion Planning*, and Chap. 26, *Motion for Manipulation Tasks*). Given geometric models of the humanoid and the environment, an initial posture, and a goal posture, the planning system automatically searches for a collision-free whole-body motion that moves the humanoid from the initial posture to the goal posture (Fig. 56.29). This type of method can also search for statically stable postures that smoothly interpolate between the initial and goal posture, and explicitly include other constraints based on the dynamics.

56.5.2 Generating Dynamically Stable Motions

The methods presented in Sect. 56.5.1 can be useful when generating coarse whole-body motions for a humanoid robot. However, for some of these methods the motions generated will not take into account the dynamic stability of the robot, and may result in the robot falling over. This subsection presents two example techniques for converting coarse motions to dynamically-stable motions: the dynamics filter, and the autobalancer (other methods such as strict trunk motion computation used in the motion generation system for waseda bipedal humanoid (WABIAN) [56.80] are also possible).

Dynamics Filter

The dynamics filter proposed by Yamane and Nakamura [56.78] can convert a physically infeasible motion into a feasible one for a given humanoid. This consists of a controller and optimizer as shown in Fig. 56.30.

The controller calculates reference joint accelerations by using local and global feedback loops with respect to the given coarse motions and the current state of the humanoid model. The optimizer calculates joint accelerations that minimize the difference between the reference joint acceleration and the current joint acceleration under the given contact constraints, such as floor friction and contact force feasibility. Figure 56.31 shows motion-captured data of a human walking and the resulting, physically feasible motion produced by the dynamics filter. The motions look similar, but the contact conditions for the feet have been modified to be physically feasible.

Autobalancer

The autobalancer calculates all joint angles at every sample in time by solving a quadratic programming op-

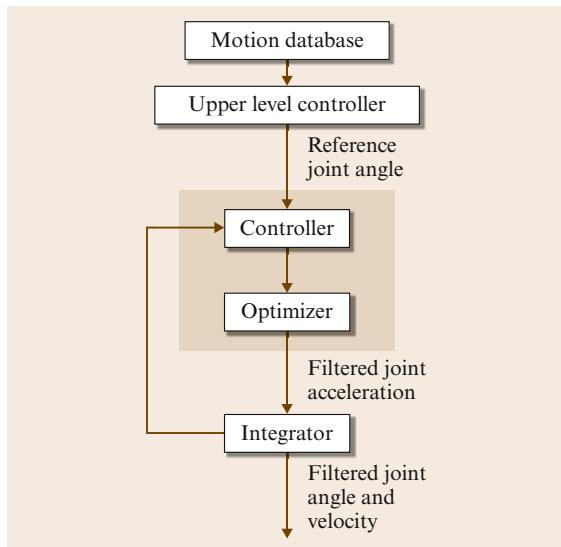

Fig. 56.30 Dynamics filter system diagram [56.78]

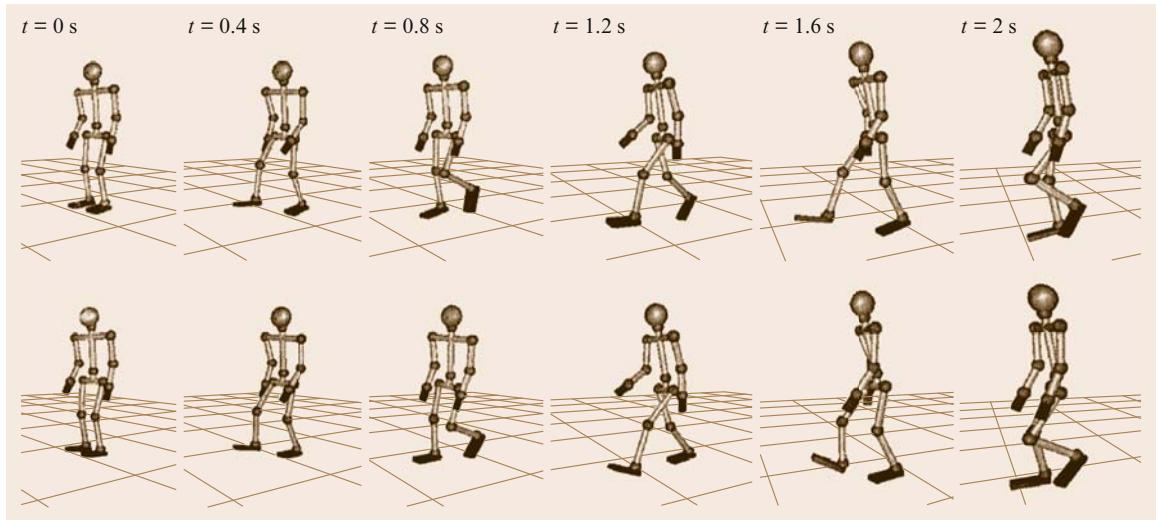

Fig. 56.31 An example of motions converted by the dynamics filter [56.78]; the top row shows the original coarse planned movements, and the lower row shows the modified movements that meet necessary constraints

timization problem in order to convert a given motion to a balanced one [56.81]. This method is not suitable for a motion in which dynamic balancing is dominant, such as during walking motions. However, this approach can be effective for a motion in which static balancing is dominant, such as when the humanoid is standing. The autobalancer can sometimes generate a walking motion if the robot can move slowly enough to minimize the influence of the dynamics while still maintaining stability [56.81].

The autobalancer calculates a whole-body motion based on the following concepts.

1. Fix the center of gravity (CoG) on the vertical axis which passes through a point in the support polygon of the humanoid;
2. Keep inertia moments around the CoG at acceptable values in order to satisfy the balancing conditions.

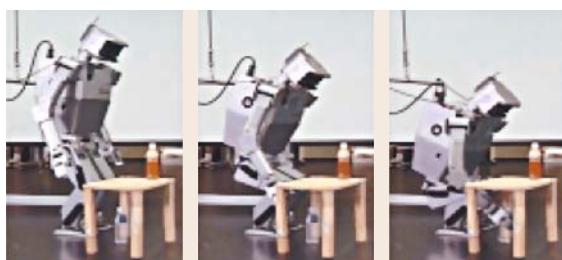

Fig. 56.32 The humanoid robot H7 executes a motion generated by the autobalancer [56.77]

Acceptable values for the moments are obtained by using constraints that keep the ZMP in the support polygon and keep the angular momentum generated by the moments close to zero over a given length of time. This problem can be handled as a quadratic programming optimization that minimizes errors between the given reference motion and the calculated motion given the constraints on the position of the CoG and the generated moments. The autobalancer solves this problem over every sampling period. Figure 56.32 shows the humanoid robot H7 executing a whole-body motion that resulted from using the autobalancer to transform the automatically planned coarse motions shown in Fig. 56.29 [56.77].

56.5.3 Generating Whole-Body Motions from Operational Point Motions

The example GUI and teleoperation interface described previously, enable a person to control the motions of particular points on a robot. Similarly, many automated control systems have been designed to control particular points on a robot, such as the end effector [56.82] (see Chap. 26, *Motion for Manipulation Tasks*). In order to control a real or simulated humanoid robot, these coarse motions must be converted to whole-body motions.

The computational efficiency and causality of this conversion is important. Teleoperation requires real-time methods, and human interfaces benefit from interactive control that provides real-time feedback.

Fig. 56.33 Forward reaching motion with balance [56.75]

Likewise, the autonomous control of real robots with nontrivial dynamics requires real-time methods. Many approaches have been developed to generate whole-body motions from operational point motions in real time, two examples of which follow.

Resolved Momentum Control

Kajita et al. proposed a framework for whole-body control based on the linear and angular momentum of the entire robot [56.85]. Intuitively, one can think of the robot as a single rigid body whose linear and angular momentum is to be controlled. For example, the center of mass of the robot might be commanded to move at a fixed height above the ground. At each point in time, this framework uses least squares to find joint velocities that will achieve the desired linear and angular momentum of the robot. Elements of the momentum can also be left unspecified as free variables, which is often done in practice with elements of the angular momentum. In addition to elements of the momentum, resolved momentum control requires that desired velocities for the feet be specified.

Neo et al. adapted this framework to generate whole-body motions from operational point motions specified

by a human operator [56.75, 76]. The human operator can control the foot motion, the overall motion of the humanoid robot, or the motion of a hand at any time by switching the mode of operation. The whole motion-generation system then computes joint velocities that meet the desired motions and additional constraints.

Reaching tasks performed by the humanoid HRP-2 provide an example of this type of operation [56.86]. Figure 56.33 shows snapshots of the robot's movement with the operator controlling only the velocity of the right hand in order to perform a horizontal reaching motion. The robot automatically moves other joints, such as its torso, in order to stay balanced while the operator solely controls the hand.

Coordinating Constraints, Tasks, and Postures

Dynamic stability is very important during whole-body activities. However, humanoid motion is often subject to many simultaneous objectives that may be in competition with one another. Sentis and Khatib proposed a framework that enables a humanoid robot to perform motions that simultaneously meet prioritized objectives in real time [56.87], and Park and Khatib

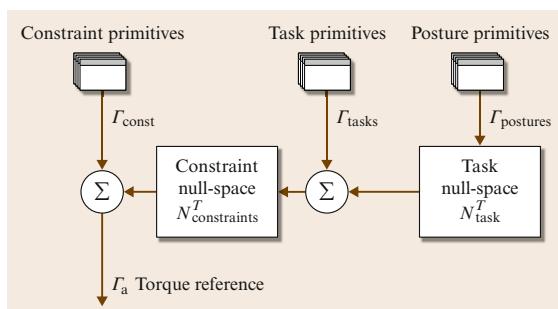

Fig. 56.34 A control hierarchy is established using null-space projections [56.83]

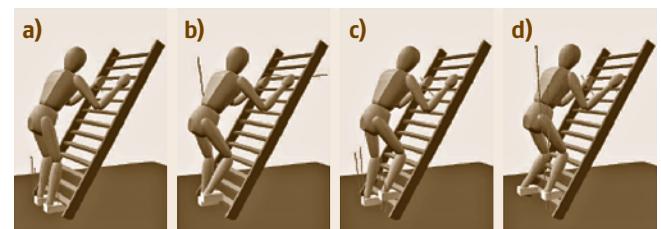

Fig. 56.35a-d Climbing a ladder. (a) The robot begins to climb; it has contacts on both hands and feet. (b) The right foot is then controlled to move up one step. (c) Next, the center of mass is controlled to move to the right in order to maintain balance with two hands and the right foot. (d) The left foot is then controlled to move up one step [56.84]

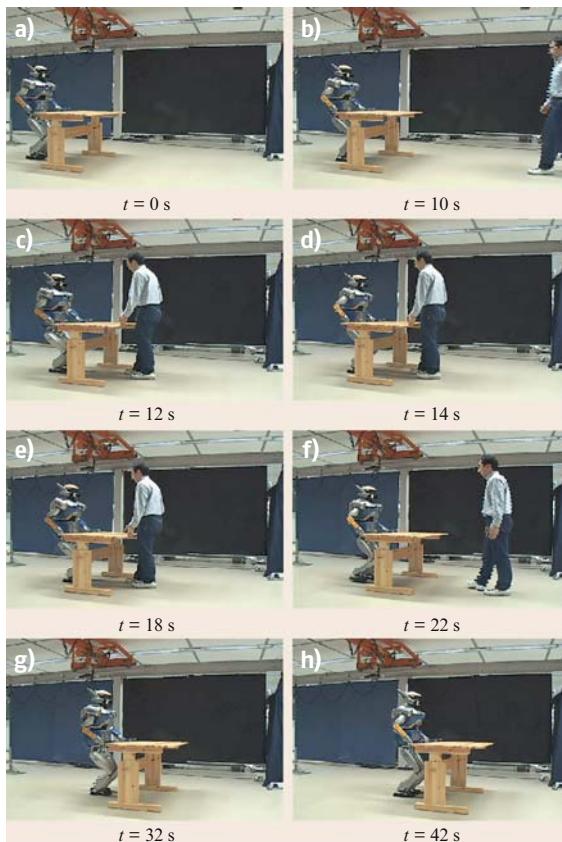

Fig. 56.36 Example of pushing manipulation and cooperation [56.88]

have augmented this approach to handle contact with the environment [56.84]. With these methods many controllers can be coordinated, and each controller can specify different objectives, such as a desired trajectory for a particular point on the robot.

This coordination of controllers uses three distinct control categories: constraint handling, operational

tasks, and postures. A control hierarchy handles conflicting scenarios among these three categories of controllers. Constraint primitives, such as joint limits, have the highest priority and the posture primitives have the lowest priority. One advantage of the posture primitives is that they can control redundant degrees of freedom in a consistent way.

To achieve this control hierarchy, operational tasks are projected into the constraint null space, and postures are projected into the task null space followed by the constraint null space (Fig. 56.34). Unlike resolved momentum control, which generates joint velocities, all of these controllers generate joint torques. When calculating these torques, the controllers use models of the dynamics of the robot and the environment.

A ladder-climbing behavior tested in simulation demonstrates this framework for control (Fig. 56.35). In this example, the desired trajectories for the center of mass, the hands, and the feet are specified in advance. When the simulation is run, the whole-body control system generates joint torques that seek to meet these coarse motion specifications, which results in the simulated robot climbing the ladder. While climbing, the simulated robot successfully resists unexpected disturbances.

Research into methods for the coordination of controllers for humanoid robots is an active area of research, for example, Mansard et al. have used a *stack of tasks* to organize prioritized controllers, including a visual servoing controller and a grasping controller, to enable a real HRP-2 robot to visually grasp a pink ball while walking [56.89].

56.5.4 Generating Motions when in Contact with an Object

Many approaches to whole-body motion generation assume that the robot is only in contact with the ground. When a humanoid robot's hands make contact with the environment, it can no longer maintain balance using

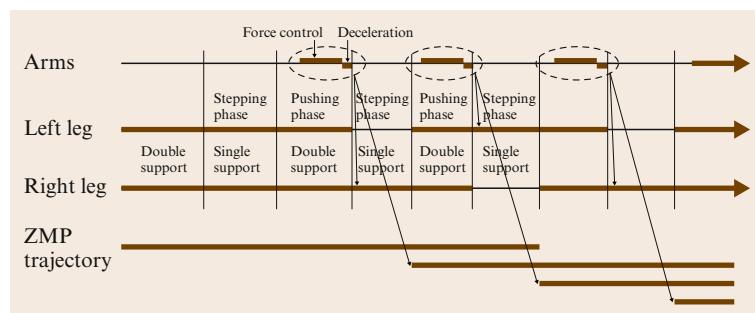

Fig. 56.37 Time chart of force-controlled pushing manipulation

the conventional **ZMP** property defined by the center of pressure of the supporting feet [56.90]. This leads to significant challenges for whole-body activities, especially since the properties of the environment with which the robot is making contact may not be known in advance.

Harada has introduced generalized **ZMP** (**GZMP**) as a method of handling some of these issues, such as the hand reaction forces generated from contact with the environment [56.91]. Researchers have developed methods that directly make use of the six-dimensional force/torque acting on the robot at the hands, which can be sensed with conventional force/torque sensors placed at the wrists [56.92]. Researchers have also developed specialized methods for generating stable robot motion while an object is being manipulated [56.88, 90, 93–95].

Carrying an Object

In a manner analogous to the previously described methods, coarse motions that do not consider the hand reaction forces can be modified [56.73, 90, 93, 96]. Figure 56.23 shows an experimental result of carrying an object that weighs 8 kg [56.73]. Based on measurements of the hand reaction force, the position of the waist is modified to compensate for the load and maintain stability.

Pushing an Object

As another example of using force sensing to adapt behavior, consider the problem of pushing a large object

placed on the floor. For such a task, if the gait pattern is determined before the robot actually moves, the robot may not stay balanced if the weight of the object or the friction coefficient between the object and the floor is different from the predicted values. To address this problem, the gait pattern can be adaptively changed depending on the output of a force sensor at the end of the arms in order to handle changes in the object's weight and the friction coefficient [56.88].

One approach to this activity is to have the robot push the object during the double support phase of walking, when both feet are in contact with the floor. A timing chart of this strategy for force-controlled pushing is shown in Fig. 56.37. During the pushing phase, the robot pushes the object while controlling the reaction forces applied at the hands. In the stepping phase, the step length is set to match the distance the object has been pushed in the pushing phase. The desired **ZMP** trajectory is recalculated and connected to the current **ZMP** trajectory. The trajectory of the center of gravity is also recalculated in order to realize this **ZMP** trajectory.

Figure 56.36 shows an experimental result for this approach [56.88]. In the experiment, the table weighs about 10 kg. Even though the motion of the table is disturbed externally during the experiment, the robot stays balanced by adaptively changing its gait pattern based on the measured forces.

56.6 Communication

Humans evaluate each others' state through body posture and movement. It is quite natural to extend this form of communication to include robots that share our morphology.

56.6.1 Expressive Morphology and Behavior

Humanoids can communicate with people through expressive morphology and behavior. As with people, humanoid robots integrate communicative and noncommunicative functionality. For example, the arms and hands of a robot can reach and grasp, but also point and gesture. Heads for humanoid robots are an especially important example of these overlapping roles, and have had an important impact on humanoid robotics and robotics in general [56.97].

The head of a humanoid robot has two main functions:

- To orient directional sensors as needed for the purposes of perception, while leaving the main body free to meet other constraints such as maintaining balance and gait. Cameras and sometimes microphones are usefully oriented in this way.
- To strike expressive poses, along with the rest of the body. Even if a robot head is not intended to be expressive, it will be interpreted as being so by humans – particularly as a cue to the robot's presumed locus of visual attention. It is also possible to deliberately engineer an approximate *face* that can be an important line of communication with humans (see Chap. 58, *Social Robots that Interact with People*).

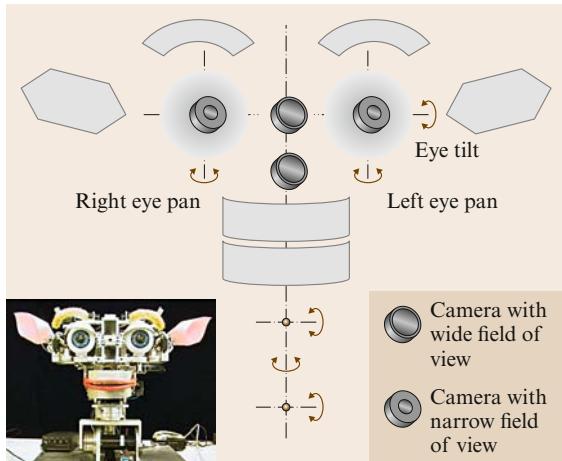

Fig. 56.38 On Kismet, foveal vision was implemented using cameras in the eyes, and peripheral vision used unobtrusive cameras on the head [56.97]. This achieved good expression of locus of attention, while simplifying the process of differentiating egomotion from motion of objects (since the head moved less frequently and more slowly than the eyes). This is an example of a partial decoupling of expressive and functional concerns, showing that many different levels of humanoid fidelity are possible

Locus of Attention

Eyes can be one of the most expressive components of a humanoid robot. For humans, eye movements are both expressive and important for sensing. Humanoid robots have the option to factor these two roles by moving eyes that are only for display, and using sensors placed elsewhere. Most humanoid robots, however, use head-mounted servoed cameras that play both expressive and sensory roles. These mechanisms exhibit different degrees of biological realism, for example, the Kismet head captured many of the expressive components of human eye movements, while having a non-human-like camera arrangement that simplified some forms of perception (Fig. 56.38).

Many humanoid robots use biologically inspired, foveated vision systems, which provide a wide field of view with low detail, combined with a narrow field of view with high detail (Fig. 56.39). With appropriate control strategies to fixate the narrow field of view on task-salient regions detected in the wide field of view, these robots achieve a practical compromise between resolution and field of view. Additionally, the configuration of the eyes communicates the robot's locus of attention in an intuitive way. Many systems use four cameras, with a narrow- and wide-angle camera for

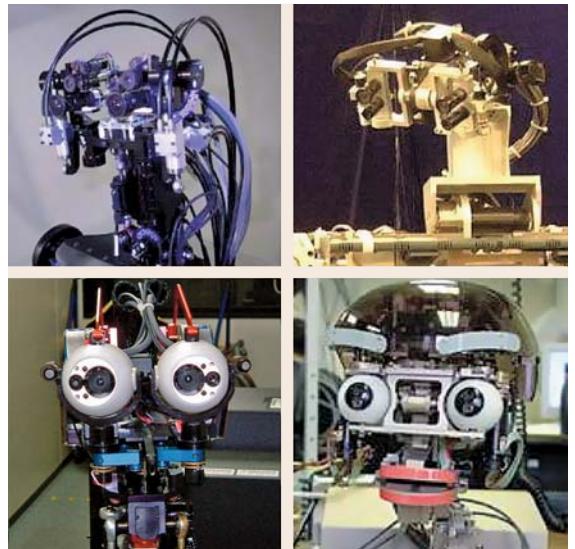

Fig. 56.39 The heads of humanoid robots come in many forms. A popular arrangement is to have two cameras per eye, as a crude approximation of foveal and peripheral vision in humans. *Top left:* biomimetic oculomotor control investigated on DB [56.98]. *Top right:* Cog's head [56.99]. *Bottom left:* the double-camera arrangement can be arranged in a less-double-barreled appearance (see Ude et al. [56.100] for more examples and an analysis) ©ATR; Humanoid head developed by ATR and SARCOS. *Bottom right:* the Infanoid robot [56.101]

each of the robot's eyes, but some researchers have also used special-purpose space-variant cameras modeled after the space-variant receptor densities in the human eye [56.102].

The eye movements of some humanoids are modeled explicitly after human eye movements. An example of a model of this kind is shown in Fig. 56.40. These bio-inspired approaches to active vision typically have four types of visual behavior:

Saccades. These are high-velocity movements to fixate a new target or *catch up* with a fast-moving target. From a control point of view, these movements are *ballistic* (at least in humans) – once initiated, they continue without responding to changing stimuli.

Smooth Pursuit. These are movements to continuously track a moving target. They apply at low velocities. These movements respond constantly to visual feedback about the target's location. A fast-moving target may also trigger small saccades.

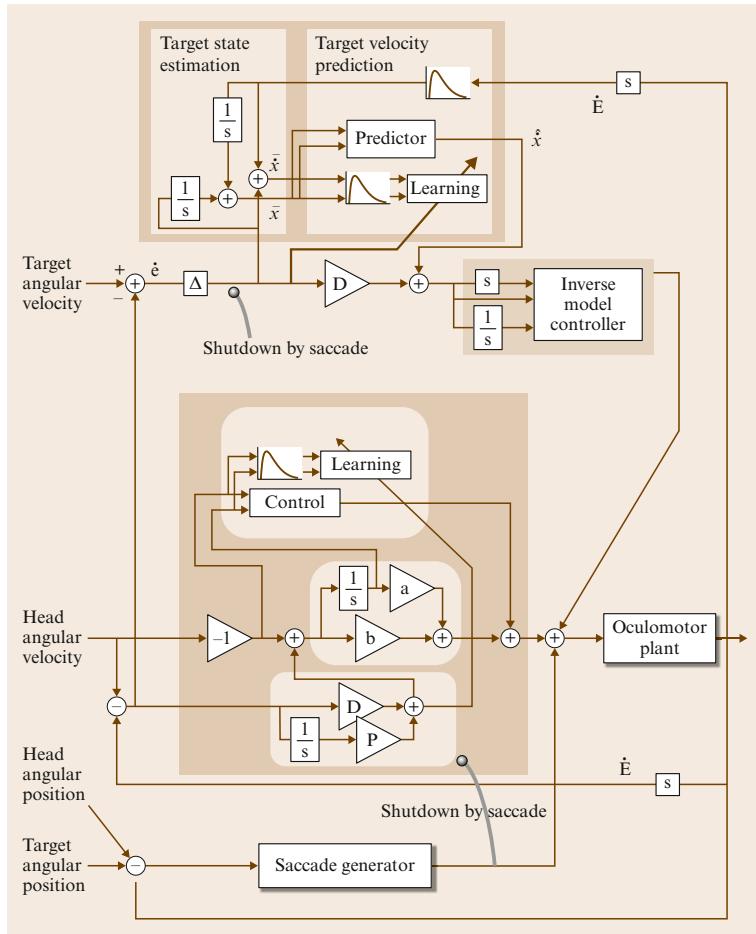

Fig. 56.40 A biomimetic control model [56.103], that integrates saccading, smooth pursuit, the vestibular-ocular reflex (VOR), and the optokinetic response (OKR). Smooth pursuit and VOR/OKR commands are summed, with periodic corrections to errors in position made by saccades

VOR and OKR. The vestibulo-ocular reflex and optokinetic response work to stabilize the direction of gaze in the presence of movement of the head and body, using inertial and visual information respectively.

Vergence. This movement drives the relative angle of the two eyes so that the same target is centered in both. This only applies to two-eyed systems that have this freedom of motion. For conventional stereo algorithms, vergence is a disadvantage, since the algorithms are simplest when the cameras remain parallel. Other algorithms are possible, but it is currently quite common not to use vergence.

56.6.2 Interpreting Human Expression

The interpretation of human expression is essential for many forms of natural human communication that could be valuable for humanoid robots.

Posture and Expression

The recognition and interpretation of the location and pose of humans is important, since humanoids are often expected to work in human environments. Algorithms for the following functions have been incorporated in various humanoids:

- Person finding
- Person identification
- Gesture recognition
- Face pose estimation

Asimo has used these functions to perform a prototypical reception task as shown in Fig. 56.41. The robot can find and identify a person, then recognize gestures such as *bye-bye*, *come here*, and *stop*, which are utilized for performing reception tasks. In general, such functions on a humanoid are not yet robust, and are active areas of research.

Fig. 56.41 Asimo recognizing a pointing gesture during a reception task

Fig. 56.43 HRP-2 recognizing face and gaze direction for communication via eye contact

Speech Recognition

Speech is a natural, hands-free mode of communication between humans, and potentially between robots and humans. Speech recognition is a popular interface utilized for commanding a humanoid, and many off-the-shelf packages are now available. However, the use of microphones embedded in the robot is problematic, because general-purpose speech recognition software is usually optimized for utterances captured by a microphone that is close to the speaker. In order to achieve sufficient recognition performance in natural interaction situations between a humanoid and a human new methods for speech recognition are being investigated. These methods compensate for sources of noise, such as the robot's motors and air flow in the environment, by using multiple microphones and multimodal cues [56.104]. However, at the time of writing researchers often circumvent these issues by using a headset, lavalier, or handheld microphones.

Auditory Scene Analysis

In order to attain more-sophisticated human–robot interaction, researchers have been developing methods for

Fig. 56.42 HRP-2 recognizing speech with background noises (TV sound)

computational auditory scene analysis on a humanoid robot. The objective of this research is to understand an arbitrary sound mixture including nonspeech sounds and voiced speech, obtained by microphones embedded in the robot. Beyond speech recognition, this also involves sound-source separation and localization.

As for sound recognition, sound categories such as *coughing*, *laughing*, *beating by hand*, *adult's voice*, and *child's voice* have been shown to be recognizable using maximum-likelihood estimation with Gaussian mixture models. This function has been utilized during interactions between the HRP-2 and a human [56.105].

Multimodal Perception

Sound-source separation can be achieved by beam forming. In order to perform beamforming effectively,

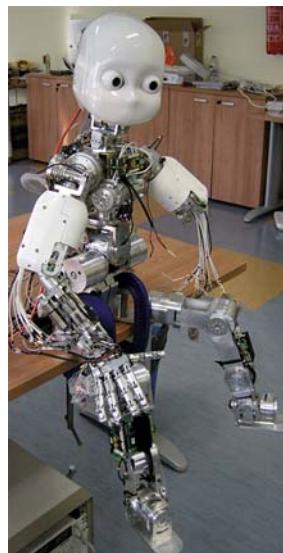

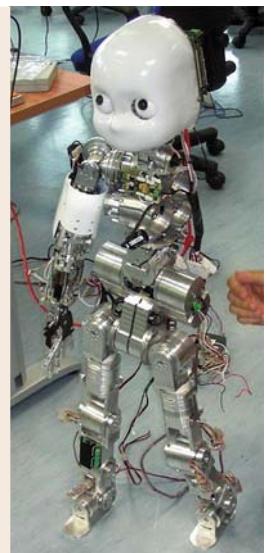

Fig. 56.44 The iCub robot [56.16], an infant-like robot that serves as an open humanoid platform for cognitive and neuroscience research

sound-source localization is essential. Vision can be utilized for finding the talker within the field of view. *Hara et al.* used a camera and an eight-channel microphone array embedded in the head of HRP-2, and succeeded in speech recognition in the presence of multiple sound sources by using sound source separation [56.106]. Figure 56.42 shows a scenario in which speech recognition is taking place with television (TV) sound playing in the background.

When integrated with speech recognition, vision can also help resolve the ambiguities of speech. For instance, the ambiguity of demonstrative pronouns such as *this* or *that* can sometimes be resolved by recognizing pointing gestures. Similarly, the face and gaze direction can be used to realize communication via eye contact, so that the humanoid only replies when a human is looking at it and talking to

it [56.105]. Multimodal interaction with these functions has also been demonstrated by HRP-2, as shown in Fig. 56.43.

56.6.3 Alternative Models for Human–Robot Communication

Humanoid robots typically use methods for perception and interaction that are similar to those found in fields such as computer vision and dialogue systems. There is also a subfield called *epigenetic* or *developmental* robotics that attempts to form an explicit bridge between robotics and human studies, such as psychology and neuroscience [56.107, 108]. Much of the research within this subfield deals with human-like perception and interaction using humanoid robots, such as the iCub shown in Fig. 56.44.

56.7 Conclusions and Further Reading

Because of the integrative nature of humanoid robotics, this chapter has avoided details and formalisms and liberally cross-referenced other chapters within the handbook that can provide the reader with deeper coverage of many of the areas of robotics on which humanoids depend. Additionally, this chapter thoroughly references work within the humanoid robotics community and related communities. Consequently, the reader should be able to use this chapter as a high-level overview of the field from which to explore specific areas of humanoid robotics.

Humanoid robotics is an enormous endeavor. The emulation of human-level abilities in a human-like robot serves as a grand challenge for robotics, with significant cultural ramifications. The motivations for humanoid robotics are as deep as they are diverse. From the earliest cave drawings, humanity has sought to represent itself. Robotics is one of the most recent mediums for this ongoing fascination. Besides this deep societal motivation, humanoid

robots offer unique opportunities for human–robot interaction, and integration into human-centric settings.

Over the last decade, the number of humanoid robots developed for research has grown dramatically, as has the research community. Humanoids have already gained a foothold in the marketplace as robots for entertainment through competitions and toys (e.g., Robo-One and RoboSapien). Time will tell whether consumers prefer robots with human-like qualities. For example, if service robots are to have two, high-degree-of-freedom arms and articulated sensing mechanisms, a human-like form may be a desirable configuration. Given the special properties of humanoid robots, they seem likely to at least fill a niche in the world of the future. Whether or not humanoids become a dominant form for robots may depend on the extent to which they can compete against specialized robots that are better suited to particular tasks, and human labor, which in some ways already meets the ultimate goals of humanoid robotics.

57. Safety for Physical Human–Robot Interaction

Antonio Bicchi, Michael A. Peshkin, J. Edward Colgate

In this chapter, we report on different approaches to dealing with the problem of achieving the best performance under the condition that safety is provided throughout task execution. We also report on intelligent assist devices (**IADS**) that go beyond conventional notions of robot safety to protect human operators from harm, such as cumulative trauma disorders. However, **IADS** and other physical human–robot interaction (**pHRI**) devices are themselves generally powerful enough to cause harm. We argue that the differences between **pHRI** applications and conventional industrial manipulation requires that safety and reliability standards be rethought, and we offer a preview of the directions currently being undertaken by international standards committees.

We chapter discuss the new frontiers of robotic physical interaction with humans, describing

motivations and applications of safe **pHRI**. The state of the art, and the technical challenges to develop new robotic systems for safe and effective collaboration with people, are discussed, subdividing the exposition into hands-off and hands-on **pHRI** systems. We present an overview of the applicable safety standards and their ongoing development.

Popular notions of robotics have long foreseen humans and robots existing side by side, sharing work, or even (as cyborgs) integrating into a greater whole. Until very recently, the reality has been quite different. Industrial robots have been far too dangerous to share space with humans, while physical interaction has (except in the case of telemanipulators, which date back to the 1940s) been far too unintuitive.

Shortly, all this is going to change radically: the next generation of robots will interact with people directly. Human–robot interaction (**HRI**) will certainly happen at the cognitive level (cHRI, Chap. 58), fundamentally concerning communication between human and robot through the many channels available to us (video displays, sounds, watching each other’s motions, spoken language, or even gaze direction or facial expression). However, robots are distinct from computers in that they physically embody the link between perception and

action. Hence, one of the most revolutionary and challenging features of the next generation of robots will be physical human–robot interaction (**pHRI**). In **pHRI**, humans and robots share the same workspace and come into contact with each other. Physical interaction may happen occasionally if normal operation is intended to be without contact, or on purpose if the operator is supposed to work in physical contact with the machine, exchanging forces and cooperating in action upon on the environment. We will designate these intended forms of interaction *hands-off* and *hands-on* **pHRI**, respectively.

pHRI robots will be designed to coexist and cooperate with humans in applications such as assisted industrial manipulation, collaborative assembly, domestic work, entertainment, rehabilitation or medical applications. Clearly, such robots must fulfill different requirements from those typically met in conventional industrial applications: while it might be possible to re-

lax requirements on velocity of execution and absolute accuracy, concerns such as safety and dependability become of paramount importance when human lives are

involved. This paradigm shift entails many differences in design and control, and opens up new challenging directions for research.

57.1 Motivations for Safe pHRI

Since the very beginning of industrial robotics, a great deal of attention has been paid to robot safety. The first line of defense has always been to take all measures to enforce segregation between robots and people. It is on such philosophy that most of the early technical literature on the topic of robotic safety is based [57.2–4], as well as the existing robotics safety regulations and standards [57.5–7]. However, the segregation paradigm fails in cases where the human and the robot must share the physical environment and in applications in which successful task completion requires collaboration.

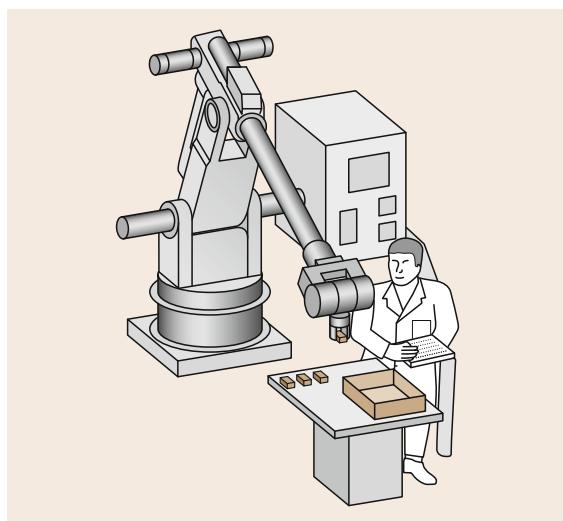

Fig. 57.1 Hazard in lead-through teaching [57.1]

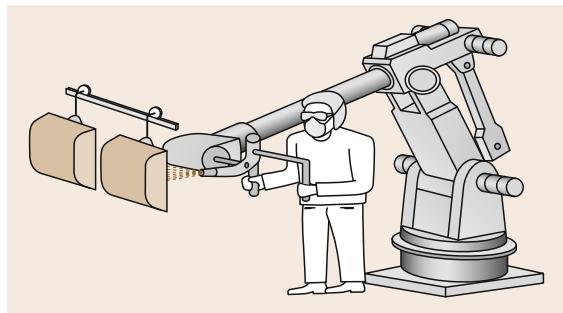

Fig. 57.2 pHRI in walk-through teaching [57.1]

Data on industrial robot-related fatalities indicate that, even in traditional applications of industrial robots, safety is not a solved problem – especially because of all the operational phases where the human operator is by necessity physically close to the mechanical arm or vehicle.

Studies reported in [57.1] show that *many robot accidents do not occur under normal operating conditions but instead during programming, program touch-up or refinement, maintenance, repair, testing, setup, or adjustment. During many of these operations the operator, programmer, or corrective maintenance worker may temporarily be within the robot's working envelope where unintended operation could result in injuries.*

People in the manufacturing environment are often injured even in the absence of robots, and curiously, this provides a major motivation for hands-on pHRI. Repetitive manual material handling exposes people to work-related musculoskeletal disorders (WMSD). In 1990, the average US worker's compensation expense for a lost-time back injury was \$24 000 (source: National Council of Compensation Insurance). The ergonomics and productivity consequences are also documented for US industries: in 2004, over 400 000 WMSD were reported involving days away from work. Approximately one-third of these injuries were in the goods-producing industries, including manufacturing [57.8]. The total cost of these and related problems is of the order of \$13–20 billion annually in the US alone. In many cases, robotic assistance could reduce WMSD drastically.

Market pressures together with ethical concerns are about to topple some of the barriers separating robots and people, and thus require a next generation of machines for safer pHRI. Consider for example the automotive industry. While the advent of robots has mitigated harsh, unsafe conditions in the body shop (where sheet metal is welded into a structure), and the paint shop, other areas have gone untouched for over three decades. The general assembly area, where the engine and cockpit subsystems and seats and tires are integrated with the painted shell, is such an untouched area. The tooling that has been used tends to be mechanical in nature and is primarily powered by human and pneumatic effort. Sensing and decision-making are the worker's responsibility. The

principal reasons for not automating general assembly are both technical and economic. From a technological perspective, using robots for assembly in processes with high geometric dimensional variability is yet to be achieved with the reliability levels required for high-volume production. Further, programming complexity grows greatly with the number of trim options offered to the customer (e.g., leather seats, two-tone color, V6 engine, overhead console). Financially, the necessary increase in physical floor space dramatically impacts costs. In summary, the worker – with unsurpassed sensing and processing abilities – is a critical component in the assembly process. The primary concern, then, is that of the worker’s well being, given that he/she tends to tire and is susceptible to injuries resulting from cognitive LAPSES and motor effort.

The case of general assembly explains why robots sometimes fail to replace people, but also motivates the close cooperation of robots and people. Humans have dense sensors (human tactile sensing especially outstripping attempts at emulation) and humans have an ability to interpret sensory data which artificial intelligence cannot approach. However humans have poor open-loop accuracy, tire easily, and are subject to repetitive stress injuries. In contrast robots have minimal sensing, not for lack of sensors but for their inability to interpret sensory input. However robots have high accuracy and speed

and work indefinitely. Even with increasing sensorization, robots are not about to match a human’s literally millions of sensory receptors.

The characteristics of robots and humans have led to a new generation of safe human-interacting machines known as intelligent assist devices (**IADs**). **IADs** are a class of robots intended principally for *comanipulation* of payloads along with a human partner. **IADs** serve principally to augment the strength of a human, but they may also serve to guide motion via virtual surfaces, tracking of a moving assembly line, or the like. Research and development into **IADs** is actively stimulated by automotive industries (General Motors and Ford Motor in the US, and Toyota in Japan taking the lead in the development of technologies and new standards). The value of robot–human collaboration is also being discovered in a variety of nonindustrial environments: from exoskeletons as human power amplifiers [57.9] or as haptic interfaces in virtual-reality environments [57.10], to medical assistants and telesurgery [57.11] in an operating room, to rehabilitation [57.12, 13] and robotic sports-trainers [57.14].

In the rest of this chapter, we will consider safety in two distinct cases of human–robot interaction: first, when physical contact occurs occasionally or by accident, and second, when physical interaction is an intentional part of planned operations.

57.2 Safety for Hands-Off pHRI

Management of risk for humans working near robots involves in general very broad considerations, ranging from potential electrical and pressurized fluid hazards, pinching hands or feet, dropping parts, etc. These however fall beyond the scope of this chapter, which focuses on the most dangerous risk specific to robots: the situation in which, in an unspecified instant during execution of a robot movement, a collision or unwanted force exertion occurs between the machine and a human.

Even under this restriction, the safety of **pHRI** involves several different aspects and depends on many factors, ranging from software dependability, to possible mechanical failures, to human errors in interfacing with the machine, etc. A thorough hazard analysis and risk evaluation must be performed according to specifically designed procedures: these methods are receiving a growing attention from the research community [57.15–18], international standardization bodies (Sect. 57.3), and industries. As an example, KUKA’s *Safe Operation* and *Safe Handling* systems, incorporat-

ing Pilz’s safety-related fieldbus, is currently in use at BMW’s *Body in White* lines [57.19], and allows safe and redundant monitoring of the robot’s position, velocity, and acceleration. Such a technology provides the basis for safe human–robot cooperation and can be used, e.g., for manual robot guidance with safely reduced speed. In the case of a malfunction (hardware or software) the robot is stopped immediately. Whether immediate stops are sufficient to guarantee safety, or even are the safest action to undertake, is not certain.

The *holy grail* of **pHRI** design is *intrinsic safety*: that is, a robot that will be safe to humans no matter what failure, malfunctioning, or even misuse might happen. Naturally, perfect safety against all odds is not feasible for machines which have to deliver performance in terms of weight lifting, swift motion, etc.: the trade-off between safety and performance is inherent to **pHRI**.

One important aspect of designing robots for safety is the ability to quantitatively assess the risk of injuries in accidents, so as to be able to compare different design

and control solutions, and optimize them. We will focus here only on a particular aspect of safety of robot manipulators, that of unexpected collisions by the manipulator with a human operator, which in the worst case could happen anywhere on the manipulator structure and on the body of the operator and at any time during the execution of a planned trajectory. Much can be learned from the biomechanics of impacts in sports and automotive applications. In the relevant literature [57.20–22], several indices of the severity of an impact are proposed, which can be mapped (through extensive experimental campaigns and statistical correlations) to the probability of causing a certain level of injury. Among these are, e.g., Gadd's severity index (**GSI**), the 3 ms criterion, the viscous injury response (**VC**), and the thoracic trauma index (**TTI**). The most widely used index in the automotive industry is presently the so-called head injury criterion (**HIC**). Most of these indices are related to a basic *tolerance curve* developed at Wayne State University (the so-called WSTC) on the basis of data experimentally acquired from animal and cadaver head collision tests. The WSTC is a curve plotting head accelerations versus impact duration, indicating that very intense head acceleration is tolerable if it is very brief, but that much less is tolerable if the pulse duration exceeds 10–15 ms (as the time of exposure to cranial pressure pulses increases, the tolerable intensity decreases).

Gadd [57.20] plotted the tolerance limit curve in log–log coordinates, obtaining a straight line of slope ≈ 2.5 , and proposed accordingly a severity index as

$$\text{GSI} = \int_0^t a^{2.5} d\tau ,$$

where a is the head acceleration (in g), and the integral is extended to the whole duration of collision. The head

injury criterion (**HIC**) was proposed by Versace [57.22] as a refinement of the **GSI**, defined as

$$\text{HIC} = T \left[\frac{1}{T} \int_0^T a(\tau) d\tau \right]^{2.5} ,$$

where T is conventionally the *duration* of the impact. As the choice of this duration is often difficult, it is recommended to consider the worst-case **HIC** at varying T . In general, both ends of the interval $T = (t_2 - t_1)$ are varied, and time t_2 is close to the time at which the head reaches its maximum velocity (typically, $t_2 - t_1 \leq 15$ ms). Generalizations of the **HIC** to collisions with other parts of the body have been proposed whereby the 2.5 exponent is replaced by other empirically determined values.

These metrics have constituted a useful basis for starting the development and evaluation of safe robotic concepts [57.23, 24]. The conditions under which these indices were formulated are quite different from those actually encountered in robotics. A recent experimental campaign [57.25] to measure the effects of impacts of a robot arm using standard crash-test facilities indicated that classical severity indices established in the automobile industry cannot be transferred without correction to the field of robotics. Indeed, the cited paper extrapolates experimental and simulation data to suggest that any robot, no matter how massive, whose parts are moving with a velocity of up to 2 m/s, would not cause impacts with a **HIC** larger than ≈ 100 , which is similar to what would occur to a person quickly walking and hitting a wall head first. Although such impacts, according to accepted standards in crash tests [57.26], would be considered to provoke only *very low injury potential*, they are still clearly unacceptable risks for a robot intended to coexist safely with humans.

57.3 Design of Intrinsically Safe Robots

Researchers have attempted to design intrinsically safer robots in various ways. The inherent danger of conventional robot arms might be mitigated by increasing their sensorial apparatus, using, e.g., proximity-sensitive skins such as those proposed in [57.27, 28], or by increasing the energy-absorbing properties of protective layers (adding enough soft and compliant coverings, or placing airbags around the arm, etc.).

An approach that has been intensively explored since the early 1980s is to design active force controllers,

e.g., Salisbury's stiffness control or Hogan's impedance control schemes, to introduce compliance with respect to sensed interactions. However, these approaches may not prove robust with respect to impacts on portions of the arm that are not equipped with force/torque sensors. Also, it is well known in the robotics literature that there are intrinsic limitations to what the controller can do to alter the behavior of the arm if the mechanical bandwidth (basically dictated by mechanism inertia and friction) is not matched to the task [57.29]. In other

Fig. 57.3 The **WAM** robot (Barrett Technology Inc., Cambridge)

words, making a rigid, heavy robot behave gently and safely is an almost hopeless task, if realistic conditions are taken into account. Probably, the first arm with a lightweight structure intended for service applications was the whole-arm manipulator (**WAM**) proposed in [57.30].

The focus on safety has in recent years encouraged a number of technological innovations in actuators, sensors, and structural design, leading to impressive realizations such as the several generations of Deutsches

Zentrum für Luft- und Raumfahrt (**DLR**) lightweight robots [57.31].

Arms in this class are primarily characterized by a low inertia of their moving parts and back-drivability. The **DLR** LWRIII arm uses high-performance actuators and integrated torque sensors, which allow sophisticated control algorithms to be run. Significant joint compliance is often present in these arms as a side-effect of other design choices such as use of cable transmissions, harmonic drives, or joint torque sensors. Suitable force-control policies have been designed to employ such arms in safety-critical applications [57.32–35].

Another approach to increasing the safety level (and psychological acceptability) of robot arms interacting with humans is to intentionally introduce mechanical compliance into the design. By this measure, which complements low-inertia design of the arm's links and soft coverings, researchers can dynamically decouple the actuators' rotor inertia from the links whenever an impact occurs. Indeed, motors contribute most of the effective inertia in conventional geared drives, while direct-drive solutions remain impractical due to their large size and cost. Naturally, compliant transmissions can diminish performance, causing slow response, increased oscillations and longer settling times. However, this might not be a problem in some applications, e.g., entertainment. In most practical applications other than entertainment, however, positioning accuracy and velocity of task execution are crucial: controlling *soft* manipulators quickly and accurately – similarly to what humans do with their own arms – is one of the main avenues open in front of **pHRI** research.

The problem of controlling passively elastic joints so as to recover performance has been studied in depth in the robotics literature, both in the general case (see, e.g., [57.36, 37] and the review in [57.38]) and in safety-

Fig. 57.4 The third version of the **DLR** lightweight robot (**LWR-III**) is capable of operating a payload equal to its own weight (13.5 kg)

Fig. 57.5 An entertainment robot by SARCOS physically interacting with a bystander. Compliance is built into the actuation system; accuracy and velocity are not primary goals

oriented design contexts [57.39, 40]. Adaptive control methods that could cope with uncertain inertia in robots with elastic joints have also been studied [57.41], although adapting to large, uncertain stiffness parameters appears to be an open problem.

It can be expected that the promptness of an elastically actuated arm is intrinsically severely reduced, if compliance is high enough to be effective for safety. In other words, even if optimal methods for controlling very compliant arms were available, there are inherent limitations on performance imposed by such hardware. To overcome these limitations, a recent trend in intrinsically safe robotics advocates the co-design of the mechanics and control of passively compliant, yet fast, strong, and accurate arms.

Very compliant transmissions may ensure natural and safe interaction but be inefficient in transferring energy from actuators to the links for fast motion. An approach to reducing the inertia of a manipulator arm for safety, while preserving performance, is distributed macro–mini actuation (DM2) [57.23, 42]. For each degree of freedom (joint), a pair of actuators is employed, connected in parallel and located in different parts of the manipulator. The key of the macro–mini actuation approach is to divide the torque generation into separate low- and high-frequency components which sum in parallel, according to an idea originally proposed in [57.43]. Gravity compensation and other large but slowly time-varying torques are generated by a *series elastic actuator* (SEA) [57.39] consisting of a relatively large actuator located at the base of the manipulator and connected to the axis through a spring, thus achieving low overall impedance. For the high-frequency torques needed, small motors collocated at the joints are used, providing high-performance motion while not significantly increasing the combined impedance of the manipulator–actuator system.

A different approach to gain performance for guaranteed-safety joint actuation is to allow the mechanical compliance (or, more generally, the impedance) of motion transmission devices to vary during the execution of tasks. As often, an inspiration can be taken from nature, with the human arm representing an instance of a powerful, agile manipulator that is at the same time safe and capable of high delicacy. The example from nature suggests that *variable compliance* can be extremely useful towards the goal of safe and fast motion: humans can vary the compliance of their arm for different tasks, and even during different phases of a task [57.44]. Unless it is intentionally used to harm, the human arm is typically controlled to move slowly when it is stiff, and

to be compliant while moving fast. This behavior also shows how the safety–performance trade-off can be addressed not by mere mechanical means, nor by control strategies alone, but by the intimate combination of the two aspects.

The idea of adapting the mechanical compliance of a robot arm to the task is almost as old as robotics itself ([57.45]) and has seen numerous implementations in different guises. Among the designs oriented towards physical human–robot interaction, we mention the mechanical impedance adjuster (MIA) [57.46] adopted in the humanoid robot WENDY, which uses a variable-length leaf spring. The MIA can realize a wide range of compliance values to adapt to different tasks in pHRI. However, similarly to many other such devices, the design mainly aims at adapting the compliance to a given task before the execution of the task itself, and keeps it constant during motion.

A different approach, called variable-impedance actuation (VIA) [57.24, 47] proposes a mechanical/control co-design that exploits rapid and continuous variations of transmission impedance during task execution (by varying its stiffness, damping, or gear ratio), so as to provide low levels of injury risk at any time during motion and minimize negative effects on control performance.

The trade-off between safety and performance also involves task motion planning. For a mechanism with given total inertia and actuator torque limits, one can formulate an optimal control problem to be used for comparing mechanical/actuation alternatives at their best possible performance. This question can be formalized as a minimum-time optimal control problem (i. e., a problem in the class of the so-called *brachistochrones*), specified for given initial and final positions of the joints and of the motors, and has to be computed taking into ac-

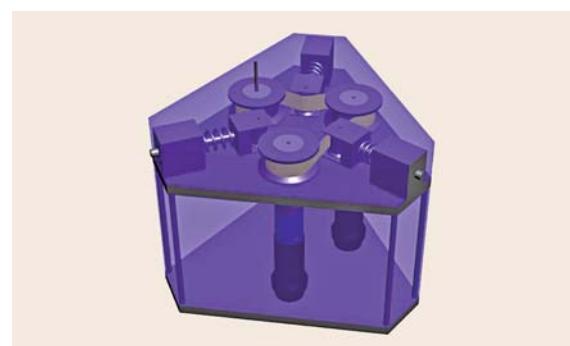

Fig. 57.6 The variable stiffness actuator of the University of Pisa implements the VIA approach by an antagonistic arrangement of nonlinear springs

count the limits on maximum motor torque and the lower and upper bounds to available transmission impedance. Admissible trajectories must satisfy a safety condition, which is expressed as a function of the velocities of the manipulator, its configuration, and the amount of inertia that is reflected on the links through the compliant transmission.

Solutions to such a *safe brachistochrone* problem for a single-joint actuator-link VIA system were obtained by numerical optimization in [57.24], showing that the optimal control policy consists of imposing high stiffness at low speeds (when the link needs accuracy and control authority to accelerate promptly), while low stiffness should be used at high speeds, to reduce the effect of the reflected motor inertia in the initial instants of impact. Such a *stiff and slow/soft and fast* control paradigm for VIA systems matches well with physical intuition (most of the motion energy transfer from the motor should occur during the initial and final acceleration/deceleration phases), and with the natural control inspiration. Although no solutions are known to the multilink safe brachistochrone problem to date, ideal solutions ob-

tained for a single joint can provide guidelines to be used also for more complex systems. The VIA concept can be realized through different arrangements, including the relocation of actuators close to the robot base and transmission of motion through steel cables and pulleys, the use of parallel and distributed macro–mini actuation with elastic couplings, the use of antagonistic actuation schemes, etc.

Once a collision has occurred, and its primary impact effects have been possibly reduced by mechanical design, further injuries can be avoided by a suitable reflex control action. A collision detection scheme based on the command inputs and sensor outputs available on the robot should trigger the switching of the control law [57.48, 49]. A physical collision can be treated as a fault condition of the robotic device. Accordingly, methods and algorithms available for the so-called fault detection and isolation problem [57.50] have recently been applied to robot collision detection [57.51, 52]. Their integration into a safety-oriented controller and their extension to the case of (possibly time-varying) compliant robot arms is an open issue for research.

57.4 Safety for Hands-On pHRI

A different set of safety methods and strategies are required in cases where successful task completion requires people and robots to collaborate intimately. This is the case for intelligent assist devices (IADs), human extenders, and collaborative robots (cobots).

IADs have their roots in Ralph Mosher's famous Handiman and Hardiman projects of the 1960s [57.54]. It was the initiative of General Motors (GM), however, that led to further active development in the mid 1990s.

Fig. 57.7 Fanuc's IAD for moving engine blocks [57.53]

Beginning in 1995, GM began to work with two groups: Kazerooni at University of California (UC) Berkeley and Colgate and Peshkin at Northwestern University. The Ford Motor Company also encouraged the participation of Fanuc Robotics, an established robotics supplier to the automotive industry. The automotive emphasis of the program helped steer the results toward applicability to general assembly (Sect. 57.1).

Fanuc developed a prototype gantry-type robot with force-input handles for human guidance, to be used at Ford to install truck instrument panels on a moving assembly line or to load cylinder heads on top of engine blocks. Fanuc's IAD possessed six powered admittance-controlled axes, like a conventional industrial robot. It was driven however by force inputs from a human user who could exert command forces on force-sensitive handles that moved with the end-effector. This is a key distinction from remote joystick or force-input devices that do not move with the payload. Operator motion together with the payload gives the operator immediacy to the task and to the motions of the robot, and even some haptic feedback from the task. In contrast, teleoperation produces distancing from the task that generally requires great cognitive effort to overcome, and leads to reduced speed. Additionally, a proximate operator can

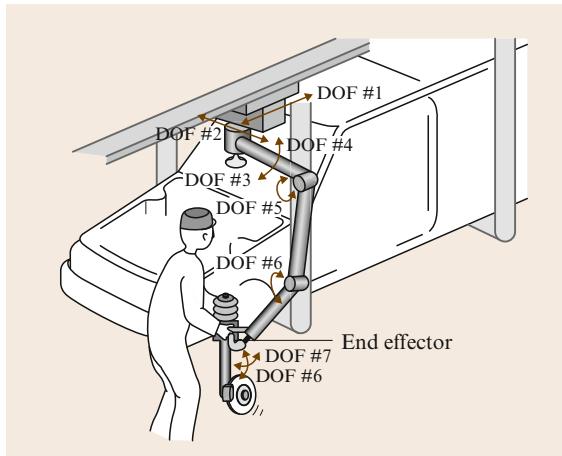

Fig. 57.8 Toyota's skill assist system [57.55]

detect and correct minor issues, such as a cable bundle that has draped the wrong way and needs to be moved. In addition the Fanuc IAD was able to implement virtual guides and walls, to be used as a *funnel* shape that assisted with moving a payload through an automobile door opening without collisions.

At the Toyota Motor Company, a similar concept, known as the skill assist, was developed at the end of the 1990s. A distinctive feature of this device was that the dynamic behavior of the assistive mechanical manipulator was varied according to the task phase. This approach was based on two observations. First, it was observed that the dynamic behavior preferred for moving a payload over long distances was primarily inertial, while the dynamic behavior preferred for precise positioning was primarily viscous. Second, it was observed that the phase of the task – start up, traversing, or fine positioning – could be automatically determined based on motion characteristics. Experiments performed with the skill assist showed significant improvements (reduction) in operator force (primarily for stopping), task completion time, and operator subjective impression.

Less structured types of IADs applications can be approached by the concept of human extenders [57.56], which emphasize amplification of human force and reach, such that for instance a human can grasp and lift a box that would otherwise be too wide and too heavy. Extenders may take the form of a robot arm or leg, or can even be worn by the user in the form of exoskeletons [57.9].

In industrial practice, it is much more common to support a payload from a cable or chain than from a rigid-link mechanism. Cables and chains have many

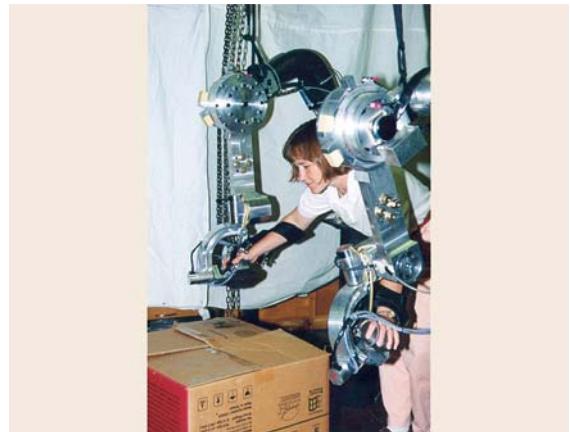

Fig. 57.9 pHRI in human power amplifiers [57.56]

advantages: they permit relatively free rotation about a vertical axis as well as small horizontal motions (or larger horizontal motions when supported by an articulated arm or crane), they have low inertia, low cost, and provide minimal obstruction. However, it is difficult to implement power assist with cable-based systems. Kazerooni built on his work with extender to develop a servo-controlled lift assist that is marketed by Gorbel, Inc. under the trade name G-Force. The key innovation of the G-Force was a slide handle inline with the cable that provided an intuitive input: sliding up to move up, and down to move down. Speed could be easily controlled.

Northwestern University's spin-off company Co-botics, Inc. (which was later acquired by the Stanley Assembly Technology division of StanleyWorks, Inc.) went a step further to develop the iLift and iTrolley modules that could be combined into a multiaxis human-assist crane. A key innovation was a cable angle sensor that could detect small departures of the cable from vertical, and use this to provide direction and speed commands to the iTrolleys, which provided motion in a horizontal plane in the manner of an overhead crane.

At this juncture it is worth noting that, while most of the IADs described so far have the structure illustrated

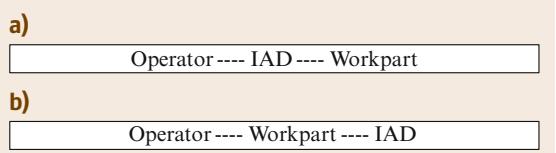

Fig. 57.10 (a) Structure in which the IAD is interposed between the operator and the workpart. (b) Structure allowing the operator to place hands directly on the workpart

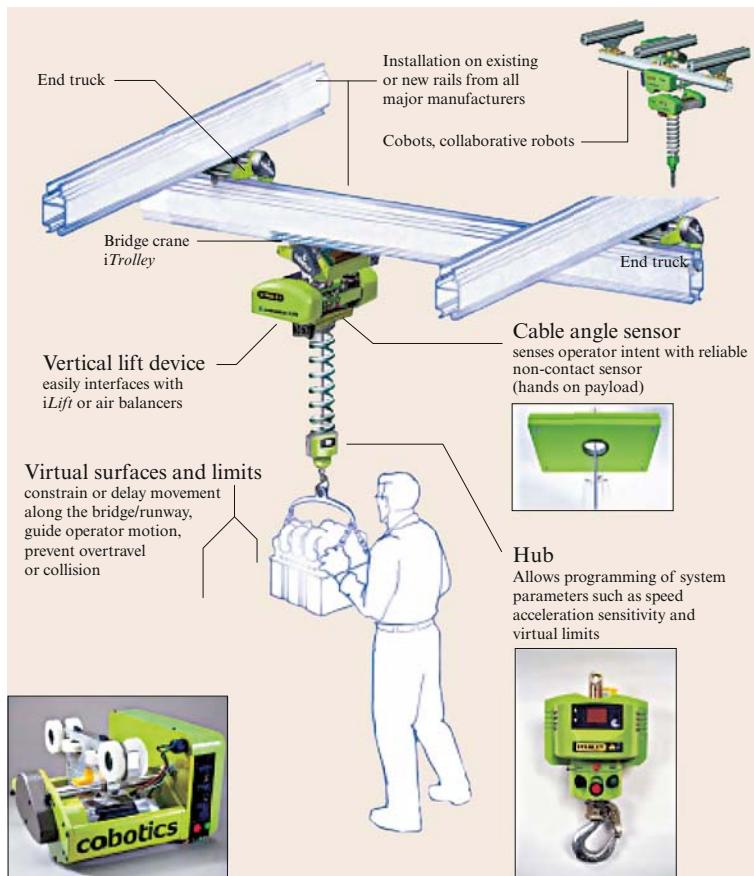

Fig. 57.11 The Stanley Cobotics modular system including lift assist, cable angle sensor, and powered trolleys

in Fig. 57.10a in which the IAD is interposed between the operator and workpart, cable-based systems are particularly amenable to the structure in Fig. 57.10b. Here, the operator manipulates the workpart directly while the IAD assists. The latter structure is often denoted *hands on payload*.

The iTrolley system illustrated in Fig. 57.11 is an example of *hands on payload*: the operator pushes on the workpart and the overhead crane follows. The strengths and weaknesses of this approach are evident. On the one hand, the operator is in intimate contact with the workpart, enabling highly intuitive movement. On the other hand, the cable can at best remain vertical at all times, contributing zero force to moving the workpart. If the cable were to *lead* the motion, the overall behavior would be unstable.

Nonetheless, *hands on payload* can provide a significant ergonomic advantage as the *pull test* data in Fig. 57.12 illustrate. Here, a subject pulled a variety of different payloads rapidly from a fixed starting

location to a fixed stopping location and his forces were recorded. Tests were run with traditional passive trolleys and with iTrolleys. The data show that the starting forces are modestly reduced with the iTrolley (because the iTrolley contributes to accelerating the overhead crane), and that the stopping forces are dramatically reduced (because the iTrolley eliminates overshoot of the overhead crane). This example illustrates an important point: IADs may be as valuable in moving the support structure as in moving the workpart itself.

Cobots – collaborative robots [57.13, 57, 58] – are a distinct approach to relieve humans from fatigue, stress, and injuries in manipulating heavy and/or awkward parts. Cobots presume a division of control between human and robot, with a robot perhaps supporting a payload and allowing a human to guide it, subject to constraint surfaces or virtual walls. Cobots are specifically designed to produce virtual guiding surfaces: software-defined paths or surfaces that constrain or direct the motion of the payload for the purpose of

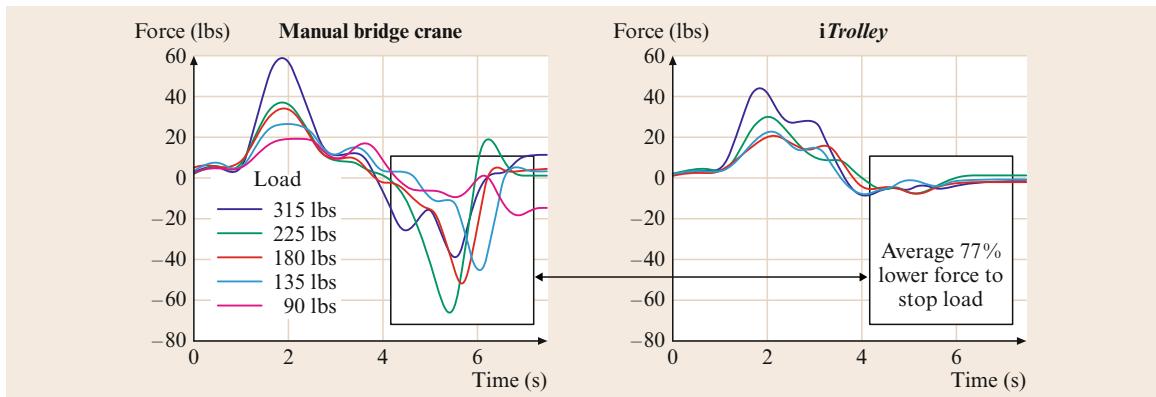

Fig. 57.12 Data from a set of pull tests showing the impact of the iTrolley and cable angle sensor on starting and stopping forces for various payloads

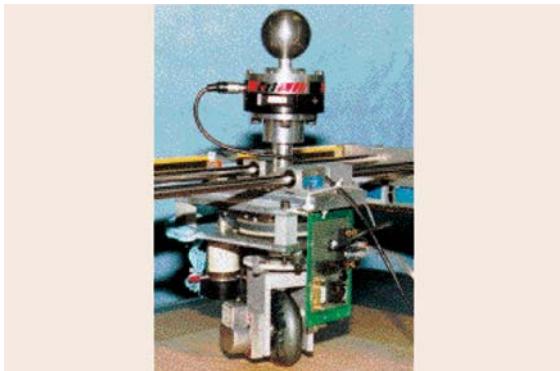

Fig. 57.13 The simplest cobot consists of a single rolling wheel on an *xy* frame [57.57]

Fig. 57.14 A cobot assisting a human in assembling a car door

guidance. Ergonomic as well as productivity benefits result from combining the strength and computer interface of the cobot with the sensing and dexterity of the human worker.

Consider the cobot shown in Fig. 57.13. A computer controls the steering of the wheel, thus confining the operator's handle to whatever virtual surfaces and free spaces are desired. In contrast to extenders and Fanuc's IADs, however, in the remaining direction – in this case the rolling path that the computer allows – the operator is in direct physical connection with payload; there is no sensor–actuator pair to interfere with the haptic sense between the payload and the operator. Additionally since computers only steer and do not drive the cobot forward, an element of inherent safety is introduced. The cobot concept has been extended to multiple degrees of

freedom: Fig. 57.14 shows a planar cobot, used for door handling at GM.

The cobot base permits planar motions on the floor (*x*, *y*, and rotation). The cobot indexes itself to the automobile's running board and guides the operator and payload (a door) along a path that brings the payload into proper alignment with the hinge axis of the automobile.

Cobots can also display the types of behavior mentioned above: free mode, in which the wheels are steered so as to comply with user forces; path mode, in which the cobot steers along a defined path through 3-space; and virtual surface mode in which the wheels are steered tangent to a software-defined constraint surface, resisting user forces that would violate the virtual surface.

57.5 Safety Standards for pHRI

In practice, standards are an important means of addressing and solving safety problems in the workplace, as well as encouraging the adoption of new and unfamiliar technology. Research work in the robotics industry and academia is both influenced by current work on standards, and has an influence on their evolution – which is particularly interesting at present.

The present landscape for robotics standards include well-established national standards (ANSI-RIA for the US, CSA in Canada, DIN in Germany, etc.), that are collected and harmonized by the International Organization for Standardization (ISO). Safety for industrial robots are addressed both by general standards on safety of machinery (e.g., ISO 12100:2003 *Basic concepts, general principles for design*; ISO 13849:1999 *Safety-related parts of control systems*; ISO 13855, *Positioning of protective equipment with respect to the approach speeds of parts of the human body*), and by robot-specific standards. The main ISO safety standard for robots is ISO 10218, which dates back to 1992 [57.6]. In 2002 a revision of the standard was undertaken. Work has been ongoing since, gradually turning what started as a simple harmonization effort into a genuine development effort introducing new and exciting concepts to the world of industrial robot safety [57.59]. The revised ISO 10218 (*Robots for industrial environment – Safety*) will be a two-part document. Part 1, entitled *Robot*, was published in 2006 [57.60]. Part 2, on which work has just begun, has a working title of *Robot System and Integration* and is not available at the time of writing. Part 2 is intended to address workplace safety requirements and is directed more to the end-user than the manufacturer.

The most salient changes of the 2006 standard revision are:

1. *new modes of operation*: the standard finally allows the introduction in the workplace of advanced robotics concepts, such as *simultaneous control* of multiple manipulators, as, e.g., in the master–slave configurations; *mobile* robots mounted on vehicles for industrial automation, and (most relevant to this chapter) *collaborative operation* in which purposely designed robots work in direct cooperation with a human within a defined workspace with the operator;
2. *control reliability*: while former standards placed reliance upon hardwired electromechanical components, the revised one allows *safety-rated soft-axis and space-limiting* control circuitry to use state-

of-the-art software, electronic, and network-based technology (including wireless);

3. *safeguarding and clearance*: instead of fixed safeguard distance, these can be evaluated based on the assessment of stopping time and distance to be provided by the robot manufacturer in different load conditions. In collaborative mode, hard limits on either the maximum dynamic power (80 W) or maximum static force (150 N) at the end-effector apply, as well as on its maximum velocity (250 mm/s).

Although the revision of ISO 10218 is already taking into consideration many more advanced features than in the past, evolution is still ongoing. In particular, in the domain of hands-on pHRI, the American National Standards Institute (ANSI) has established a committee, T-15, that has published a draft safety standard for intelligent assist devices (IADs) [57.61]. The committee defined IADs as *single- or multiple-axis devices that employ a hybrid, programmable, computer–human control system to provide human strength amplification, guiding surfaces or both*. Notable aspects of the standard include:

1. Risk assessments replace fixed rules: instead of declarations regarding how to accomplish safe operation, risk assessment procedures were advised for IAD and pHRI robotic technologies, to identify and mitigate risks in proportion to their seriousness and probability;
2. Safety-critical software: the greater complexity of human–robot interaction, and the observation that an abrupt power-down is not always a safe solution, necessitate a greater reliance on safety-critical software rather than safety-critical hardware. The T-15 draft standard requires that software- and firmware-based controllers shall, under any single component failure, lead to the shutdown of the system in a safe state, maintenance of a safe load position, and the prevention of subsequent automatic operation. For example, this degree of safety may be achieved by using microprocessor redundancy, microprocessor diversity, and self-checking;
3. Dynamic limits: physical limits of people are taken into account by requiring that operators be able to *outrun, overpower, or turn off* IADs. Speed must not exceed 2.0 m/s, a fast walk; overforce or overload devices or techniques must be used that can reliably detect an impulse force of 267 N (60 lbf) (the committee dictated that a human operator should win

- a fight). These and similar limits could be further reduced to the extent practical as determined by a risk assessment;
4. Emergency stops: sole reliance on the traditional red mushroom e-stop button was felt to create a hazard. For instance, in some unexpected situations one might want an IAD to continue to actively track a moving vehicle, rather than come immediately to a halt and possibly drag a part and a person engaged in a moving line. The T-15 draft standard demands a traditional e-stop, but also permits *an IAD may have one or more context-based safety stop*
- circuits. When used, inputs should be provided to allow application-specific external devices to initiate context-based safety stops;*
5. Man-machine interface: IADs may operate in different modes (free mode, hands-on-controls, hands-on-payload, line tracking, etc.). The T-15 committee found that *mode misunderstanding* was a likely cause of safety problems. IADs should have few modes, well understood by their operators, well communicated to the operator (*what mode is this IAD in?*) and well commanded by the operator to the IAD (*go into free mode!*).

57.6 Conclusions

The next generation of robots will coexist with humans and will interact with us physically. In this chapter we have illustrated some of the motivations and economic factors that are pushing this revolution forward. A robot arm that is to interact with humans must place safety at a premium as a design consideration. As Asimov's laws of robotics have it 'A robot

may not injure a human being...', or, to rephrase the science fiction author, under no circumstances should a robot cause harm to people, directly or indirectly, in regular operation or in failures. Another requirement on robot manipulators remains their performance: their accuracy and speed in performing tasks as required.

58. Social Robots that Interact with People

Social Robots

Cynthia Breazeal, Atsuo Takanishi, Tetsunori Kobayashi

This chapter surveys some of the principal research trends in social robotics and its application to human–robot interaction (**HRI**). Social (or sociable) robots are designed to interact with people in a natural, interpersonal manner – often to achieve social–emotional goals in diverse applications such as education, health, quality of life, entertainment, communication, and collaboration. The long-term goal of creating social robots that are competent and capable partners for people is quite a challenging task. They will need to be able to communicate naturally with people using both verbal and nonverbal signals. They will need to engage us not only on a cognitive level, but on an emotional level as well. They will need a wide range of social–cognitive skills and a theory of other minds to understand human behavior, and to be intuitively understood by people. A deep understanding of human intelligence and behavior across multiple dimensions (i.e., cognitive, affective, physical, social, etc.) is necessary in order to design robots that can successfully play a beneficial role in the daily lives of people. This requires a multidisciplinary approach where the design of social robot technologies and methodologies are informed by robotics, artificial intelligence,

chology, neuroscience, human factors, design, anthropology, and more.

The way a person interacts with a social robot (or sociable robot) is quite different from interacting with the majority of autonomous mobile robots today. Modern autonomous robots are generally viewed as tools that human specialists use to perform hazardous tasks in remote environments (i.e., sweeping minefields, inspecting oil wells, mapping mines, etc.). In dramatic contrast, social (or sociable) robots are designed to engage people in an interpersonal manner, often as partners, in order to achieve social or emotional goals.

The development of socially intelligent and socially skillful robots drives research to develop autonomous or semiautonomous robots that are natural and intuitive for the general public to interact with, communicate with, work with as partners, and teach new capabilities. *Dautenhahn's* work is among the earliest in thinking about robots with interpersonal social intelligence where relationships between specific individuals are important [58.1,2]. These early works pose the question *What are the common social mechanisms of communication and understanding that can produce efficient, enjoyable,*

natural, and meaningful interactions between humans and robots?

Promisingly, there have been initial and ongoing strides in all of these areas ([58.3–11], etc.). In addition, this domain motivates new questions for robotics researchers, such as how to design for a successful long-term relationship where the robot remains appealing and provides consistent benefit to people over weeks, months, and even years. The benefit that social robots provide people extends far beyond strict task performing utility to include educational (Chap. 55), health and therapeutic (Chap. 53), domestic (Chap. 54), social and emotional goals (e.g., entertainment, companionship, communication, etc.), and more.

We begin this chapter with a brief overview of a wide assortment of socially interactive robots that have been developed around the world (Sect. 58.1). We follow with selected topics that highlight some of the representative research themes: multimodal communication (Sect. 58.2), expressive emotion-based interaction (Sect. 58.3), and social-cognitive skills (Sect. 58.4). We rely on examples from our own research programs to illustrate these trends, while making reference to other excellent work performed in other research labs. The following robotic platforms are used as case studies through the sections: Kismet and Leonardo developed at MIT, and Waseda Eye No. 4 Refined II (WE-4RII), ROBISUKE, and ROBITA developed also at Waseda University.

58.1 Social Robot Embodiment

Social robots are designed to interact with people in human-centric terms and to operate in human environments alongside people. Many social robots are humanoid or animal-like in form, although this does not have to be the case. A unifying characteristic is that social robots engage people in an interpersonal manner, communicating and coordinating their behavior with humans through verbal, nonverbal, or affective modalities. As can be seen in the following examples, social robots exploit many different modalities to communicate and express social-emotional behavior. These include whole-body motion, proxemics (i.e., interpersonal distance), gestures, facial expressions, gaze behavior, head orientation, linguistic or emotive vocalization, touch-based communication, and an assortment of display technologies.

For social robots to close the communication loop and coordinate their behavior with people, they must also be able to perceive, interpret, and respond appropriately to verbal and nonverbal cues from humans.

Given the richness of human behavior and the complexity of human environments, many social robots are among the most sophisticated, articulate, behaviorally rich, and intelligent robots today.

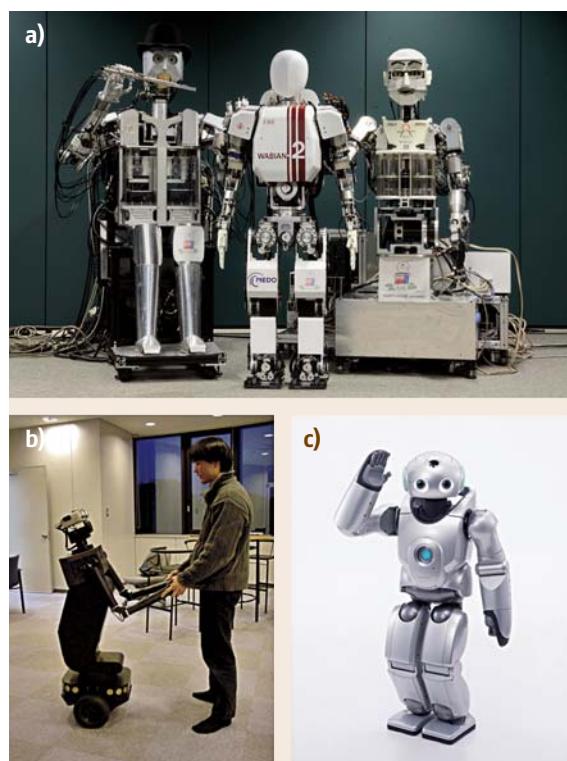

Fig. 58.1a–c Examples of socially interactive humanoid robots: (a) humanoid robots developed at Waseda University from *left to right*: a flautist robot WF-4RII [58.12], WABIAN-2 [58.13], and WE-4RII [58.14] (b) Robovie III developed by the Advanced Telecommunications Research Institute International (ATR) Intelligent Robotics and Communication Laboratories, which is able to gesture with its arms and give a hug (c) Qrio for curiosity (Qrio), a small biped entertainment robot previously developed by Sony, is very well known for its impressive dancing ability

As shown in Fig. 58.1, a number of socially interactive humanoid robots have been developed (see Chap. 56) that can participate in whole body social interaction with people such as dancing [58.15], walking hand-in-hand [58.16, 17], playing a musical duet [58.12], or transferring skills to unskilled persons [58.18]. Their arms and hands are designed to exhibit human-like gestures such as pointing, shrugging shoulders, shaking hands, or giving a hug [58.19–21]. Some of them are designed with mechanical faces to communicate with humans via facial expressions.

Whereas many of these humanoids have a mechanical appearance, android robots are designed to have a very human-like appearance with skin, teeth, hair, and clothes (Fig. 58.2). A design challenge of android robots is to avoid the *uncanny valley* where the appearance and movement of the robot resemble more of an animate corpse than a living human. Designs that fall within the *uncanny valley* elicit a strong negative reaction from people [58.30].

There are a number of more creature-like social robots that take their aesthetic and behavioral inspiration from animals (Fig. 58.3). Given that people pet and stroke companion animals, touch-based communication has been explored in several of these more animal-inspired robots. Sony's entertainment robot dog, AIBO [58.26], is a well-known commercial example. Other robots in this category have a more organic appearance, such as the therapeutic companion robot seal, Paro [58.27]. Researchers have also chosen to design robots with a more fanciful appearance, melding anthropomorphic with animal-like qualities such as Leonardo ([58.28, 29, 31], etc.).

Many social robots are not overtly humanoid or zoomorphic, but still capture key social attributes (Fig. 58.4), for instance, one of the best-known and pioneering social robots Kismet [58.3] developed at the MIT Artificial Intelligence Lab. Kismet had a very expressive mechanical face with anthropomorphic features like large blue eyes. Another example is the dancing robot Keepon developed by National Institute of Information and Communications Technology (NiICT) (Japan). This small yellow robot has a simplistic face and uses a classic animation technique called *squash and stretch* for expression of the body [58.32].

Many mobile social robots have been fitted with faces to enhance social interaction (Fig. 58.4). Some examples are the elder-care robot, Pearl, and the robotic receptionist Valerie with a graphical face on a liquid-crystal display (LCD) screen [58.33], both developed at Carnegie Mellon University [58.34]. Other examples are

robots like PaPeRo developed by NEC, aiming at a commercial product [58.35]. Still, some social robots have

Fig. 58.2a–d Some examples of androids: (a) one of the earliest face robots developed at the Science University of Tokyo [58.22] (b) Geminoid HI-1 developed by the ATR Intelligent Robotics and Communication Laboratories [58.23] (c) ROMAN, developed at the University of Kaiserslautern [58.24] (d) the Waseda DOCOMO FACE Robot No. 2 developed by Waseda University [58.25]

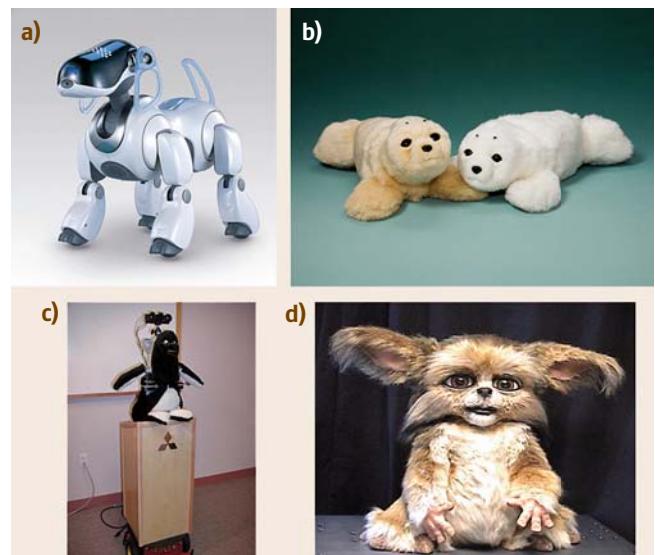

Fig. 58.3a–d Examples of social robots inspired by animals with anthropomorphic qualities (from left to right): (a) AIBO, the robotic dog previously developed by Sony [58.26], (b) Paro the therapeutic seal robot developed at AIST [58.27], (c) Mel the conversational robotic penguin developed at MERL [58.28], and (d) Leonardo developed at the MIT Media Lab [58.29]

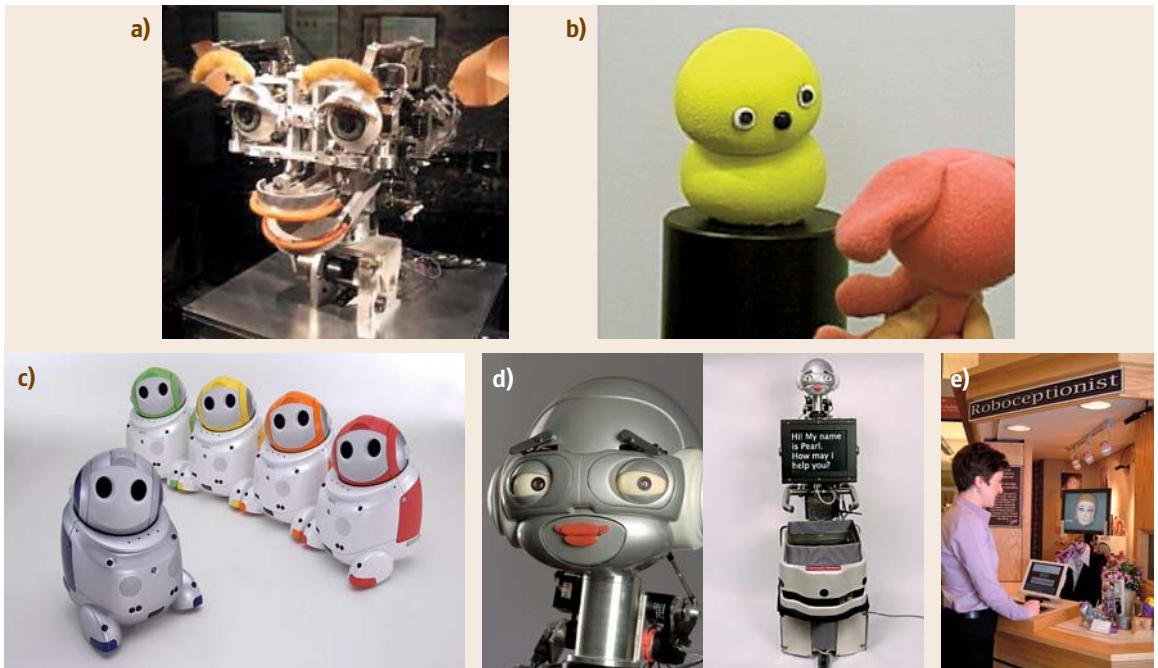

Fig. 58.4a–e Examples of social robots that are neither humanoid nor zoomorphic but capture key social attributes: (a) Kismet [58.3], (b) Keepon [58.32], (c) PaPeRo [58.35], (d) Pearl [58.34], (e) Valerie [58.33]

no overt social features like faces or eyes, but rely purely on language-based communication. Issues of proxemics on mobile social robots have also been explored such as

how a robot should approach a person [58.36], follow a person [58.37], or maintain appropriate interpersonal distance [58.38].

58.2 Multimodal Communication

Natural conversational ability is an important skill for social robots. Historically, even first-generation humanoid robots developed in the 1970s and 1980s (i.e., WABOT and WABOT-2) had primitive conversational skills modeled as simple combinations of speech input/output mappings [58.39, 40]. More recent examples are PaPeRo [58.35] and receptionist robot (**ASKA**) [58.41] that have conversational functions to work as information terminals.

In natural human conversation, however, people send and receive nonverbal information that supplements linguistic information. These paralinguistic cues help smooth and regulate communication between individuals.

The representative roles of paralinguistic information are as follows:

1. *Regulators*: expressions such as gestures, poses, and vocalizations that are used to regulate/control conversational turn-taking.
2. *State displays*: signs of internal state including affect, cognitive, or conversational states that improve interface transparency.
3. *Illustrators*: gestures that supplement information for the utterance. These include pointing gestures, iconic gestures,

This section focuses on conversational robots with paralinguistic communication abilities. Modern social robots employ both linguistic and paralinguistic information to perform different kinds of tasks [58.28, 29, 33].

58.2.1 Robots that Express Paralinguistic Information

In many cases, the same paralinguistic information can be conveyed through auditory or visual channels. However the characteristics of these channels have different properties. Sound has a strong property of attracting attention instantaneously. It can be used effectively for interruption, but it can also be disruptive and annoying. In addition, the timing of auditory paralinguistic cues is very strict. Overall, auditory paralinguistic signals are not suitable for continuous display. Visual paralinguistic cues are silent, the timing is a slightly less critical, and they can be used continuously. Hence, auditory and visual cues can be effectively used together to cooperatively convey the same information and emphasize it, or they can be used to convey different information simultaneously and contribute to efficiency. Thus, it is very important to choose the proper combination of modality and paralinguistic cues according to the situation. We provide examples below.

Regulatory Cues

Some of the earliest social robots displayed paralinguistic information to regulate interaction with people. Hadaly2 was the first robot to use mutual gaze as a paralinguistic cue to regulate conversation [58.42, 43]. When the robot and human achieved mutual gaze, approximated using face recognition to determine when the human's face was facing the robot, Hadaly2 expressed readiness to commence conversation by blinking its eyes. Other examples are *Kismet* [58.44] and *Leonardo* [58.29], which have implemented paralinguistic cues called *envelope displays* to regulate the exchange of speaking turns. Humans tend to make eye contact and raise their eyebrows when ready to relinquish their speaking turn, and tend to break gaze and blink when starting their speaking turn. These cues were shown to be effective in smoothing and synchronizing the exchange of speaking turns with human subjects, resulting in fewer interruptions and awkward long pauses between turns [58.3, 45].

State-Display Cues

Other robots use state-display cues whereby the face or gaze of the robot is used to indicate its conversational or cognitive state. In general, this makes the robot's internal state more transparent to a person, so they can better predict and interpret the robot's conversational state and level of understanding. ROBITA used the tightness of its facial expression to indicate readiness to engage in

conversation; a tight face was used to express conversational readiness, while a lose face communicated a lack of readiness to engage [58.5, 46].

Other state-display cues are back-channel responses. Human listeners use back-channel feedback (such as small head nods) to convey when speakers are successfully following the conversation. Response time for back-channel cues is very important because that cue is associated with the corresponding content. ROBISUKE [58.47] employed finite-state transducer (FST) technology to achieve rapid understanding of the speech signal. This allowed the robot to resolve ambiguities in meaning and prepare its own responses even when the speaker was in mid-sentence. ROBITA [58.5] provided humans with back-channel information via head nods and a tight face expression while listening.

Another back-channel signal is an expression of confusion by the listener (verbal or nonverbal). This flags the speaker to stop and try to repair the broken communication. Robots such as Leonardo and ROBITA use facial displays of confusion when speech recognition fails in order to intuitively communicate to the human that he or she should repeat their last utterance.

Similarly, gaze direction is a highly salient cue to convey the attentional focus of a robot. This is very useful if a human is trying to point out a particular object as a shared referent – such as pointing to an object before labeling it for the robot. These paralinguistic cues are useful for facilitating efficient conversational progress whereby errors and misunderstandings are identified and repaired immediately [58.45]; for instance, Leonardo's gaze behavior is used for performing envelope displays as well as for establishing shared attention with the human partner. Human subject studies have verified that Leonardo's paralinguistic cues contribute positively to the transparency of the robot's behavior and make the overall interaction more robust and efficient [58.45].

Illustrator Cues

A number of robots have implemented *illustrator* cues to direct the attention of a human [58.28, 48]. Often these robots use a variety of cues and the timing between them (such as gaze, head pose, pointing gestures, and conversational speech) to perform joint attention. In cases where a robot may be interacting with more than one person, the robot must properly take into account the location and orientation of the object, itself, and the individuals. ROBITA used such information to choose the proper gesture while considering the other people's point of view.

58.2.2 Robots that Understand Paralinguistic Information

Humans readily express paralinguistic cues when interacting with robots just as they do with people. Consequently, conversational robots must be able to recognize and properly respond to these cues as well. This is a very difficult research challenge given the wide variety, subtlety, and timing of these human cues.

Regulatory Cues

A few robots can track a human's paralinguistic cues to help regulate the conversation. The most common cues used for recognizing the end of the human's speaking turn are mutual gaze (estimated using head pose to determine when human looks back to the robot) and paused speech. As a more sophisticated example, humans frequently provide short acknowledgement utterances (e.g., 'uh-huh', 'um-hmm', 'huh', etc.) as the robot explains something. These responses are either acknowledgments or acknowledgment-like repetitions, or

ask-backs or ask-back-like repetitions. It is very difficult to distinguish these two kinds of utterances from the linguistic information as represented by the transcription of the utterance. The only way to distinguish them is by their prosody (not what, but how something is said). ROBISUKE could distinguish the utterance as either an acknowledgment or an ask-back from the prosody of the utterance [58.49].

State-Display Cues

A number of robots are able to recognize and respond to state-display cues such as back-channel feedback nods, acknowledgement of an utterance, and attentional focus. One of the most robust systems for handling back channel feedback nods is Mel [58.28]. A sophisticated head nod recognition system was developed whereby the robot could successfully distinguish small feedback nods from other kinds of head nods such as those that communicate agreement. Mel used this information to determine its own nodding behavior in order to be an appropriate response for the human. In a series of human subject studies, Sidner et al. found these paralinguistic cues to enhance the social engagement of the robot to people [58.28]. With respect to recognizing successful or unsuccessful acknowledgement of an utterance, ROBISUKE used facial expression and prosody of the person's utterance [58.50] to make this determination. In a collaborative assembly task scenario, Sakata et al. [58.51] presented a robotic system that used human gaze information to deduce the human's intention of which object to operate upon next. The robot used this information to choose an appropriate cooperative action such as either taking over for a human, settling a human's hesitation, or executing simultaneously with a human.

Illustrator Cues

A number of robots are able to recognize deictic gestures of a person conveyed either through pointing gestures or head pose. For example, Leonardo is able to infer the object referent in an interaction by considering a number of factors including pointing gesture, head pose, and speech. Brooks and Breazeal [58.52] developed a deictic recognition system that enabled a robot to infer the correct object referent from correlated speech and deictic gesture. Interestingly, it was found that the accuracy of the human's pointing gesture is surprisingly poor. As a result, the deictic recognition system relies on coordinated speech and gesture information, with spatial knowledge provided by a three-dimensional (3-D) spatial database constructed by the robot using real-time vision, and a deictic spatial reasoning system. This sys-

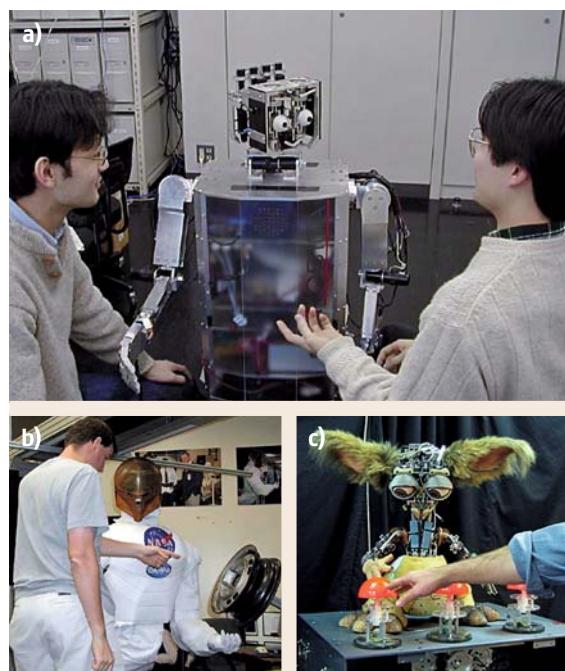

Fig. 58.5a–c Examples of conversational robots: (a) ROBITA performing group conversation; (b) Robonaut interpreting the pointing gestures of a human to determine which nut to fasten on the wheel; (c) Leonardo uses gaze and joint attention to ground the human's pointing gesture for the desired referent

tem was successfully demonstrated on the dexterous humanoid Robonaut developed at National Aeronautics and Space and Administration (NASA) Johnson Space Center (JSC) (Fig. 58.5b) where the human points to and labels a set of four bolts on a wheel to be fastened in order by the robot.

58.2.3 Group Conversation

The ability to express and understand paralinguistic cues plays an important role in face-to-face conversation. The same is true for group conversation where a robot converses with two or more people. We use ROBITA, shown in Fig. 58.5a, as the illustrative example of this ability [58.46].

To continue a conversation, it is important for all conversational participants to understand who plays which role. ROBITA frames this problem with respect to information flow – to understand who is speaking to whom and when, and to determine each person’s presence as a conversational partner. During group conversation, ROBITA tries to classify the participants as the speaker or as listeners. There is only one speaker at a time and the rest are listeners. The listeners are classified into a primal listener, to whom the utterance is directed, and secondly listeners, who observe the message exchange between the speaker and the primal listener. ROBITA discerns these roles by recognizing the face direction of the speaker. The person to whom the speaker is looking is recognized as the primal listener.

To convey participation and improve its social presence in conversation, ROBITA tries to understand the conversational roles to look at the appropriate person. If the speaker faces ROBITA, then the robot recognizes itself as the primal listener and that the message is intended for itself. ROBITA faces the speaker when it is the primal listener. When ROBITA is a secondary listener, it looks at either the speaker or the primal listener.

58.2.4 Communication in Collaboration

Verbal and paralinguistic communication plays a very important role in coordinating joint action during collaborative tasks. Sharing information through communication acts is critical given that each teammate often has only partial knowledge relevant to solving the problem, each has different capabilities, and possibly diverging beliefs about the state of the task. For instance, all teammates need to establish and maintain a set of mutual beliefs regarding the current state of the task, the

respective roles and capabilities of each member, and the responsibilities of each teammate [58.53]. This is called *common ground* [58.54].

Dialog certainly plays an important role in establishing common ground. Each conversant is committed to the shared goal of establishing and maintaining a state of mutual belief with the other. To succeed, the speaker composes a description that is adequate for the purpose of being understood by the listener, and the listener shares the goal of understanding the speaker. This communication acts serve to achieve robust team behavior despite adverse conditions, including breaks in communication and other difficulties in achieving the team goals.

Humans also use nonverbal skills such as visual perspective taking and shared attention to establish common ground with others. They orient their own gaze and direct the gaze of their teammate through deictic cues such as pointing gestures in order to establish common ground. Given that visual perspective taking, shared attention, and the use of deictic cues to direct attention are core psychological processes that people use to coordinate joint action about objects and events in the world, robot teammates must be able to display and interpret these behaviors and cues when working with humans in a manner that adheres to human expectations.

Breazeal et al. [58.45] investigated the impact of grounding using nonverbal social cues and behavior on task performance by a human–robot team. In a human subject experiment, participants guided Leonardo to perform a physical task using speech and gesture. The robot communicates either implicitly through behavior (such as gaze and facial expressions) or explicitly through nonverbal social cues (i.e., explicit pointing gestures). The robot’s explicit grounding acts include visually attending to the human’s actions to acknowledge their contributions, issuing a short nod to acknowledge the success and completion of the task or subtask, visually attending to the person’s attention directing cues such as to where the human looks or points, looking back to the human once the robot operates on an artifact to make sure its contribution is acknowledged, and pointing to artifacts in the workspace to direct the human’s attention toward them. Both self-reporting via questionnaire and behavioral analysis of video support the hypothesis that implicit nonverbal communication positively impacts human–robot task performance with respect to understandability of the robot, efficiency of task performance, and robustness to errors that arise from miscommunication [58.45].

58.3 Expressive Emotion-Based Interaction

Humans are fundamentally emotional beings. Consequently, human communication and social interaction often includes affective or emotive factors. To support the emotional side of human behavior, researchers are exploring affective interaction and communication between people and robots. To participate in emotion-based interactions, robots must be able to recognize and interpret affective signals from humans, possess their own internal models of emotions (often inspired by psychological theories), and be able to communicate this affective state to others.

The robot's computational model of emotion determines the robot's emotional responses according to its interactions with the external environment and its own internal cognitive-affective state. In psychology, emotional behavior depends upon many internal factors (i.e., the current emotional state, the cognitive state, current desires, physical states, etc.) These physical, cognitive, and affective states are deeply interrelated, and modulate and bias one another.

A growing number of socio-emotional robots have been designed, such as AIBO [58.26], QRIO [58.55], FEELIX [58.56], and many others. In this section, we highlight research in this area using two primary examples: Kismet and the Waseda Emotion Expression Humanoid Robot No. 4 Refined II.

58.3.1 Kismet: Inspiration from Developmental Psychology

Kismet is the first autonomous robot explicitly designed to explore socio-emotive face-to-face interactions with people [58.3]. Research with Kismet focused on exploring the origins of social interaction and communication in people, namely that which occurs between caregiver and infant, though extensive computational modeling guided by insights from psychology and ethology.

Protosocial Responses and Origins of Communication

Early infant-caregiver exchanges are heavily grounded in the regulation of emotion and its expression. Inspired by these interactions, Kismet's cognitive-affective architecture was designed to implement core protosocial responses exhibited by infants given their critical role in normal social development (see Fig. 58.6). Guided by recent psychological theories, Kismet's cognitive-affective architecture (Fig. 58.6) emphasized parallel and interacting systems of emotion and cog-

nition [58.57]. Internally, Kismet's models of emotion interacted intimately with its cognitive systems to influence behavior and goal arbitration [58.58]. Through a process of behavioral homeostasis [58.59], these emotive responses served to restore the robot's internal affective state to a mildly aroused, slightly positive state – corresponding to a state of interest and engagement in people and its surroundings that fosters learning.

One purpose of Kismet's emotive responses was to reflect the degree to which its drives and goals were being successfully met [58.60]. A second purpose was to use emotive communication signals to regulate and negotiate its interactions with people [58.61]. Specifically, Kismet utilized emotive displays to regulate the intensity of playful interactions with people, making sure to keep the complexity of the perceptual stimulus within a range the robot could handle and potentially learn from [58.62]. In effect, Kismet socially negotiated its interaction with people via its emotive responses to have humans help it achieve its goals, and satiate its drives, and maintain a suitable learning environment.

Multimodal Expressive Skills

With respect to its expressive abilities, Kismet generated a wide assortment of facial expressions with corresponding body posture to mirror its affective state. Kismet's facial expressions are generated using an interpolation-based technique over a three-dimensional space (Fig. 58.8). The basis facial postures are designed according to the componential model of facial expressions theorized by *Smith and Scott* [58.63] (Fig. 58.9) whereby individual facial features move to convey affective information. The three affective dimensions of the interpolation space correspond to arousal, valence, and stance. These same three attributes are used to affectively appraise the myriad of environmental and internal factors (stimuli, goals, motives, etc.) that contribute to Kismet's *emotional state* [58.64].

In addition to facial expression, Kismet used an expressive vocalization system to generate a wide range of emotive utterances corresponding to joy, sorrow, disgust, fear, anger, surprise, and interest [58.65]. The robot's speech was accompanied with appropriate motor movements of the lips, jaw, and face [58.65].

Breazeal and Aryananda [58.66] found that even simple acoustic features (such as pitch mean and energy variance) can be used by the robot to classify the affective prosody of an utterance along valence

| Antecedent conditions | Emotion | Behavior | Function |
|----------------------------------------------------------|--------------------|------------------|-----------------------------------------------------------------------------------------------------|
| Delay, difficulty in achieving goal of adaptive behavior | Anger, frustration | Complain | Show displeasure to caregiver to modify his/her behavior |
| Presence of an undesired stimulus | Disgust | Withdraw, reject | Signal rejection or presented stimulus to caregiver |
| Presence of a threatening, overwhelming stimulus | Fear, distress | Escape | Move away from a potentially dangerous stimuli |
| Prolonged presence of a desired stimulus | Calm | Engage | Continued interaction with a desired stimulus |
| Success in achieving goal of active behavior, or praise | Joy | Display pleasure | Reallocate resources to the next relevant behavior (or to reinforce behavior in a learning context) |
| Prolonged absence of a desired stimulus, or scolding | Sorrow | Display sorrow | Evoke sympathy and attention from caregiver (or to discourage behavior in a learning context) |
| A sudden, close stimulus | Surprise | Startle response | Alert |
| Appearance of a desired stimulus | Interest | Orient | Attend to new, salient object |
| Need of an absent and desired stimulus | Boredom | Seek | Explore environment for desired stimulus |

Fig. 58.6 A table summarizing the protosocial emotive responses of Kismet (adapted from Plutchik [58.59])

and arousal dimensions. Using these acoustic features and others suggested by Fernald [58.67], Kismet could recognize the affective intent in human speech as communicated through vocal prosody that corresponds to praising, soothing, scolding, and attentional bids [58.66].

58.3.2 WE-4RII: A Model of Emotion Inspired by Motion

As another example of a cognitive-affective architecture, the mental model of WE-4RII is shown in Fig. 58.10. In this section, we offer a more technical description of this model to illustrate how such mental models can be computationally implemented [58.68].

The core of this architecture is the emotion model. In dynamics, the movement of objects is described by the equation of motion. The WE-4RII mental model posits that the dynamics of mental transitions might be expressed by similar equations. Hence, the robot implements *equations of emotion* as shown in (58.1) as a second-order differential equation analogous to the equation of motion. Also, three *emotional coefficient matrixes* corresponding to the *emotional inertia*, *emotional viscosity*, and *emotional elasticity* matrixes are introduced:

$$\mathbf{M}\ddot{\mathbf{E}} + \Gamma\dot{\mathbf{E}} + \mathbf{K}\mathbf{E} = \mathbf{F}_{EA}, \quad (58.1)$$

where \mathbf{M} is the emotional inertia matrix, Γ is the emotional viscosity matrix, \mathbf{K} is the emotional elasticity matrix, and \mathbf{F}_{EA} is the emotional appraisal.

Here, *emotional appraisal* stands for the total effect of the stimuli on mental state. By using the *equations*

of *emotion*, the robot can express the transient aspects of the mental state after the robot senses the stimuli from the environment. Moreover, the robot can express different reactions to the same stimuli by changing the *emotional coefficient matrixes*, and the robot can obtain complex and various mental trajectories, such as a slow reaction or an oscillated reaction [58.69, 70].

Mood Model

Human mental states are affected not only by emotion but also by mood. While emotion is characterized as a strong change that is caused in a short time, moods change more gradually over an extended time. Emotion and mood are closely related, so in this model, moods are represented by introducing the *mood vector* \mathbf{M}_d that consists of a *pleasantness axis* and an *activation axis* shown in (58.2)

$$\mathbf{M}_d = (M_{dP}, M_{dA}, 0). \quad (58.2)$$

Because the robot's current mental state influences the pleasantness component of the *mood vector* M_{dP} , M_{dP} is defined as the integral of the pleasantness component of the *emotion vector* as shown in (58.3). On the other hand, because the activation component of the *mood vector* M_{dA} is similar to human biological rhythm such as the internal clock [58.69, 70], the van del Pol equation (which is an equation of self-excited oscillation) is applied to describe it as (58.4).

$$M_{dP} = \int E_P dt, \quad (58.3)$$

$$\ddot{M}_{dA} + (1 - M_{dA}^2) \dot{M}_{dA} + M_{dA} = 0. \quad (58.4)$$

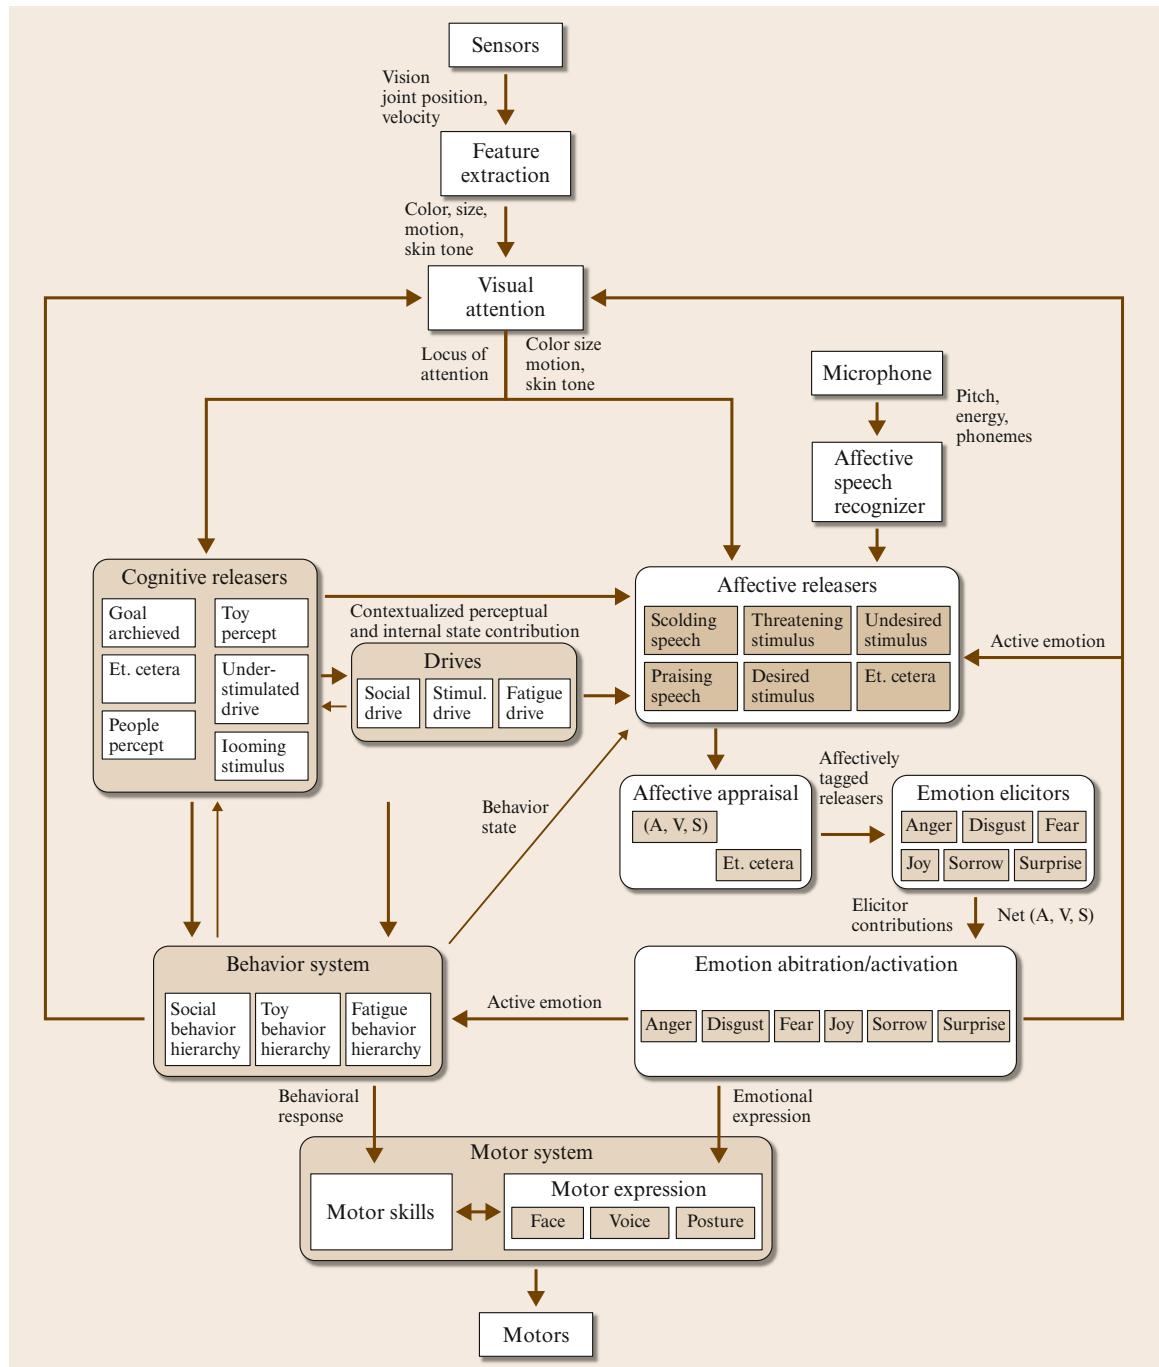

Fig. 58.7 The cognitive-affective architecture of Kismet. The gray boxes with rounded corners represent the cognitive systems responsible for perception, attention, drives, goal arbitration and execution. The white boxes represent the affective processes including affective appraisals of incoming events, basic emotive responses, and expressive motor behavior (vocalizations, facial expressions, etc.)

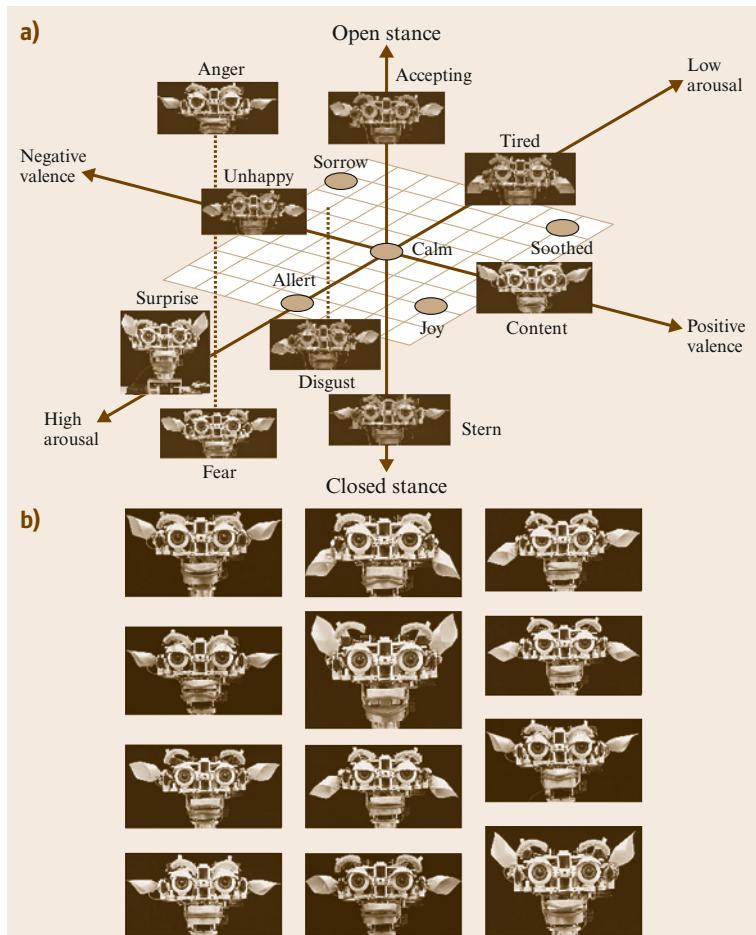

Fig. 58.8 (a) The basis facial poses of Kismet that are interpolated to generate a wide repertoire of expressions. The blend is determined according to the net affective state of the robot (arousal, valence, and stance). **(b)** A sampling of a range of Kismet's facial expressions from interpolation within this space of basis poses

Need model

For bilateral interaction, humans as well as robots should not only react to an individual's behavior but also behave according to internal needs. As a motivator of spontaneous behavior, a *need model* has been integrated with the mental model. Stimuli from the internal and external environment affect both the needs and the emotions of the robot. Therefore, WE-4RII has a two-layered structure of emotions and needs.

The need state of the robot is described by the *need matrix* N . The *need matrix* of WE-4RII is comprised of three kinds of needs (*appetite*, *need for security*, and *need for exploration*). However, the *need matrix* can be expanded to include other needs. The *need matrixes* N_t at time t and $N_{t+\Delta t}$ at $t + \Delta t$ are described by (58.5).

$$N_{t+\Delta t} = N_t + P_N \Delta N, \quad (58.5)$$

where P_N is the need personality matrix, and ΔN are small differences between two need states.

Equation (58.5) determines the robot need based on the stimuli from the internal and external environments. It is considered a differential equation for a continuous dynamical system. Therefore, (58.5) are named the *equations of need* [58.69, 71].

Facial Expression

WE-4RII can express seven basic emotions defined by Ekman [58.72]. To express them, a three-dimensional mental space consisting of *pleasantness*, *activation*, and *certainty* axes is defined based on psychological research ([58.73, 74]). This is represented as the *emotion vector* E described in (58.6)

$$E = (E_P, E_A, E_C). \quad (58.6)$$

| Facial action | | | | | | | | |
|---------------------------|---------------|-------------|--------------------|----------------------|---------------------|------------|---------------|------------|
| Meaning | Eyebrow frown | Raise brows | Raise upper eyelid | (Raise lower eyelid) | Up turn lip centers | Open mouth | Tighten mouth | Raise chin |
| Pleasantness | Less | Disgust | | | More | More | Less | Less |
| Goal obstacle/discrepancy | More | More | | | | | | |
| Anticipated effort | More | | | | | | | |
| Attentional activity | | More | More | (More) | | | | |
| Certainty | | Less | | | | More | | |
| Novelty | | More | More | | | | | |
| Personal agency/control | | Less | Less | | | Less | | |

Fig. 58.9 A mapping of how facial features relate to underlying affective dimensions, inspired by *Smith and Scott* [58.63]. Kismet does not have lower eyelids, so we note this in parentheses

Seven emotions and their corresponding expressions are mapped into the 3-D mental space shown in Fig. 58.11.

WE-4RII determines its emotion by the *emotion vector* E passing through each region ([58.69, 70]).

58.4 Socio-cognitive Skills

Socially intelligent robots, however, must understand and interact with animate entities (i.e., people, animals, and other social robots) whose behavior is governed by having a mind and body. In other words, social robots need the ability recognize, understand, and predict human behavior in terms of the underlying mental states such as beliefs, intents, desires, feelings, etc. Psychology calls this ability *theory of mind* (also known as mindreading, mental perception, social commonsense, folk psychology, social understanding, among others).

This section reviews research in implementing models of human socio-cognitive skills and abilities on robots. Social robots will need a diverse repertoire of such skills to realize their full potential in daily human life – to communicate, cooperate, and learn from people in a humancentric and human-compatible manner.

For instance, social robots will need to be aware of people's goals and intentions so that they can appropriately adjust their behavior to help us as our goals and needs change. They will need to be able to draw their attention flexibly to what we currently find of interest so that their behavior can be coordinated and information can be focused about the same thing. They need to realize that perceiving a given situation from different perspectives impacts what we know and believe to be true about it. This will enable them to bring important

information to our attention that is not easily accessible to us when we need it. Social robots will need to be deeply aware of our emotions, feelings, and attitudes to be able to prioritize what is the most important thing to do for us according to what pleases us or to what we find to be most urgent, relevant, or significant.

Furthermore, the behavior of social robots will need to adhere to people's expectations. Namely, people will apply their theory of mind to understand the robot in terms of these mental states as well.

58.4.1 Shared Attention

Scassellati's [58.75] was one of the earliest works to pose the question of how to endow robots with a theory of other minds. Inspired by the theoretical viewpoints proposed from the study of autism (believed to be a deficit of theory of mind), Scassellati implemented a hybrid model of those models proposed by *Leslie* [58.76] and *Baron-Cohen* [58.77] where shared attention is viewed to be a critical (and missing) precursor to the theory of mind competence. This hybrid model was implemented on the humanoid robot Cog. The robot was able to exhibit an assortment of social-cognitive skills such as joint attention, distinguishing an entity in the environment as either being animate or inanimate, and imitating only entities deemed to be animate.

Several researchers have explored models of joint reference, guided by insights provided by developmental psychology and autism research [58.78–80]. Normal human infants first demonstrate the ability to share attention with others at 9–12 months of age, such as following the adult's gaze or pointing gestures to the object being referred [58.77, 81]. In these works, joint attention is a learned process. For instance, the robot learns the visual motor mapping from the human's attentional cue (often using head pose as a popular indicator of what

the human is currently looking at) to the motor commands necessary to have the robot look at the same thing. This process is often bootstrapped by having the human look to where the robot initiates its gaze. In *Fasel* et al. [58.80], the robot learns a model of joint attention because it discovers that the human's gaze is a reliable indicator of where there is something interesting to look.

Thomaz et al. [58.82] explore attention-monitoring behavior of a robot in a social referencing interaction. In the developmental psychology literature, the ability for babies to actively monitor that others are looking at the same thing is a strong indicator of shared attention [58.83]. Social referencing is considered to be an early demonstration of shared attention because the baby looks back and forth between the novel object and the adult's emotive reaction toward that object to learn the association between the two. To implement shared attention, the robot's attentional state is modeled with two related but distinct foci: the current attentional focus (what is being looked at right now) and the referential focus (the current topic of shared focus, i. e., what communication, activities, etc. are *about*). Furthermore, the robot maintains a model for its own attentional state and a model for the attentional state of the human. The robot uses the heuristic of looking time upon a shared object

to infer the referent of the interaction. Once the referent has been identified, the robot monitors the attention of the human in order to associate their emotional reaction about that object to the intended target.

58.4.2 Emotional Empathy

For humans, the dynamic coupling of like minds through the actions of similar bodies is critical for acquiring human-like intuitions about the internal states of others. *Dautenhahn* [58.2] is one of the earliest works to explore *empathic* mechanisms of understanding others in social robot–robot interaction.

It is likely that emotional empathy in humans is learned, beginning in infancy. Various experiments with human adults have shown a dual affect–body connection whereby posing one’s face into a specific emotive facial expression actually *elicits* the feeling associated with that emotion [58.84, 85]. Hence, imitating the facial expressions of others could cause an infant to feel what the other is feeling, thereby allowing the infant to learn the association of observed emotive expressions of others with the infant’s own internal affective states. Other time-locked multimodal cues

may facilitate learning this mapping, such as affective speech that accompanies emotive facial expressions during social encounters between caregivers and infants.

Using a similar approach, *Breazeal* et al. [58.86] posit that a robot could learn the affective meaning of emotive expressions signaled through another person’s facial expressions, body language, and synchronized multimodal cues such as vocal prosody (see Fig. 58.12). For the robot, certain kinds of stimuli, such as pleasing or soothing tones of speech, have hardwired affective appraisals with respect to arousal and valence [58.66]. This computational model is based on the developmental findings of *Fernald* [58.67] that showed that certain prosodic contours are indicative of different affective intents in infant-directed speech. These affective intents are highly correlated with the corresponding emotive facial expression.

The tasks that couple these heterogeneous processes are face-to-face interactions and imitations. Via dual body–affect pathways, when the robot imitates the emotive facial expressions of others, it evokes the corresponding internal affective state (in terms of arousal and valence variables as described in Sect. 58.3.1) that would ordinarily give rise to the same expression during an emotive response. This is reinforced by affective information coming from the person’s speech signal.

These time-locked multimodal states occur because of the similarity in bodies and body–affect mappings, and they enable the robot to learn to associate its internal affective state with the corresponding observed expression. Thus, the robot uses its own cognitive and affective mechanisms and dual body–affect pathways as a simulator for inferring the human’s affective state as conveyed through behavior. This enables the robot to learn the association between visually observed facial expressions to the underlying affective meaning of those expressions. This is an *empathetic* approach because the robot takes on the corresponding affective state of the human in order to learn and recognize the emotional meaning of the particular facial expression.

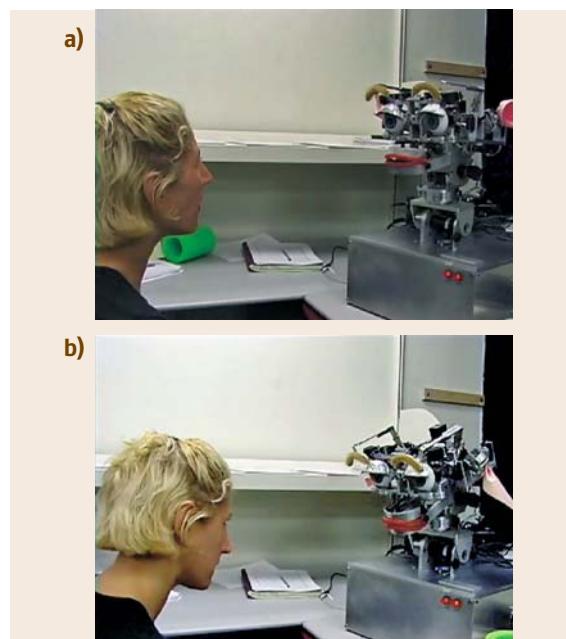

Fig. 58.12a, b Kismet and a young woman mirroring affect. Facial expression and affective tone of voice are tightly correlated: (a) mirroring interest/arousal, (b) mirroring negative affect.

58.4.3 Mental Perspective Taking

This section explores this empathetic, self-as-simulator approach further to address more general challenges in endowing robots with mental perspective-taking abilities. These approaches are inspired and informed by theories championed by neuroscience and embodied cognition called *simulation theory*.

Simulation Theory

Simulation theory holds that certain parts of the brain have dual use; they are used not only to generate our own behavior and mental states, but also simulate the introceptive states of the other person [58.87]. In other words, we engage in a process of perspective taking and mental simulation.

For instance, *Gallese* and *Goldman* [58.88] proposed that a class of neurons discovered in monkeys (called *mirror neurons*) is a possible neurological mechanism underlying both imitative abilities and simulation theory-type prediction of the behavior of others and their mental states. Further, *Meltzoff* and *Decety* [58.89] posit that imitation is the critical link in the story that connects the function of mirror neurons to the development of adult mindreading skills. From the field of embodied cognition, *Barsalou* et al. [58.90] present additional evidence from various social embodiment phenomena that, when observing an action, people activate some part of their own representation of that action as well as other cognitive states that relate to that action.

Mirror Systems for Recognizing Actions

Inspired by these theories and findings, *Johnson* and *Demiris* [58.91] employ a simulation of visual perception to recreate the visual egocentric sensory space and corresponding egocentric behavioral space of the observed agent to increase the accuracy of action recognition. This approach is based on their hierarchical attentive multiple models for execution and recognition (**HAMMER**) architecture that takes an approach inspired by mirror neurons to action recognition and imitation by directly involving the observer's motor system in the action recognition process. Specifically, during observation of another's actions, all of the observer's inverse models (akin to motor programs) are executed in parallel via simulation using forward models, and then compared to the observed action. The one that matches best is selected as being the recognized action. Perceptual perspective taking is needed to provide meaningful data for comparison. The simulated actions used by the observer during recognition must be generated as though from the point of view of the other person. They demonstrate this approach in an experiment where a robot attributes perceptions and recognizes the actions of a second robot [58.91].

Mental Perspective-Taking for Inferring Beliefs and Goals

Gray et al. [58.92] have implemented computational models of simulation-theoretic mechanisms throughout

several systems within Leonardo's cognitive architecture to enable the robot to infer beliefs and goal states of a human collaborator.

The robot reuses its belief-construction systems from the visual perspective of the human to predict the beliefs the human is likely to hold to be true given what he or she can visually observe. This enables the robot to recognize and reason about the beliefs held by a person, even when they diverge from the robot's own beliefs about the same situation.

In psychology, the ability to appreciate the divergent beliefs of another is classically demonstrated by the famous *false-belief* task. In this task, subjects are told a story with pictorial aides that typically proceeds as follows: two children, Sally and Anne, are playing together in a room. Sally places a toy in one of two containers. Sally then leaves the room, and while she is gone, tricky Anne moves the toy into the other container. Sally returns. At this point the human subject is asked "Where will Sally look for the toy?"

The robot, Leonardo, has demonstrated its ability to pass these sorts of false-belief tasks where it observes two humans playing the roles of *Sally* and *Anne* [58.93]. Within the robot's goal-directed behavior system (where schemas relate preconditions and actions with desired outcomes) motor information is used along with perceptual and other contextual clues (such as hierarchically structured task knowledge) to infer the human's goals and how he or she might be trying to achieve them (i.e., plan recognition).

58.4.4 Perspective Taking in Collaboration

By using a simulation-theoretic methodology, mental inferences made across different cognitive systems can interact in interesting and useful ways to support collaborative behavior where a robot offers its human teammate appropriate assistance.

Using Visual Perspective Taking to Resolve Ambiguous Referents

Trafton et al. [58.94] have developed and implemented visual and spatial perspective-taking abilities based on mental simulation to support human–robot interaction and collaboration. Their cognitive architecture, *polyscheme*, is designed to model how humans integrate multiple representational methods, reasoning, and planning methods to keep track of the world, including rich facilities for representing counterfactual worlds. It thus supports simulations of other people's visual perspective to reason about interac-

tions and the world from this alternate point of view.

They have demonstrated these skills in a number of experiments, such as demonstrating the robot's ability to learn how to play *hide and seek* with a person, where the robot learns what makes a good hiding place with respect to being completely occluded from the human seeker's point of view [58.95]. They have also demonstrated the usefulness of this system for a robot that solves a series of perspective-taking problems using the same frames of references and spatial reasoning abilities that astronauts do to facilitate collaborative problem solving – such as repairing a vehicle with another person that has a different vantage point [58.94]. For instance, the robot can handle egocentric requests (i.e., “hand me the cone to my right”), addressee-centric requests (i.e., “hand me the cone to your right”), or object-centered requests (i.e., “hand me the cone in front of the box”).

In *Trafton et al.* [58.96], a human interacts with the robot using a multimodal interface that supports speech and gesture. The robot's perspective-taking skills are used to resolve ambiguous referents that can arise when a person asks a robot perform an action in relation to an object (i.e., asking the robot to “hand me the wrench” when there are multiple wrenches to choose from). In particular, a visual occlusion in the workspace might hide another candidate wrench from the person's viewpoint but not from the robot's viewpoint (see Fig. 58.13). The robot can infer which is the intended object by taking the visual perspective of the human and applying principles of *joint salience* and *least effort*. If there still remains an ambiguity, the robot can act to resolve it by asking “which one?”

Providing Informational or Instrumental Support

Gray et al. have demonstrated the ability for the Leonardo robot to successfully infer its human partner's beliefs, desires, and intentions from real-time behavior during collaborative tasks. The shared workspace can have either visual occlusions [58.92] or can change dynamically where not all participants know of these changes [58.93]. The robot can integrate these mental state inferences to decide how best to help the person such as offering instrumental support (acting on the environment to help the human complete their goal) or provide informational support (giving relevant information that the person needs to successfully achieve his or her goal).

Consider the following scenario: a helpful robot is introduced to two people, Sally and Anne. All three

watch as Anne hides chips in a box to the left of the robot and cookies in a box to the right. Sally leaves the room, at which point Anne plays a trick on Sally by swapping the contents of the boxes and then locks both boxes with a combination lock. Anne leaves, and Sally soon returns craving the chips she saw placed in one of the boxes. Sally remembers seeing the chips placed in the left box and attempts to open it by working the combination lock. The robot has matching chips and cookies that it can give out. What should the robot do to assist Sally?

Mindreading skills play an important role in this plan recognition scenario where the robot must observe Sally in real time to infer Sally's misconception of where the chips are (Anne switched the location when Sally was out of the room), to infer what her desire is based on her behavior (Sally never explicitly said she wants the chips), and to recognize that Sally's plan for how to get the chips is actually invalid (she is trying to open

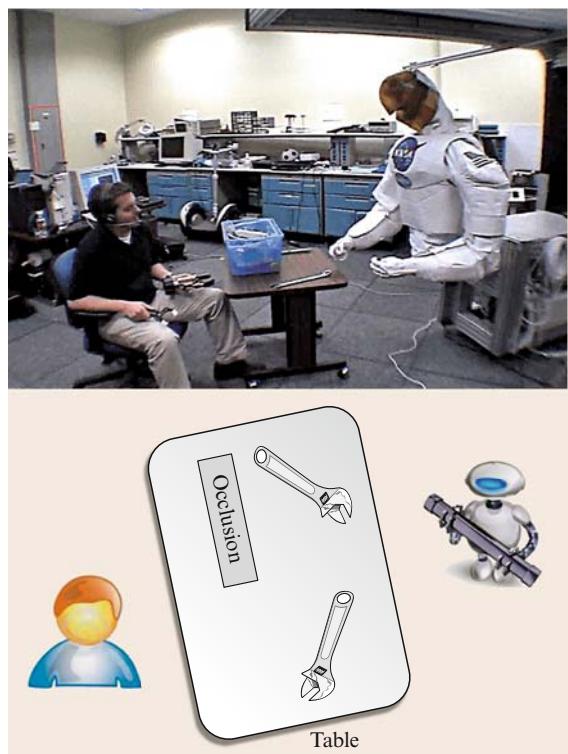

Fig. 58.13 Robonaut using visual perspective taking to disambiguate the intended referent when asked to *hand me the wrench*. The human can only see one wrench, but the robot can see both. The robot correctly hands the wrench that both can see

the wrong box). The robot has true knowledge of the situation, and must then reason about how best to help Sally get the object of her desire.

Gray et al. [58.93] combines these three kinds of mental inferences to demonstrate intention recognition with divergent beliefs for collaborative robots. Specifically, for the case of informational support, Leonardo relates its own beliefs about the state of the shared workspace to those of the human based on the visual

perspective of each. If a visual occlusion exists or an event occurs that prevents the human from knowing important information about the workspace, the robot knows to direct the human's attention to bring that information into common ground. For instance, Leonardo points to the box that actually holds the chips. For the case of instrumental support, Leonardo helps the person by directly giving the person a matching bag of chips.

58.5 Conclusion and Further Reading

In this chapter, we have presented some of the principal research trends in social robotics and human–robot interaction. We have relied heavily on examples from our own research to illustrate these trends, and have used excellent examples drawn from other research groups around the world.

From this overview, we have shown that one of the most important goals social robots as applied [HRI](#) is the creation of robots that are human-compatible and human-centered in their design. Their differences from human abilities should complement and enhance our strengths. Their similarities to human abilities, such as computationally implementing human cognitive or affective models, may help us to understand ourselves better. We expect that in the coming decades many other researchers, especially young researchers, will actively contribute to the transition from today's robots into capable robot partners of tomorrow.

For further reading, we recommend the following conference proceedings, books, articles, and journal special issues on [HRI](#).

59. Robot Programming by Demonstration

Robot Programming by Demonstration

Aude Billard, Sylvain Calinon, Rüdiger Dillmann, Stefan Schaal

Robot programming by demonstration (**PbD**) has become a central topic of robotics that spans across general research areas such as human-robot interaction, machine learning, machine vision and motor control.

Robot **PbD** started about 30 years ago, and has grown importantly during the past decade. The rationale for moving from purely preprogrammed robots to very flexible user-based interfaces for training robots to perform a task is three-fold.

First and foremost, **PbD**, also referred to as *imitation learning*, is a powerful mechanism for reducing the complexity of search spaces for learning. When observing either good or bad examples, one can reduce the search for a possible solution, by either starting the search from the observed good solution (local optima), or conversely, by eliminating from the search space what is known as a bad solution. Imitation learning is, thus, a powerful tool for enhancing and accelerating learning in both animals and artifacts.

Second, imitation learning offers an implicit means of training a machine, such that explicit and tedious programming of a task by a human user can be minimized or eliminated (Fig. 59.1). Imitation learning is thus a *natural* means of interacting with a machine that would be accessible to lay people.

Third, studying and modeling the coupling of perception and action, which is at the core of imitation learning, helps us to understand the mechanisms by which the self-organization of perception and action could arise during development. The reciprocal interaction of perception and action could explain how competence in motor control can be grounded in rich structure of perceptual variables, and vice versa, how the processes of perception can develop as means to create successful actions.

PbD promises were thus multiple. On the one hand, one hoped that it would make learning faster, in contrast to tedious reinforcement learning methods or trials-and-error learning. On the other hand, one expected that the methods, being user-friendly, would enhance the application of robots in human daily environments. Recent progresses in the field, which we review in this chapter, show that the field has made a leap forward during the past decade toward these goals. In addition, we anticipate that these promises may be fulfilled very soon.

Section 59.1 presents a brief historical overview of robot Programming by Demonstration (**PbD**), introducing several issues that will be discussed later in this chapter. Section 59.2 reviews engineering approaches to robot **PbD** with an emphasis on machine learning approaches that provide the robot with the ability to *adapt* the learned skill to different situations (Sect. 59.2.1). This section discusses also the different types of representation that one may use to encode a skill and presents incremental learning techniques to refine the skill progressively (Sect. 59.2.4). Section 59.2.3 emphasizes the importance to give the teacher an active role during learning and presents different ways in which the user can convey cues to the robot to help it to improve its learning. Section 59.2.4 discusses how **PbD** can be jointly used with other learning strategies to overcome some limitations of **PbD**. Section 59.3 reviews works that take a more biological approach to robot **PbD** and develops models of either the cognitive or neural processes of imitation learning in primates. Finally, Sect. 59.4 lists various open issues in robot **PbD** that have yet been little explored by the field.

59.1 History

At the beginning of the 1980s, **PbD** started attracting attention in the field of manufacturing robotics. **PbD** appeared as a promising route to automate the tedious manual programming of robots and as way to reduce the costs involved in the development and maintenance of robots in a factory.

As a first approach to **PbD**, symbolic reasoning was commonly adopted in robotics [59.2–6], with processes referred to as *teach-in*, *guiding* or *play-back* methods. In these works, **PbD** was performed through manual (teleoperated) control. The position of the end-effector and the forces applied on the object manipulated were stored throughout the demonstrations together with the

positions and orientations of the obstacles and of the target. This sensorimotor information was then segmented into discrete subgoals (keypoints along the trajectory) and into appropriate primitive actions to attain these subgoals (Fig. 59.2). Primitive actions were commonly chosen to be simple point-to-point movements that industrial robots employed at this time. Examples of subgoals would be, e.g., the robot's gripper orientation and position in relation to the goal [59.4]. Consequently, the demonstrated task was segmented into a sequence of state-action-state transitions.

To take into account the variability of human motion and the noise inherent to the sensors capturing the movements, it appeared necessary to develop a method that would consolidate all demonstrated movements. For this purpose, the state-action-state sequence was converted into symbolic *if-then* rules, describing the states and the actions according to symbolic relationships, such as *in contact*, *close-to*, *move-to*, *grasp-object*, *move-above*, etc. Appropriate numerical definitions of these symbols (i. e., when would an object be considered as *close-to* or *far-from*) were given as prior knowledge to the system. A complete demonstration was thus encoded in a graph-based representation, where each state constituted a graph node and each action a directed link between two nodes. Symbolic reasoning could then unify different graphical representations for the same task by merging and deleting nodes [59.3].

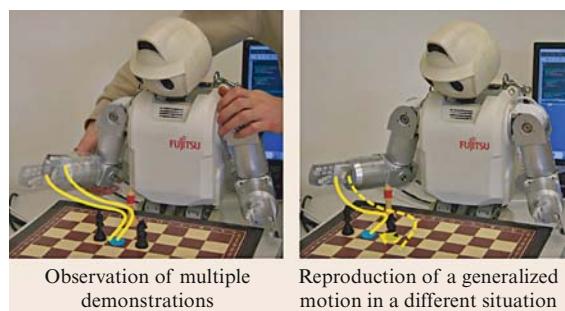

Fig. 59.1 *Left:* A robot learns how to make a chess move (namely moving the queen forward) by generalizing across different demonstrations of the task performed in slightly different situations (different starting positions of the hand). The robot records its joints' trajectories and learns to extract *what-to-imitate*, i. e. that the task constraints are reduced to a subpart of the motion located in a plane defined by the three chess pieces. *Right:* The robot reproduces the skill in a new context (for different initial position of the chess piece) by finding an appropriate controller that satisfies both the task constraints and constraints relative to its body limitation (*how-to-imitate* problem), adapted from [59.1]

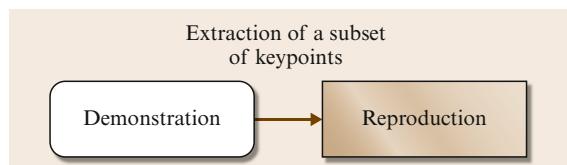

Fig. 59.2 Exact copy of a skill by interpolating between a set of pre-defined keypoints, [59.2]

Muench et al. [59.7] then suggested the use of *machine learning* (**ML**) techniques to recognize *elementary operators* (**EOs**), thus defining a discrete set of basic motor skills, with industrial robotics applications in mind. In this early work, the authors already established several key-issues of **PbD** in robotics. These include questions such as how to generalize a task, how to reproduce a skill in a completely novel situation, how to evaluate a reproduction attempt, and how to better define the role of the user during learning. Muench et al. [59.7] admitted that generalizing over a sequence of discrete actions was only one part of the problem since the controller of the robot also required the learning of continuous trajectories to control the actuators. They proposed that the missing parts of the learning process could be overcome by adapting them to the user who had taken an active role in the teaching process.

These early works highlighted the importance of providing a set of examples that the robot can use:

1. by constraining the demonstrations to modalities that the robot can understand; and
2. by providing a sufficient number of examples to achieve a desired generality.

They noted the importance of providing an adaptive controller to reproduce the task in new situations, that is, how to adjust an already acquired program. The evaluation of a reproduction attempt was also leveraged to the user by letting him/her provide additional examples of the skill in the regions of the learning space that had not been covered yet. Thus, the teacher/expert could control the generalization capabilities of the robot.

In essence, much current work in **PbD** follows a conceptual approach very similar to older work. Recent progresses affected mostly the interfaces at the basis of teaching. Traditional ways of guiding/teleoperating the robot were progressively replaced by more user-friendly interfaces, such as vision [59.9–11], data gloves [59.12], laser range finder [59.13] or kinesthetic teaching (i.e., by manually guiding the robot's arms through the motion) [59.1, 14, 15].

The field progressively moved from simply copying the demonstrated movements to generalizing across sets of demonstrations. Early work adopted a user-guided generalization strategy, in which the robot may ask the user for additional sources of information, when needed. As Machine Learning progressed, **PbD** started incorporating more of those tools to tackle both the perception issue, i.e., how to generalize across demonstrations, and the production issue, i.e., how to generalize the move-

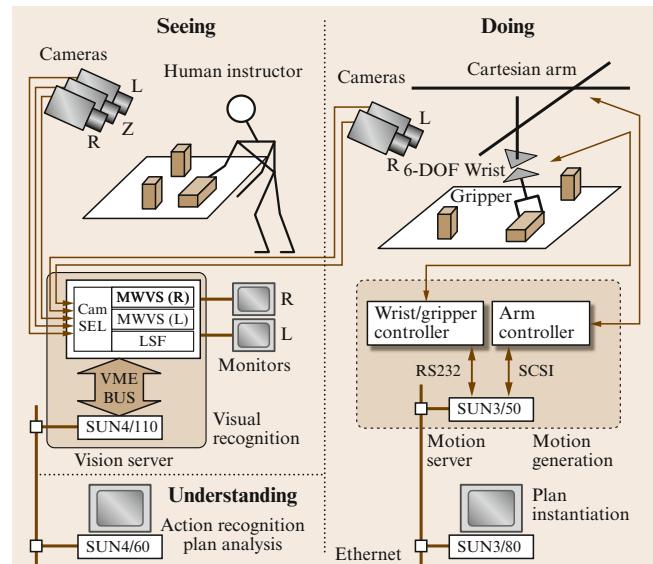

Fig. 59.3 Early approaches to robot programming by demonstration decomposed a task into functional and symbolic units. Temporal dependencies across these units were used to build a hierarchical task plan that drove the robot's reproduction of the task. (After [59.8])

ment to new situations. These tools include *artificial neural networks* (**ANNs**) [59.16, 17], *radial-basis function networks* (**RBFs**) [59.18], *fuzzy logic* [59.19], or *hidden markov models* (**HMMs**) [59.20–24].

As the development of mobile and humanoid robots more animal-like in their behaviors increased, the field went towards adopting an interdisciplinary approach. It took into account evidence of specific neural mechanisms for visuo-motor imitation in primates [59.25, 26] as well as evidence of developmental stages of imitation capacities in children [59.27, 28]. Eventually, the notion of *robot programming by demonstration* was replaced by the more biological labelling of *imitation learning*.

New learning challenges were, thus, set forth. Robots were expected to show a high degree of flexibility and versatility both in their learning system and in their control system in order to be able to interact naturally with human users and demonstrate similar skills (e.g., by moving in the same rooms and manipulating the same tools as humans). Robots were expected more and more to act *human-like* so that their behavior would be more predictable and acceptable.

Thanks to this swift bioinspiration, Robot **PbD** became once again a core topic of research in robotics [59.29–32]. This after the original wave of robotic imitation based on symbolic artificial intelli-

gence methods lost its thrust in the late 1980s. Robot PbD is now a regular topic at the two major conferences on robotics (IROS and ICRA), as well as at

conferences on related fields, such as human-robot interaction (HRI, AISB) and biomimetic robotics (BIOROB, HUMANOIDS).

59.2 Engineering-Oriented Approaches

Engineering-oriented and Machine Learning approaches to robot PbD focus on developing algorithms that are generic in their representation of the skills and in the way they are generated.

Current approaches to represent a skill can be broadly divided between two trends: a low-level representation of the skill, taking the form of a non-linear mapping between sensory and motor information, which we will later refer to as *trajectories encoding*, and, a high-level representation of the skill that decomposes the skill in a sequence of action-perception units, which we will refer to as *symbolic encoding*.

The field has identified a number of key problems that need to be solved to ensure such a generic approach for transferring skills across various agents and situations [59.33, 34]. These have been formulated as a set of generic questions, namely *what to imitate*, *how to*

imitate, *when to imitate* and *who to imitate*. These questions were formulated in response to the large body of diverse work in Robot PbD that could not easily be unified under a small number of coherent operating principles [59.18, 35–39]. The above four questions and their solutions aim at being generic in the sense of making no assumptions on the type of skills that may be transmitted. Who and When to imitate have been largely unexplored so far. Here we essentially review approaches to tackling What and How to imitate, which we refer to as *learning a skill* (what to imitate) and *encoding a skill* (how to imitate). See Fig. 59.4 for an illustration.

59.2.1 Learning a Skill

As mentioned in Sect. 59.1, early approaches to solving the problem of how to generalize a given skill to a new/unseen context consisted in explicitly asking the teacher for further information (Fig. 59.5).

Another way of providing further information to the robot without relying on symbolic/verbal cues consists in doing part of the training in *virtual reality* (VR) or *augmented reality* (AR) and providing the robot with *virtual fixtures*, see Fig. 59.6 and [59.40–43].

Additionally, one sees further methods of learning a skill by allowing a robot to automatically extract the important features characterizing the skill and to look for a controller that optimizes the reproduction of these characteristic features. Determining a *metric of imitation performance* is a key concept at the bottom of these approaches. One must first determine the metric, i. e. de-

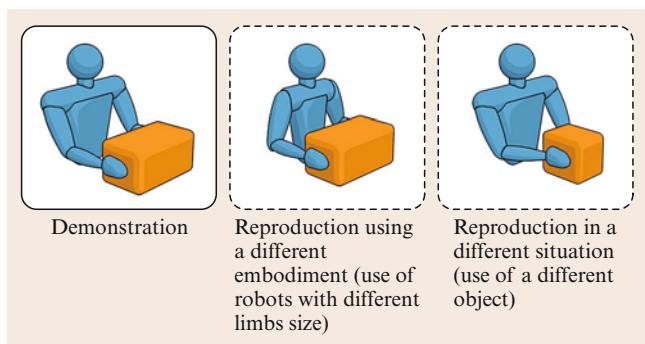

Fig. 59.4 Illustration of the correspondence problems

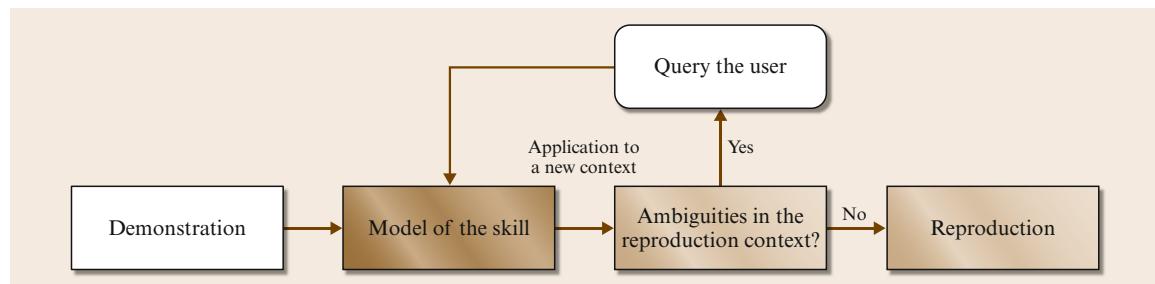

Fig. 59.5 Learning of a skill through a query-based approach, [59.7]

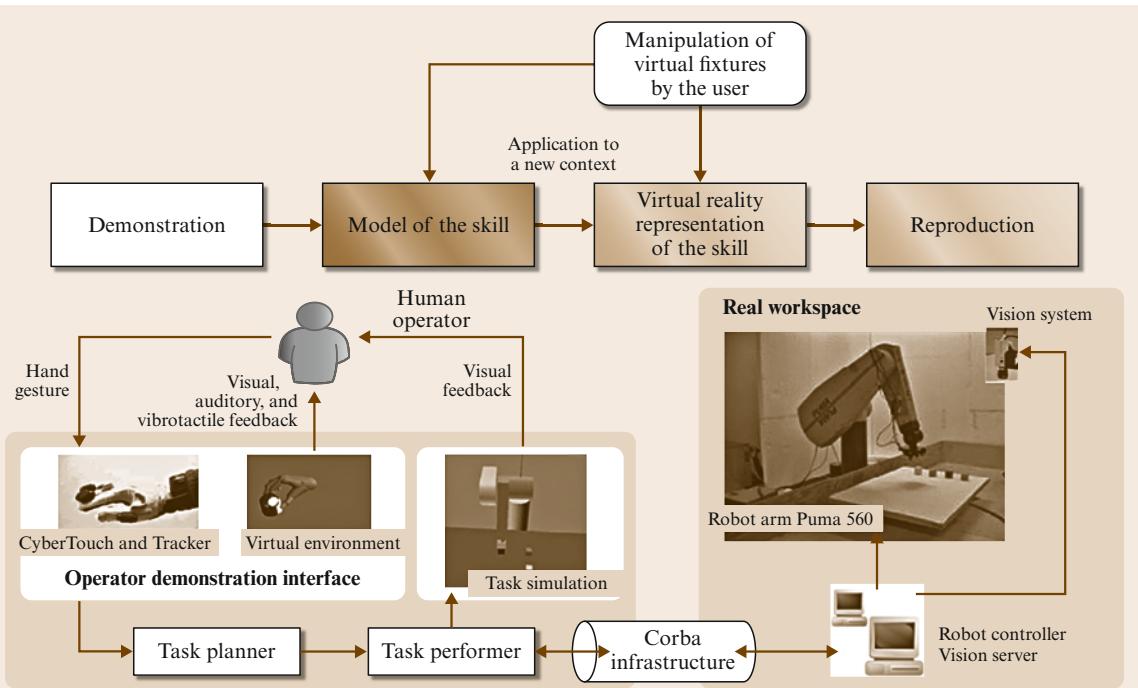

Fig. 59.6 PbD in a virtual reality (VR) setup, providing the robot with virtual fixtures. VR acts as an intermediate layer of interaction to complement real-world demonstration and reproduction. (After [59.44])

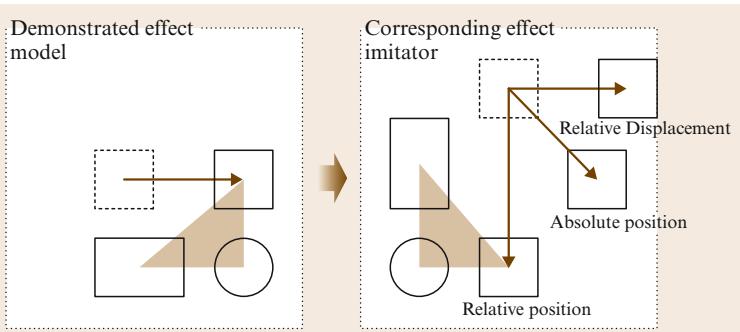

Fig. 59.7 Use of a metric of imitation performance to evaluate a reproduction attempt and find an optimal controller for the reproduction of a task (here, to displace the square in a 2D world). (After [59.45])

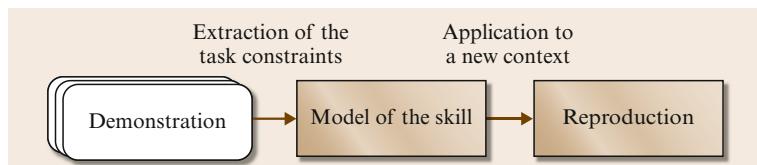

Fig. 59.8 Generalization of a skill by extracting the statistical regularities across multiple observations, [59.46]

termine the weights one must attach to reproducing each of the components of the skill. Once the metric is determined, one can find an optimal controller to imitate by trying to minimize this metric (e.g., by evaluating several reproduction attempts or by deriving the metric

to find an optimum). The metric acts as a cost function for the reproduction of the skill [59.33]. In other terms, a metric of imitation provides a way of expressing quantitatively the user's intentions during the demonstrations and to evaluate the robot's faithfulness at reproducing

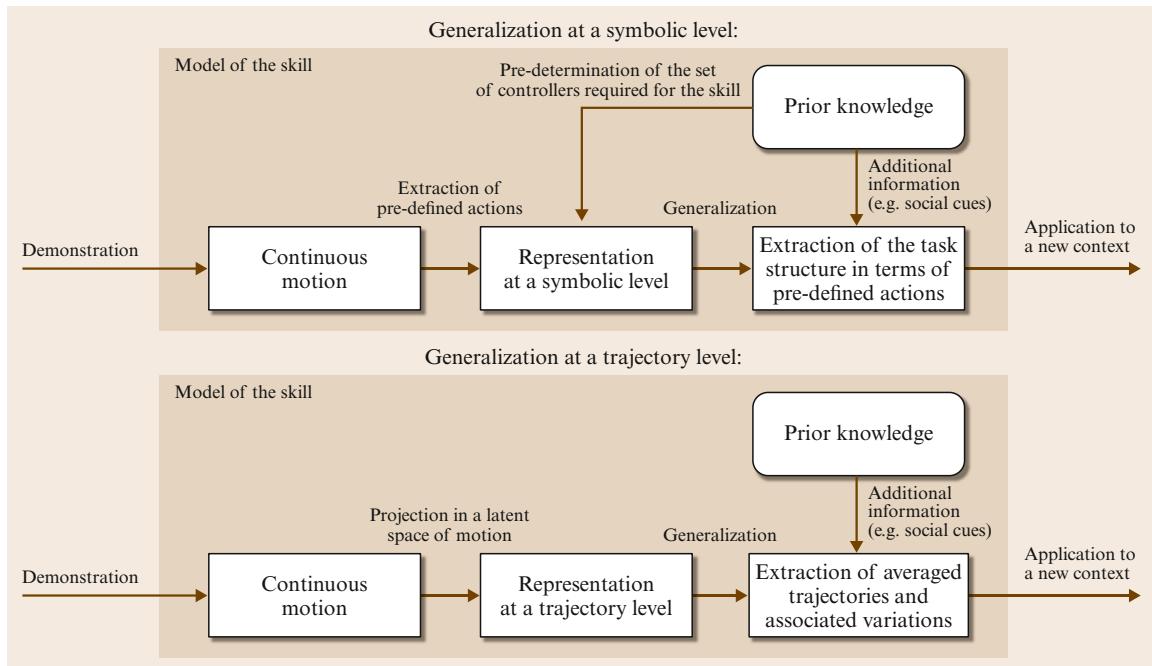

Fig. 59.9 Illustration of the different levels of representation for describing the skill

those. Figure 59.7 shows an illustration of the concept of a metric of imitation performance and its use to drive the robot's reproduction.

To learn the metric (i.e., to infer the task constraints), one common approach consists in creating a model of the skill based on several demonstrations of the same skill performed in slightly different conditions (Fig. 59.8). This generalization process consists of exploiting the variability inherent to the various demonstrations and to extract the essential components of the task. These essential components should be those that remain unchanged across the various demonstrations [59.1, 46–52].

Figure 59.9 presents a schematic of the learning process by considering either a representation of the skill at a symbolic level or at a trajectory level (these two schemas are detailed versions of the tinted boxes depicted in Fig. 59.8). Table 59.1 summarizes the advantages and drawbacks of the different approaches.

Next, we review a number of specific approaches to learning a skill at the symbolic and trajectory levels.

Symbolic Learning and Encoding of Skills

A large body of work uses a symbolic representation of both the learning and the encoding of skills and tasks [59.7, 22, 49, 50, 52–55]. This symbolic way of

Table 59.1 Advantages and drawbacks of representing a skill at a symbolic/trajectory level

| | Span of the generalization process | Advantages | Drawbacks |
|------------------|--------------------------------------------------------|----------------------------------------------------------------------------------------------------|--------------------------------------------------------------------|
| Symbolic level | Sequential organization of pre-defined motion elements | Allows to learn hierarchy, rules and loops | Requires to pre-define a set of basic controllers for reproduction |
| Trajectory level | Generalization of movements | Generic representation of motion which allows encoding of very different types of signals/gestures | Does not allow to reproduce complicated high-level skills |

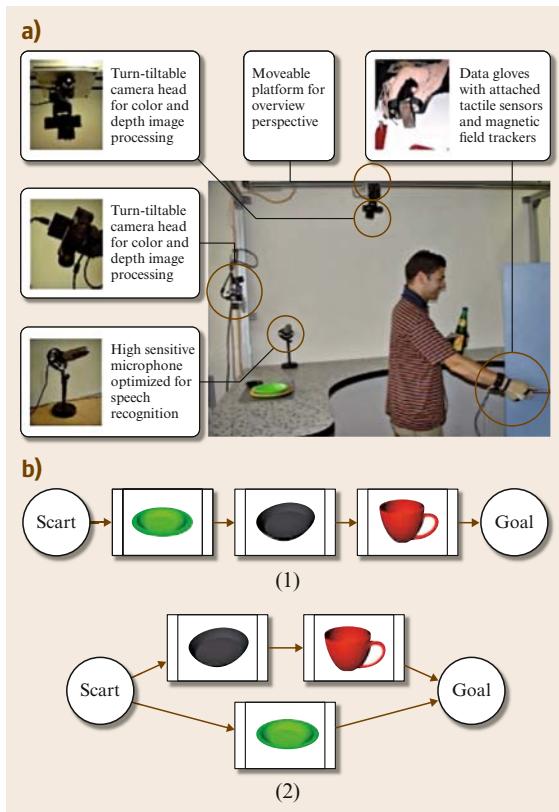

Fig. 59.10 (a) Training center with dedicated sensors. (b) Precedence graphs learned by the system for the ‘setting the table’ task. (a) Initial task precedence graph for the first three demonstrations. (b) Final task precedence graph after observing additional examples. (After [59.50])

encoding skills may take several forms. One common way is to segment and encode the task according to sequences of *predefined* actions, described symbolically. Encoding and regenerating the sequences of these actions can, however, be done using classical machine learning techniques, such as HMM [59.22].

Often, these actions are encoded in a hierarchical manner. In [59.49], a graph-based approach is used to generalize an object’s transporting skill by using a wheeled mobile robot. In the model, each node in the graph represents a complete behaviour and generalization takes place at the level of the topological representation of the graph. The latter is updated incrementally.

References [59.50] and [59.52] follow a similar hierarchical and incremental approach to encode various household tasks (such as setting the table and putting

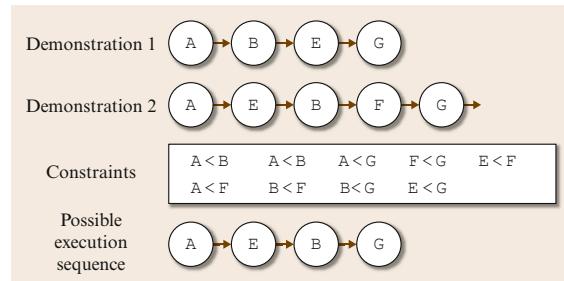

Fig. 59.11 Extraction of the task constraints by considering a symbolic representation of the skill. (After [59.52])

dishes in a dishwasher), Fig. 59.10. There, learning consists in extracting symbolic rules that manages the way each object must be handled (Fig. 59.11).

Reference [59.54] also exploits a hierarchical approach to encoding a skill in terms of pre-defined behaviours. The skill consists in moving through a maze where a wheeled robot must avoid several kinds of obstacles and reach a set of specific subgoals. The novelty of the approach is that it uses a symbolic representation of the skill to explore the teacher’s role in guiding the incremental learning of the robot.

Finally, [59.55] takes a symbolic approach to encoding human motions as sets of pre-defined postures, positions or configuration and considers different levels of granularity for the symbolic representation of the motion. This a priori knowledge is then used to explore the correspondence problem through several simulated setups including motion in joint space of arm links and displacements of objects on a 2D plane (Fig. 59.7).

The main advantage of these symbolic approaches is that high-level skills (consisting of sequences of symbolic cues) can be learned efficiently through an interactive process. However, because of the symbolic nature of their encoding, the methods rely on a large amount of prior knowledge to predefine the important cues and to segment those efficiently (Table 59.1).

Learning and Encoding a Skill at Trajectory-Level

Choosing the variables well to encode a particular movement is crucial, as it already gives part of the solution to the problem of defining what is important to imitate. Work in PbD encodes human movements in either joint space, task space or torque space [59.56–58]. The encoding may be specific to a cyclic motion [59.14], a discrete motion [59.1], or to a combination of both [59.59].

Encoding often encompasses the use of dimensionality reduction techniques that project the recorded signals

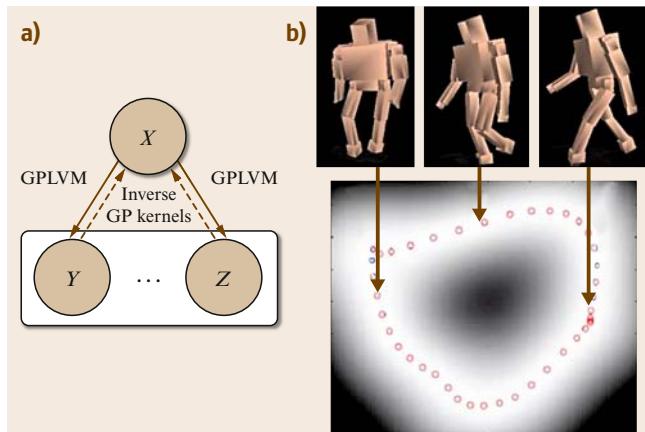

Fig. 59.12a,b Motion learning in a subspace of lower dimensionalality by using a non-linear process based on *gaussian processes* (GP) [59.63]. (a) Graphical model of imitation consisting of two pairs of Gaussian Process regression models. In the forward direction, latent variable models map from a low-dimensional latent space X to the human joint space Y and robot joint space Z . In the inverse direction, a regression model maps human motion data to points in the latent space, where two similar human postures in the joint angle space produce two points in the latent space that are close one to the other. Thus, the use of generative regression models allows one to interpolate between known postures in the latent space to create reasonable postures during the reproduction. (b) The model provides a smooth certainty estimate in the posture's latent space it infers (*shaded map* from black to white), where training data are represented with circles (here, a walking motion is depicted). Once a latent variable model has been learned, a new motion can be quickly generated from the learned kernels

into a latent space of motion of reduced dimensionality. These techniques may either perform locally linear transformations [59.60–62] or exploit global non-linear methods [59.63–65] (Fig. 59.12).

The most promising approaches to encoding human movements are those that encapsulate the dynamics of the movement into the encoding itself [59.59, 67–70]. Several of these methods are highlighted below.

Skill Encoding Based on Statistical Modeling. One trend of work investigates how statistical learning techniques deal with the high variability inherent to the demonstrations.

For instance, Ude et al. [59.56] use spline smoothing techniques to deal with the uncertainty contained in several motion demonstrations performed in a *joint space* or in a *task space*.

Table 59.2 Probabilistic encoding and reproduction of a skill through *gaussian mixture regression* (GMR) [59.66]

A dataset $\xi = \{\xi_j\}_{j=1}^N$ is defined by N observations $\xi_j \in \mathbb{R}^D$ of sensory data changing through time (e.g., joint angle trajectories, hand paths), where each datapoint $\xi_j = \{\xi_t, \xi_s\}$ consists of a temporal value $\xi_t \in \mathbb{R}$ and a spatial vector $\xi_s \in \mathbb{R}^{(D-1)}$. The dataset ξ is modelled by a gaussian mixture model (GMM) of K components, defined by the probability density function

$$p(\xi_j) = \sum_{k=1}^K \pi_k \mathcal{N}(\xi_j; \mu_k, \Sigma_k),$$

where π_k are prior probabilities and $\mathcal{N}(\xi_j; \mu_k, \Sigma_k)$ are Gaussian distributions defined by *mean* vectors μ_k and *covariance* matrices Σ_k , whose temporal and spatial components can be represented separately as

$$\mu_k = \{\mu_{t,k}, \mu_{s,k}\}, \quad \Sigma_k = \begin{pmatrix} \Sigma_{tt,k} & \Sigma_{ts,k} \\ \Sigma_{st,k} & \Sigma_{ss,k} \end{pmatrix}.$$

For each component k , the expected distribution of ξ_s given the temporal value ξ_t is defined by

$$\begin{aligned} p(\xi_s|\xi_t, k) &= \mathcal{N}(\xi_s; \hat{\xi}_{s,k}, \hat{\Sigma}_{ss,k}), \\ \hat{\xi}_{s,k} &= \mu_{s,k} + \Sigma_{st,k} (\Sigma_{tt,k})^{-1} (\xi_t - \mu_{t,k}), \\ \hat{\Sigma}_{ss,k} &= \Sigma_{ss,k} - \Sigma_{st,k} (\Sigma_{tt,k})^{-1} \Sigma_{ts,k}. \end{aligned}$$

By considering the complete GMM, the expected distribution is defined by

$$p(\xi_s|\xi_t) = \sum_{k=1}^K \beta_k \mathcal{N}(\xi_s; \hat{\xi}_{s,k}, \hat{\Sigma}_{ss,k}),$$

where $\beta_k = p(k|\xi_t)$ is the probability of the component k to be responsible for ξ_t , i.e.,

$$\beta_k = \frac{p(k)p(\xi_t|k)}{\sum_{i=1}^K p(i)p(\xi_t|i)} = \frac{\pi_k \mathcal{N}(\xi_t; \mu_{t,k}, \Sigma_{tt,k})}{\sum_{i=1}^K \pi_i \mathcal{N}(\xi_t; \mu_{t,i}, \Sigma_{tt,i})}.$$

By using the linear transformation properties of Gaussian distributions, an estimation of the conditional expectation of ξ_s given ξ_t is thus defined by $p(\xi_s|\xi_t) \sim \mathcal{N}(\hat{\xi}_s, \hat{\Sigma}_{ss})$, where the parameters of the Gaussian distribution are defined by

$$\hat{\xi}_s = \sum_{k=1}^K \beta_k \hat{\xi}_{s,k}, \quad \hat{\Sigma}_{ss} = \sum_{k=1}^K \beta_k^2 \hat{\Sigma}_{ss,k}.$$

By evaluating $\{\hat{\xi}_s, \hat{\Sigma}_{ss}\}$ at different time steps ξ_t , a generalized form of the motions $\hat{\xi} = \{\xi_t, \hat{\xi}_s\}$ and associated covariance matrices $\hat{\Sigma}_{ss}$ describing the constraints are computed. If multiple constraints are considered (e.g., considering actions $\xi^{(1)}$ and $\xi^{(2)}$ on two different objects), the resulting constraints are computed by first estimating $p(\xi_s|\xi_t) = p(\xi_s^{(1)}|\xi_t) \cdot p(\xi_s^{(2)}|\xi_t)$ and then computing $\mathbb{E}[p(\xi_s|\xi_t)]$ to reproduce the skill. See Fig. 59.14 for an illustration of this method to learning continuous constraints in a set of trajectories. (After [59.66])

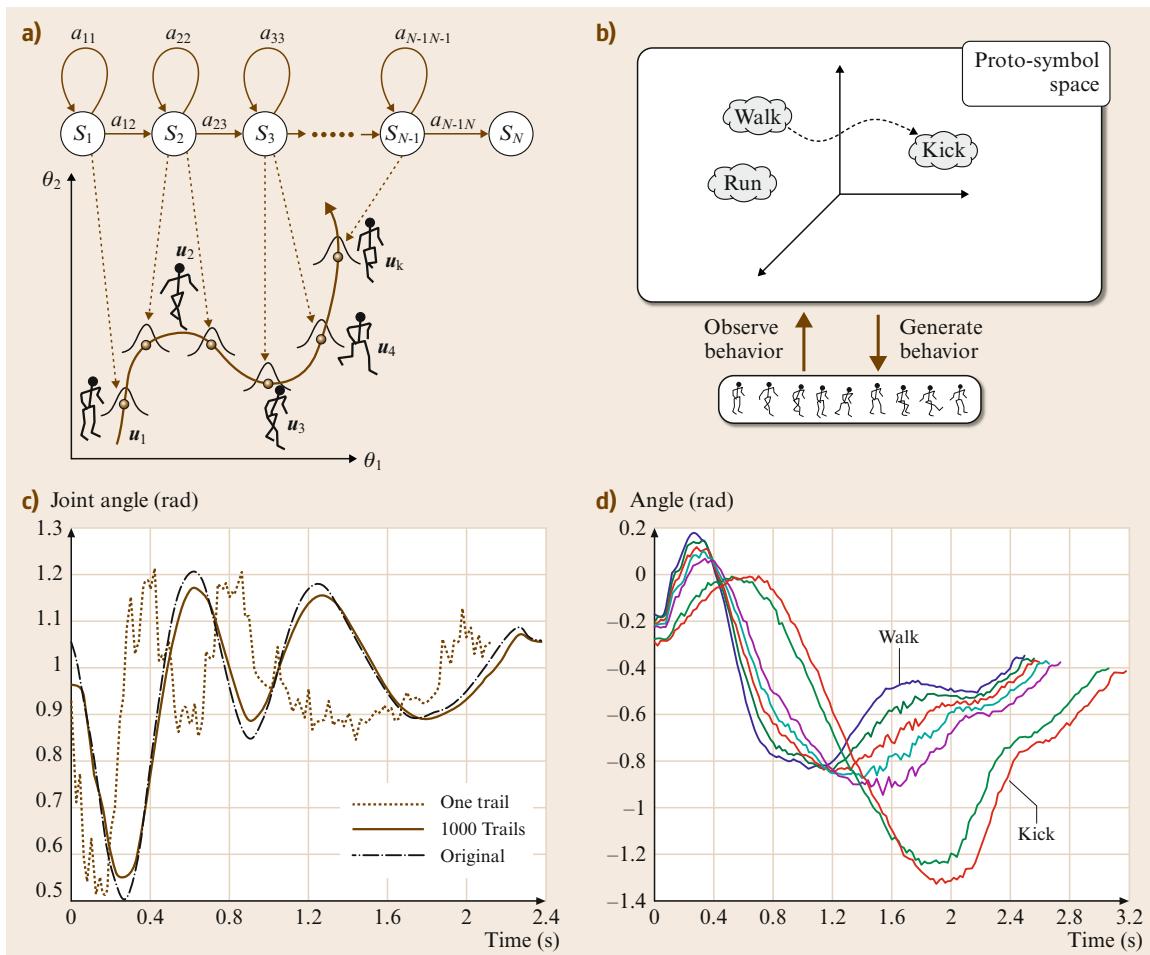

Fig. 59.13a–d Learning of a gesture through the *mimesis model* by using *hidden markov model* (*HMM*) to encode, recognize and retrieve a generalized version of the motion [59.71]. *Top-left*: Encoding of a full-body motion in a *HMM*. *Top-right*: Representation of different gestures in a proto-symbol space where the different models are positioned according to the distance between their associated *HMM* representations. *Bottom-left*: Retrieval of a gesture by using a stochastic generation process based on the *HMM* representation. *Bottom-right*: Combination of different *HMMs* to retrieve a gesture combining different motion models

In [59.46], using different demonstrators ensures variability across the demonstrations and quantifies the accuracy required to achieve a *pick and place* task. The different trajectories form a boundary region that is then used to define a range of acceptable trajectories.

In [59.48], the robot acquires a set of sensory variables while demonstrating a manipulation task consisting of arranging different objects. At each time step, the robot stores and computes the mean and variance of the collected variables. The sequence of means and associated variance is then used as a simple generalization

process, providing respectively a generalized trajectory and associated constraints.

A number of authors following such statistically-based learning methods exploited the robustness of *hidden markov models* (*HMMs*) in order to encode the temporal and spatial variations of complex signals, and to model, recognize and reproduce various types of motions. For instance, Tso et al. [59.23] use *HMM* to encode and retrieve Cartesian trajectories, where one of the trajectories contained in the training set is also used to reproduce the skill (by keeping the trajectory of the dataset

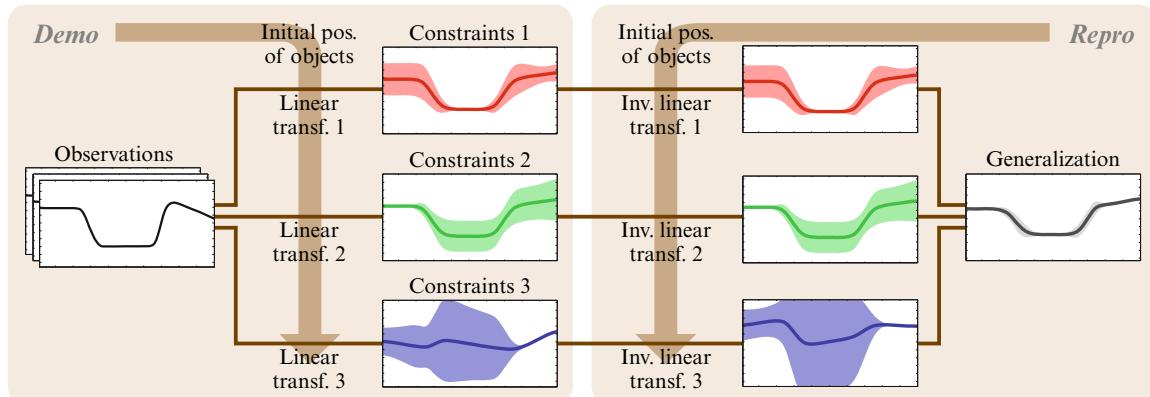

Fig. 59.14 Schematic illustration showing continuous constraints extracted from a set of demonstrations performed in different contexts (namely, different initial positions of objects). Each set of signals recorded during the demonstration is first projected into different latent spaces (through an automatic process of reduction of the dimensionality, such as *principal component analysis (PCA)* or *independent component analysis (ICA)*). Each constraint in this constricted space is then represented probabilistically through *gaussian mixture regression (GMR)* (see Table 59.2). In order to reproduce the task, each constraint is first re-projected in the original data space and a trajectory satisfying optimally all constraints is then computed, after [59.66]

with the highest likelihood, i. e., the one that generalizes the most compared to the others). Yang et al. [59.57] use **HMMs** to encode the motion of a robot's gripper either in the *joint space* or in the *task space* by considering either the positions or the velocities of the gripper.

The *mimesis model* [59.72–75] follows an approach in which the **HMM** encodes a set of trajectories, and where multiple **HMMs** can be used to retrieve new generalized motions through a stochastic process (Fig. 59.13). A drawback of such an approach is that it generates discontinuities in the trajectories regenerated by the system. Interpolation techniques have been proposed to deal with this issue [59.76–78]. Another approach consists of pre-decomposing the trajectories into a set of relevant keypoints and to retrieve a generalized version of the trajectories through spline fitting techniques [59.79–81].

As an alternative to **HMM** and interpolation techniques, Calinon et al. [59.1] used *gaussian mixture model (GMM)* to encode a set of trajectories, and *gaussian mixture regression (GMR)* to retrieve a smooth generalized version of these trajectories and associated variabilities (Fig. 59.14 and Table 59.2).

Skill Encoding Based on Dynamical Systems. Dynamical systems offer a particularly interesting solution to an imitation process aimed at being robust to perturbations which is robust to dynamical changes in the environment.

The first work to emphasize this approach was that of Ijspeert et al. [59.59], who designed a motor representation based on dynamical systems for encoding movements and for replaying them in various conditions (Fig. 59.15). The approach combines two ingredients: nonlinear dynamical systems for robustly encoding the trajectories, and techniques from non-parametric regression for shaping the attractor landscapes according to the demonstrated trajectories. The essence of the approach is to start with a simple dynamical system, e.g., a set of linear differential equations, and to transform it into a nonlinear system with prescribed attractor dynamics by means of a learnable autonomous forcing term. One can generate both point attractors and limit cycle attractors of almost arbitrary complexity. The point attractors and limit cycle attractors are used to respectively encode discrete (e.g. reaching) and rhythmic movements (e.g. drumming).

Locally weighted regression (LWR) was initially proposed to learn the above system's parameters [59.82–84]. It can be viewed as a memory-based method combining the simplicity of linear least squares regression and the flexibility of nonlinear regression. Further work mainly concentrated on moving on from a memory-based approach to a model-based approach, and moving on from a batch learning process to an incremental learning strategy [59.61, 85, 86]. Schaal et al. [59.86] used *receptive field weighted regression (RFWR)* as a non-parametric approach to incrementally

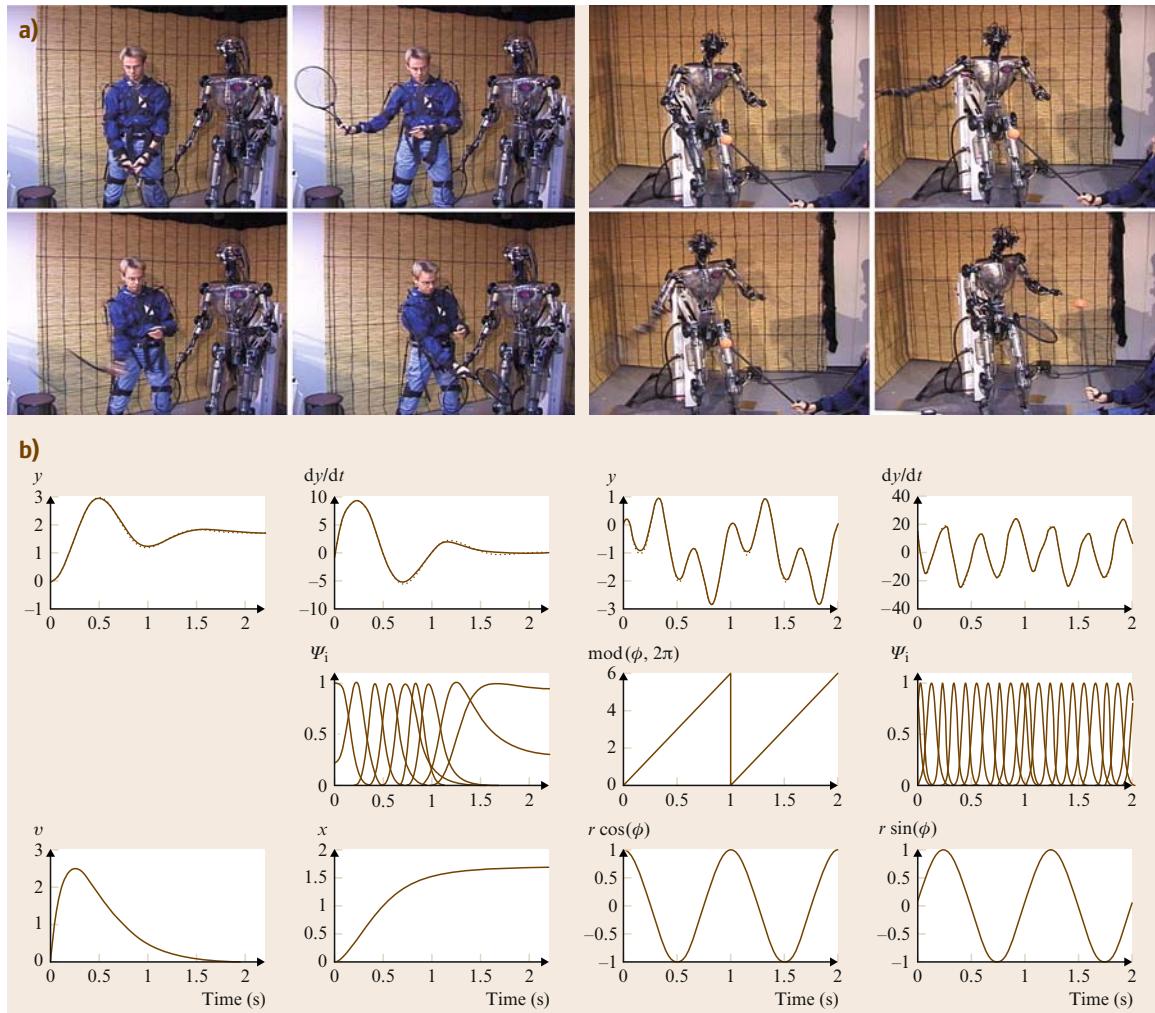

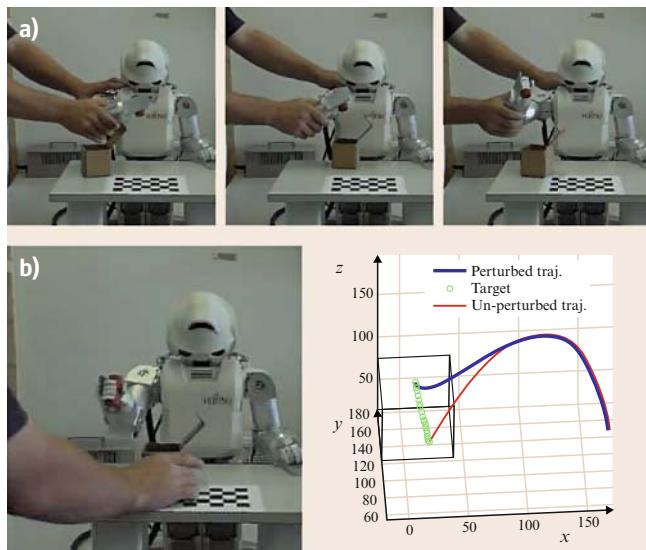

Fig. 59.15 (a) Humanoid robot learning a forehand swing from a human demonstration. (b) Examples of time evolution of the discrete (left) and rhythmic dynamical movement primitives (right). (After [59.59, 88])

learn the fitting function with no need to store the whole training data in memory. *Vijayakumar et al.* [59.61] then suggested that one uses locally weighted projection regression LWPR to improve the way one approaches operating efficiently in high dimensional space. *Hersch et al.* [59.87] extended the above dynamical approach to learning combinations of trajectories in a multidimensional space (Fig. 59.16). The dynamical system is modulated by a set of learned trajectories encoded in a gaussian mixture model (Sect. 59.2.1).

The approach offers four interesting properties. First, the learning algorithm, locally weighted regression, is very fast. It does one-shot learning and therefore avoids

the slow convergence exhibited by many neural network algorithms, for instance. Second, the dynamical systems are designed so that, from a single demonstration, they can replay similar trajectories (e.g. tennis swings) with the online modification of a few parameters (e.g. the attractor coordinates). This is of great importance for reusing the dynamical systems in new tasks, i.e. the notion of generalization. Third, dynamical systems are designed to be intrinsically robust in the face of perturbations. Small random noise will not affect the attractor dynamics. In the event of a large constraint (e.g. someone blocking the arm of the robot), feedback terms can be added to the dynamical systems and accordingly mod-

ify the trajectories online. Finally, the approach can also be used for movement classification. Given the temporal and spatial invariance of the representation, similar parameters tend to adjust to trajectories that are topologically similar. This means that the same representation used for encoding trajectories can also help classifying them, e.g. it provides a tool for measuring the similarities and dissimilarities of trajectories.

Fig. 59.16a,b Dynamical systems provide a robust robot controller in the face of perturbations during the reproduction of a learned skill. (a) The robot is trained through kinesthetic demonstrations by a human trainer (here, the skill consists of putting an object into a box). During these different demonstrations (starting from different positions for both hand and target), the robot records the various velocity profiles its right arm follows. (b) Handling of dynamic perturbations during the reproduction. Here, the perturbations are produced by the user who displaces the box during the reproduction attempts. We see that the robot smoothly adapts its original generalized trajectory (thin line) to this perturbation (thick line). (After [59.87]) ◀

Ito et al. [59.14] proposed another way to encode implicitly the dynamics of bimanual and unimanual tasks, using a recurrent neural networks. The model allows online imitation. Of interest is that fact that the network can switch across those motions in a smooth manner when trained separately to encode two different sensorimotor loops (Fig. 59.17). The approach was validated for modelling dancing motions during which the user first initiated imitation and where the roles of the imitator and demonstrator could then be dynamically interchanged. They also considered cyclic manipulation tasks during which the robot continuously moved a ball from one hand to the other and was able to switch dynamically to another cyclic motion that consisted of lifting and releasing the ball.

59.2.2 Incremental Teaching Methods

The statistical approach described previously (Sect. 59.2.1), has its limitations though it is an interesting way to autonomously extract the important features of the task. In addition, it avoids putting too much prior knowledge in the system. For instance, one can expect that requesting multiple demonstrations of a single task would annoy the user. Therefore, PBD systems should be capable of learning a task from as few demonstrations as possible. Thus, the robot could start performing its tasks right away and gradually improve its performance

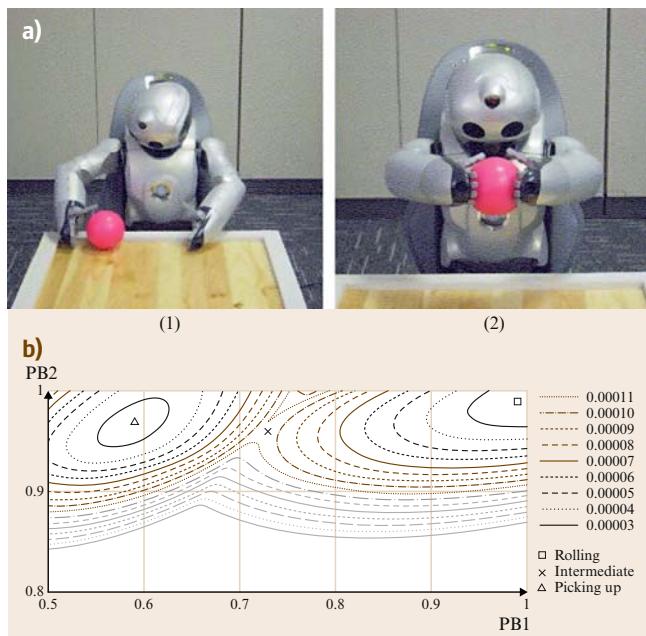

Fig. 59.17a,b Dynamical encoding of the imitation process by using recurrent neural networks. (a) Online switching between two interactive behaviours, namely rolling a ball from one hand to the other and lifting the ball. (b) Prediction error distribution in the parameters space representing the two behaviours. One can see how the robot can switch smoothly across the behaviors by moving continuously in the parameter space. (After [59.14]) ◀

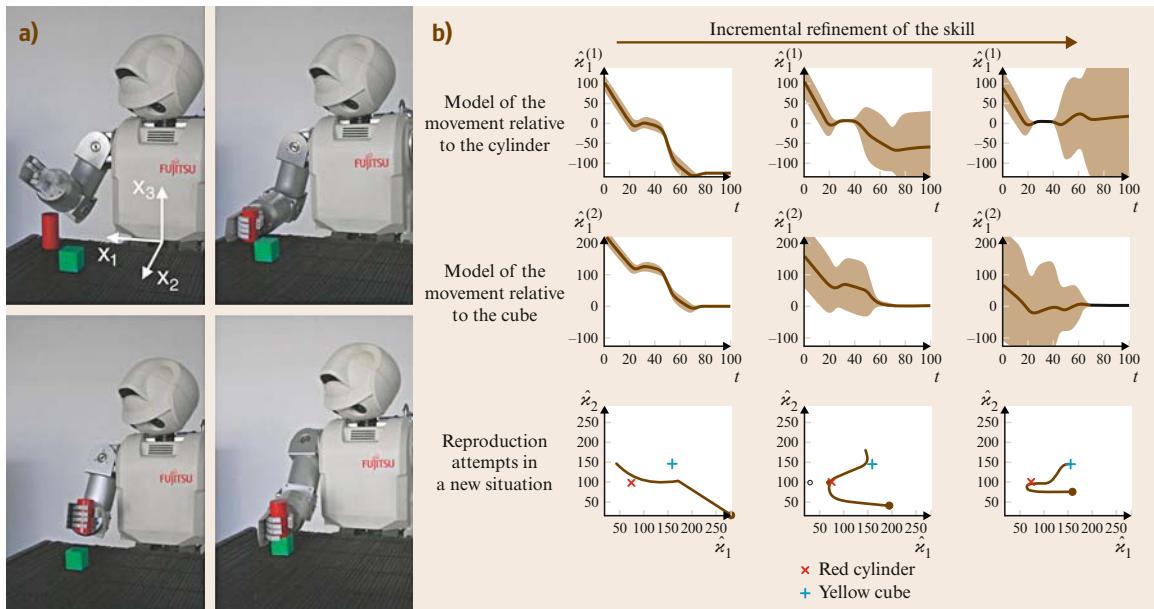

Fig. 59.18a,b Incremental refinement of movements coded in a frame of reference located on the objects that are manipulated. The task constraints are encoded at the trajectory-level. (a) Example of a task consisting of grasping a cylinder and placing it on top of a cube. (b) Refinement of the *Gaussian mixture regression* (GMR) models representing the constraints all along the movement (see Table 59.2). After a few demonstrations, we see that the trajectories relative to the two objects are highly constrained for particular subparts of the task, namely when reaching for the cylinder (thin envelope around time step 30) and when placing it on top of the cube (thin envelope around time step 100). (After [59.66])

while, at the same time, being monitored by the user. Incremental learning approaches that gradually refine the task knowledge as more examples become available pave the way towards PbD systems suitable for real-time human-robot interactions.

Figure 59.18 shows an example of such incremental teaching of a simple skill, namely grasping and placing an object on top of another object, see [59.66] for details.

These incremental learning methods use various forms of deixis, verbal and non-verbal, to guide the robot's attention to the important parts of the demonstration or to particular mistakes it produces during the reproduction of the task. Such incremental and guided learning is often referred to as *scaffolding* or *moulding* of the robot's knowledge. It was deemed most important to allow the robot to learn tasks of increasing complexity [59.54, 89].

Research on the use of incremental learning techniques for robot PbD has contributed to the development of methods for learning complex tasks within the household domain from as few demonstrations as possible. Moreover, it contributed to the development and application of machine learning that allow continuous and

incremental refinement of the task model. Such systems have sometimes been referred to as *background knowledge based* or *EM deductive PbD-systems*, as presented in [59.90, 91]. They usually require very few or even only a single user demonstration to generate executable task descriptions.

The main objective of this type of work is to build a meta-representation of the knowledge the robot has acquired on the task and to apply reasoning methods to this knowledge database (Fig. 59.10). This reasoning involves recognizing, learning and representing repetitive tasks.

Pardowitz et al. [59.92] discuss how different forms of knowledge can be balanced in an incrementally learning system. The system relies on building *task precedence graphs*. Task precedence graphs encode hypotheses that the system makes on the sequential structure of a task. Learning the task precedence graphs allows the system to schedule its operations most flexibly while still meeting the goals of the task (see [59.93] for details). Task precedence graphs are directed acyclic graphs that contain a temporal precedence relation that can be learned incrementally. Incremental learning of

task precedence graphs leads to a more general and flexible representation of the task knowledge (Fig. 59.10).

59.2.3 Human-Robot Interaction in PbD

Another perspective adopted by PbD to make the transfer of skill more efficient is to focus on the interaction aspect of the transfer process. As this transfer problem is complex and involves a combination of social mechanisms, several insights from human-robot interaction (HRI) were explored to make efficient use of the teaching capabilities of the human user.

The development of algorithms for detecting *social cues* (given implicitly or explicitly by the teacher during training) and their integration as part of other generic mechanisms for PbD has become the focus of a large body of work in PbD. Such social cues can be viewed as a way to introduce priors in a statistical learning system, and, by so doing, speed up learning. Indeed, several hints can be used to transfer a skill not only by demonstrating the task multiple times but also by highlighting the important components of the skill. This can be achieved by various means and by using different modalities.

A large body of work explored the use of pointing and gazing (Fig. 59.19) as a way to convey the intention of the user [59.41, 95–101]. Vocal deixis, using a standard speech recognition engine, has also been explored widely [59.41, 102]. In [59.50], the user makes vocal comments to highlight the steps of the teaching that are deemed most important. In [59.103, 104], sole the prosody of the speech pattern is looked at, rather than the exact content of the speech, as a way to infer some information on the user's communicative intent.

In [59.94], these social cues are learned through an imitative game, whereby the user imitates the robot. This allows the robot to build a user-specific model of these social pointers, and to become more robust at detecting them.

Finally, a core idea of HRI approach to PbD is that imitation is goal-directed, that is, actions are meant to fulfill a specific purpose and convey the intention of the actor [59.105]. While a longstanding trend in PbD approached the problem from the standpoint of trajectory following [59.106–108] and joint motion replication, see [59.81, 88, 109, 110] and Sect. 59.2.1, recent works, inspired by the above rationale, start from the assump-

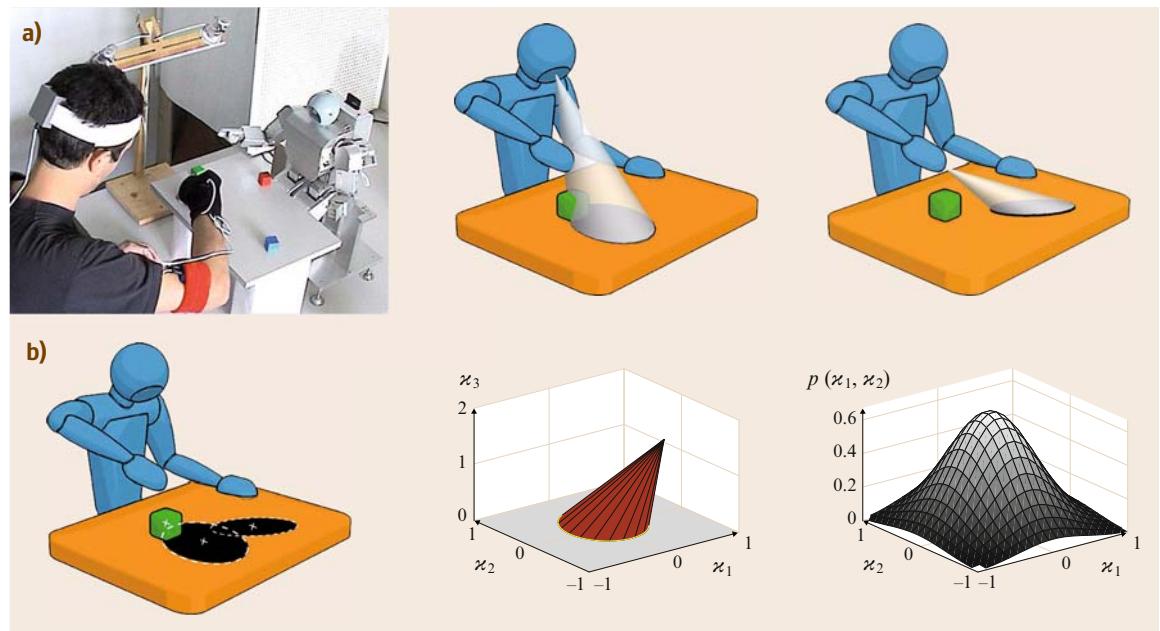

Fig. 59.19a,b Illustration of the use of social cues to speed up the imitation learning process. Here, gazing and pointing towards information are used to select probabilistically the objects relevant for different subparts of a manipulation skill. (a) Illustration of the setup proposed in [59.94] to probabilistically highlight the importance of a set of objects through the use of motion sensors recording gazing and pointing directions. (b) Probabilistic representation of the intersection between the gazing/pointing cone and the table to estimate where the attention of the user is focused on

tion that imitation is not just about observing and replicating the motion, but rather about *understanding* the goals of a given action. Learning to imitate relies importantly on the imitator's capacity to infer the demonstrator's intentions [59.89, 111]. However, demonstrations may be ambiguous and extracting the intention of the demonstrator requires building a cognitive model of the demonstrator [59.51, 112], as well as exploiting other social cues to provide complementary knowledge [59.54, 89, 113].

Understanding the way humans learn to both extract the goals of a set of observed actions and to give these goals a hierarchy of preference is fundamental to our understanding of the underlying decisional process of imitation. Recent work tackling these issues has followed a probabilistic approach to explain both a goal's derivation and sequential application. The explanation in turn makes it possible to learn manipulatory tasks that require the sequencing of a goal's subsets [59.92, 106, 115, 116].

Understanding the goal of the task is still only half of the picture, as there may be several ways of achieving the goal. Moreover, what is good for the demonstrator may not necessarily be good for the imitator [59.33]. Thus, different models may be allowed to compete to find a solution that is optimal both from the point of view of the imitator and that of the demonstrator [59.77, 117].

59.2.4 Joint Use of Robot PbD with Other Learning Techniques

To recall, a main argument for the development of PbD methods was that it would speed up learning by providing an example of *good solution*. This, however, is

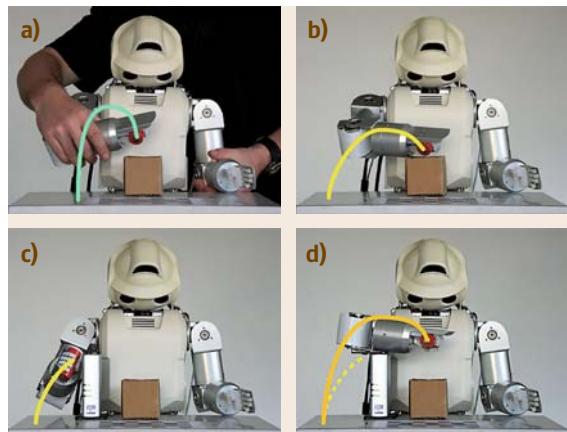

Fig. 59.20a–d Illustration of the use of reinforcement learning to complement PbD. (a) The robot is trained through kinesthetic demonstration on a task that consists of placing a cylinder in a box. (b) The robot reproduces successfully the skill when the new situation is only slightly different from that of the demonstration, using the dynamical system described in Fig. 59.16. (c) The robot fails at reproducing the skill when the context has changed importantly (a large obstacle has been placed in the way). (d) The robot relearns a new trajectory that reproduces the essential aspect of the demonstrated skill, i.e. putting the cylinder in the box, but avoiding the obstacle. (After [59.114])

true insofar that the context for the reproduction is sufficiently similar to that of the demonstration. We have seen in Sect. 59.2 that the use of dynamical systems allows the robot to depart to some extent from a learned trajectory to reach for the target, even when both the object and the hand of the robot have moved

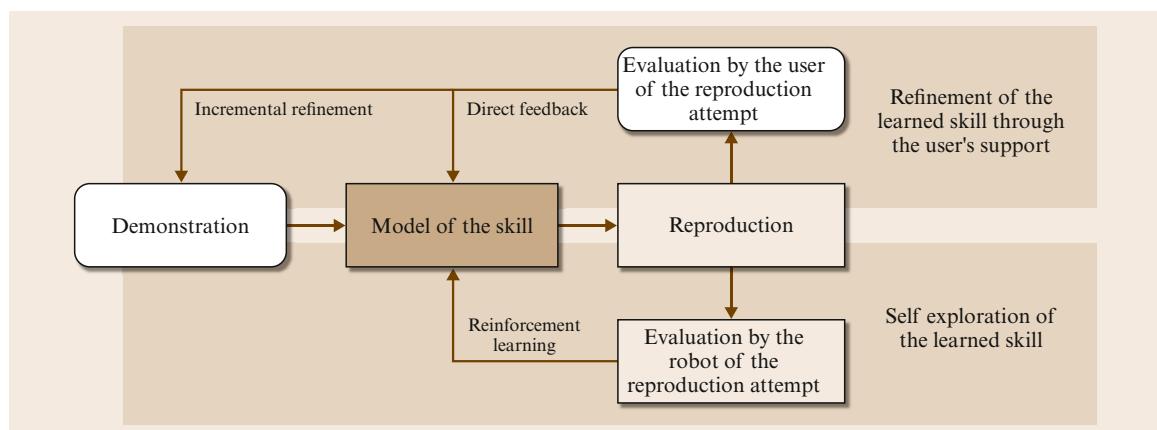

Fig. 59.21 Iterative refinement of the learned skill through teacher's support or through self-exploration by the robot

from the location shown during the demonstration. This approach would not work in some situations, for example, when placing a large obstacle in the robot's path (Fig. 59.20). Besides, robots and humans may differ significantly in their kinematics and dynamics of motion and, although there are varieties of ways to bypass the so-called correspondence problem (Fig. 59.4), re-learning a new model may still be required in special cases.

To allow the robot to learn how to perform a task again in any new situation, it appeared important to combine PbD methods with other motor learning techniques. *Reinforcement learning* (RL) appeared particularly indicated for this type of problem, see Figs. 59.21 and 59.20.

Early work on PbD using RL began in the 1990s and featured learning how to control an inverse pendulum and make it swing up [59.83]. More recent efforts [59.118–120] have focused on the robust control of the upper body of humanoid robots while performing various manipulation tasks.

One can also create a population of agents that copy (mimic) each other so that robots can learn a control strategy by making experiments themselves and by watching others. Such an evolutionary approach, using genetic algorithms, has been investigated by a number of authors, e.g. for learning manipulation skills [59.121], navigation strategies [59.51] or sharing a common vocabulary to name sensoriperception and actions [59.122].

59.3 Biologically-Oriented Learning Approaches

Another important trend in robot PbD takes a more biological stance and develops computational models of imitation learning in animals. We here briefly review recent progresses in this area.

59.3.1 Conceptual Models of Imitation Learning

Bioinspiration is first revealed in the conceptual schematic of the sensorimotor flow which is at the basis of imitation learning that some authors in PbD have followed over the years.

Figure 59.22 sketches the major ingredients of such a conceptual imitation learning system based on sensorimotor representation [59.123]. Visual sensory information needs to be parsed into information about objects and their spatial location in an internal or external coordinate system; the depicted organization is largely inspired by the dorsal (what) and ventral (where) stream as discovered in neuroscientific research [59.124]. As a result, the posture of the teacher and/or the position of the object while moving (if one is involved) should become available. Subsequently, one of the major questions revolves around how such information can be converted into action. For this purpose, Fig. 59.22 alludes to the concept of movement primitives, also called *movement schemas*, *basis behaviors*, *units of action*, or *macro actions* [59.34, 125–127]. Movement primitives are sequences of action that accomplish a complete goal-directed behavior. They could be as simple as an elementary action of an actuator (e.g., *go forward*, *go*

backward, etc.), but, as discussed in [59.123], such low-level representations do not scale well to learning in systems with many degrees-of-freedom. Thus, it is useful for a movement primitive to code complete temporal behaviors, like *grasping a cup*, *walking*, *a tennis serve*, etc.. Figure 59.22 assumes that the perceived action of the teacher is mapped onto a set of existing primitives in an assimilation phase, which is also suggested in [59.128, 129]. This mapping process also needs to resolve the correspondence problem concerning a mismatch between the teacher's body and the student's body [59.130]. Subsequently, one can adjust the most appropriate primitives by learning to improve the performance in an accommodation phase. Figure 59.22 indicates such a process by highlighting the better-matching primitives with increasing line widths. If no existing primitive is a good match for the observed behavior, a new primitive must be generated. After an initial imitation phase, self-improvement, e.g., with the help of a reinforcement-based performance evaluation criterion [59.131], can refine both movement primitives and an assumed stage of motor command generation (see later) until a desired level of motor performance is achieved.

59.3.2 Neural Models of Imitation Learning

Bioinspiration is also revealed in the development of neural network models of the mechanisms at the basis of imitation learning. Current models of Imitation

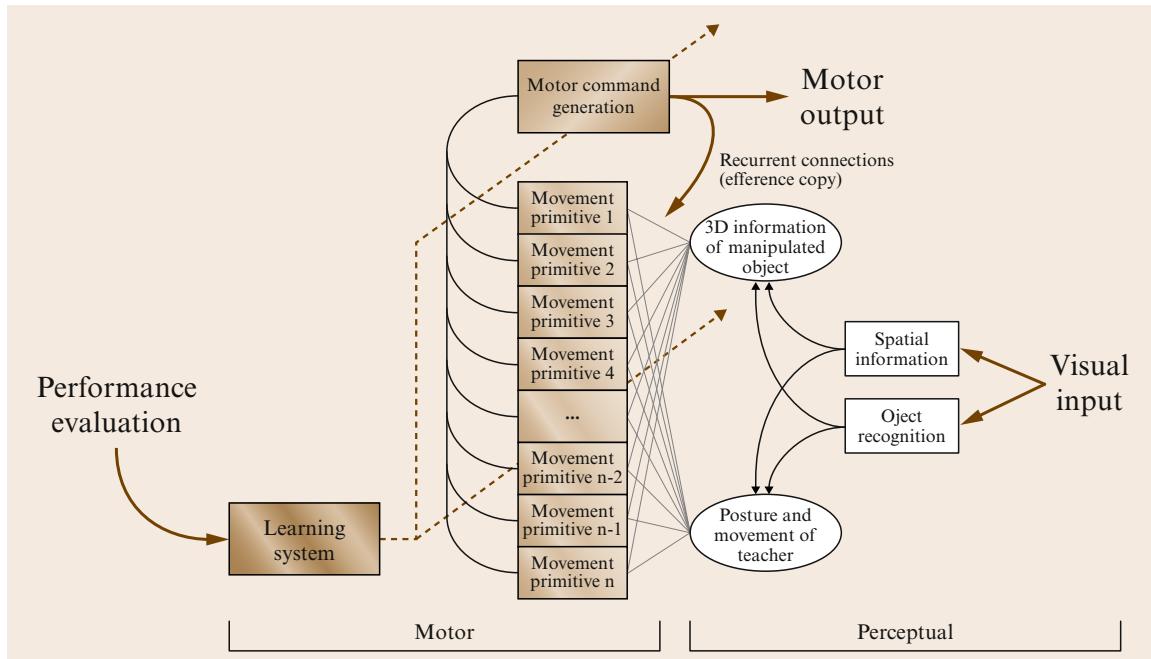

Fig. 59.22 Conceptual sketch of an imitation learning system. The right side of the figure contains primarily perceptual elements and indicates how visual information is transformed into spatial and object information. The left side focuses on motor elements, illustrating how a set of movement primitives competes for a demonstrated behavior. Motor commands are generated from input of the most appropriate primitive. Learning can adjust both movement primitives and the motor command generator. (After [59.123])

Learning all ground their approach on the idea that imitation is at core driven by a *mirror neuron* system. The mirror neuron system refers to a network of brain areas in premotor and parietal cortices that is activated by both the recognition and the production of the same kind of object oriented movements performed by oneself and by others. See [59.26, 132, 133] for recent reports on this system in monkeys and humans, and its link to imitation.

Models of the mirror neuron system assume that somewhere, sensory information about the motion of others and about self-generated motion is coded using the same representation and in a common brain area. The models, however, differ in the way they represent this common center of information. Besides, while all models draw from the evidence of the existence of a mirror neuron circuit and of its application to explain multimodal sensory-motor processing, they, however, go further and tackle the issue of how the brain manages to process the flow of sensorimotor information that is at the basis of how one observes and produces actions. For a comprehensive and critical review of computational

models of the mirror neuron system, the reader may refer to [59.134]. Next, we briefly review the most recent works among those.

One of the first approaches to explaining how the brain processes visuomotor control and imitation was based on the idea that the brain relies on forward models to compare, predict and generate motions [59.129]. These early works set the ground for some of the current neural models of the visuomotor pathway underlying imitation. For instance, recent work by Demiris and colleagues [59.117, 128] combines the evidence there is a mirror neuron system which is the basis of recognition and production of basic grasping motions and which proves the existence of forward models for guiding these motions. These models contribute both to the understanding of the mirror neuron system (MNS) in animals as well as its use in controlling robots. For instance, the models successfully reproduce the timing of neural activity in animals while observing various grasping motions and reproducing the kinematics of arm motions during these movements. The models were implemented to control reaching

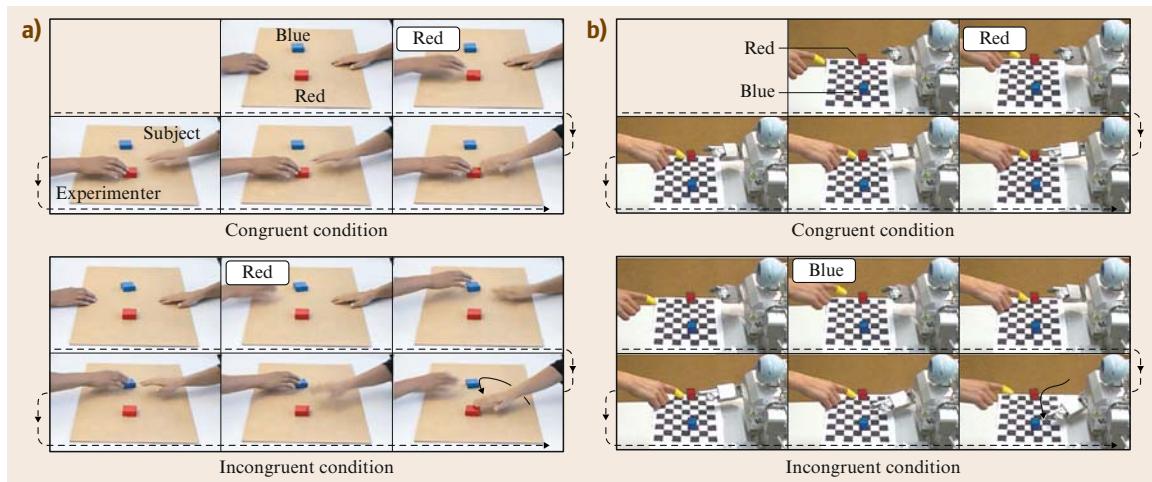

Fig. 59.23 A human experimenter, a human imitator and a robot imitator play a simple imitation game, in which the imitator must point to the object named by the experimenter and not to the object which the experimenter points at. The robot's decision process is controlled by a neural model similar to that found in humans. As a result, it experiences the same associated deficit, known as the principle of *ideomotor compatibility*, stating that *observing the movements of others influences the quality of one's own performance*. When presented with conflicting cues (incongruent condition), e.g. when the experimenter points at a different object than the one named, the robot, like the human subject, either fails to reach for the correct object, or hesitates and later corrects the movement. (After [59.135])

and grasping motions in humanoid and non-humanoid robots.

In contrast, Arbib and colleagues' models take a strong biological stance and follow an evolutionary approach to modeling the mirror neuron system (**MNS**), emphasizing its application to robotics in a second stage only. They hypothesize that the ability to imitate we find in humans has evolved from Monkeys' ability to reach and grasp and from Chimpanzees' ability to perform simple imitations. They develop models of each of these evolutionary stages, starting from a detailed model of the neural substrate underlying Monkeys' ability to reach and grasp [59.136], extending this model to include the Monkey **MNS** [59.137] and finally moving to models of the neural circuits underlying a human's ability to imitate [59.138]. The models replicate findings of brain imaging and cell recording studies, as well as make predictions on the time course of the neural activity for motion prediction. As such, the models reconcile a view of forward models of action with an immediate **MNS** representation of these same actions. They

were used to control reaching and grasping motions in humanoid robotic arms and hands [59.139].

Expanding on the concept of a **MNS** for sensorimotor coupling, *Sausser and Billard* [59.140, 141] have explored the use of competitive neural fields to explain the dynamics underlying multimodal representation of sensory information and the way the brain may disambiguate and select across competitive sensory stimuli to proceed to a given motor program. This work explains the principle of *ideomotor compatibility*, by which *observing the movements of others influences the quality of one's own performance*, and develops neural models which account for a set of related behavioral studies [59.142], see Fig. 59.23. The model expands the basic mirror neuron circuit to explain the consecutive stages of sensory-sensory and sensory-motor processing at the basis of this phenomenon. *Sausser et al.* [59.135] discuss how the capacity for ideomotor facilitation can provide a robot with human-like behavior at the expense of several disadvantages such as hesitation and even mistakes (Fig. 59.23).

59.4 Conclusions and Open Issues in Robot PbD

This chapter aimed at assessing recent progress in modelling the cognitive or neural mechanisms underlying imitation learning in animals and the application of these models to controlling robots, on the one hand. On the other hand, it summarized various machine learning and computational approaches to providing the necessary algorithms for robot programming by demonstration.

Key questions remaining to be assessed by the field are:

- Can imitation use known motor learning techniques or does it require the development of new learning and control policies?
- How does imitation contribute and complement motor learning?
- Does imitation speed up skill learning?
- What are the costs of imitation learning?
- Do models of human kinematics used in gesture recognition drive the reproduction of the task?

- Can one find a level of representation of movement common to both gesture recognition and motor control?
- How could a model extract the intent of the user's actions from watching a demonstration?
- How can we create efficient combinations of imitation learning and reinforcement learning, such that systems can learn in rather few trials?
- What is the role of imitation in human-robot interactions?
- How to find a good balance between providing enough prior knowledge for learning to be fast and incremental, as in task/symbolic learning, and avoid restricting too much the span of learning?

In conclusion, robot PbD contributes to major advances in robot learning and paves the way to the development of robust controllers for both service and personal robots.

Biologically Inspired Robots

Jean-Arcady Meyer, Agnès Guillot

After having stressed the difference between bio-inspired and biomimetic robots, this chapter successively describes bio-inspired morphologies, sensors, and actuators. Then, control architecture that, beyond mere reflexes, implement cognitive abilities like memory or planning, or adaptive processes like learning, evolution and development are described. Finally, the chapter also reports related works on energetic autonomy, collective robotics, and biohybrid robots.

60.1 General Background

Human inventors and engineers have always found in Nature's products an inexhaustible source of inspiration. About 2400 years ago, for instance, Archytas of Tarentum allegedly built a kind of flying machine, a wooden pigeon balanced by a weight suspended from a pulley, and set in motion by compressed air escaping from a valve. Likewise, circa 105 AD, the Chinese eunuch Ts'ai Lun is credited with inventing paper, after watching a wasp create its nest. More recently, Antoni Gaudi's design of the still-unfinished Sagrada Familia cathedral in Barcelona displays countless borrowings from mineral and vegetal exuberance.

Although a similar tendency underlined all attempts at building automata or protorobots up to the middle of the last century [60.1], in the last decades roboticists borrowed much more from mathematics, mechanics,

electronics, and computer science than from biology. On the one hand, this approach undoubtedly solidified the technical foundations of the discipline and led to the production of highly successful products, especially in the field of industrial robotics. On the other hand, it served to better appreciate the gap that still separates a robot from an animal, at least when qualities of autonomy and adaptation are sought. As such qualities are required in a continually growing application field – from planetary exploration to domestic uses – a spectacular reversal of interest towards living creatures can be noticed in current-day robotics, up to the point that it has been said that natural inspiration is the *new wave* of robotics [60.2].

Undoubtedly, this new wave would not have been possible without the synergies generated by recent

advances in biology – where so-called *integrative approaches* now produce a huge amount of data and models directly exploitable by roboticists – and in technology – with the massive availability of low-cost and power-efficient computing systems, and with the development of new materials exhibiting new properties. This will be demonstrated in this chapter, which first reviews recent research efforts in bio-inspired morphologies, sensors, and actuators. Then, control architectures that, beyond mere reflexes, implement cognitive abilities – like memory or planning – or adaptive processes – like learning, evolution and development – will be described. Finally, the chapter will also report related works on energetic autonomy, collective robotics, and biohybrid robots.

It should be noted that this chapter will describe both bio-inspired and biomimetic realizations. In fact, these two terms characterize, respectively, the extremi-

ties of a continuum in which, on the one side, engineers seek to reproduce some natural result, but not necessarily the underlying means, while, on the other side, they seek to reproduce both the result and the means. Thus, bio-inspired robotics tends to adapt to traditional engineering approaches some principles that are abstracted from the observation of some living creature, whereas biomimetic robotics tends to replace classical engineering solutions by as detailed mechanisms or processes that it is possible to reproduce from the observation of this creature. In practice, any specific application usually lies somewhere between these two extremities. Be that as it may, because biomimetic realizations are always bio-inspired, whereas the reverse is not necessarily true, qualifying expressions like bio-inspired or biologically inspired will be preferentially used in this chapter.

60.2 Bio-inspired Morphologies

Although not comparable to that of real creatures, the diversity of bio-inspired morphologies that may be found in the realm of robotics is nevertheless quite impressive. Currently, a huge number of robots populates the terrestrial, as well as aquatic and aerial, environments and look like animals as diverse as dogs, kangaroos, sharks, dragonflies, or jellyfishes, not to mention humans (Fig. 60.1).

In nature, the morphology of an animal fits its ecology and behavior. In robotics applications, bio-inspired morphologies are seldom imposed by functional considerations. Rather, as close a resemblance as possible to a given animal is usually sought per se, as in animatronics applications for entertainment industry. However, several other applications are motivated by the functional objective of facilitating human–robot interactions, thus allowing, for instance, children or elderly people to adopt artificial pets and enjoy their company. Such interactions are facilitated in the case of so-called *anthropopathic* or *human-friendly* robots, such as Kismet at MIT [60.3] or WE-4RII at Waseda University [60.4], which are able to perceive and respond to human emotions, and do themselves express apparent emotions influencing their actions and behavior (Fig. 60.2a,b).

Likewise, the Uando robot of Osaka University [60.5] is controlled by air actuators providing 43 degrees of freedom. The android can make facial ex-

pressions, eye, head, and body movements, and gestures with its arms and hands. Touch sensors with sensitivity to variable pressures are mounted under its clothing and silicone skin, while floor sensors and omnidirectional vision sensors serve to recognize where people are in order to make eye contact while addressing them during conversation. Moreover, it can respond to the content and prosody of a human partner by varying what it says and the pitch of its voice (Fig. 60.2c). See Chap. 58 for more references on human-friendly robots.

Another active research area in which functional considerations play a major role is that of shape-shifting robots that can dynamically reconfigure their morphology according to internal or external circumstances. Biological inspiration stems from organisms that can regrow lost appendages, like the tail in lizards, or from transitions in developmental stages, like morphogenetic changes in batrachians. For instance, the base topology of the Conro self-reconfigurable robot developed in the Polymorphic Robotics Laboratory at USC-ISI is simply connected as in a snake, but the system can reconfigure itself in order to grow a set of legs or other specialized appendages (Fig. 60.3) thanks to a dedicated hormone-like adaptive communication protocol [60.6, 7].

Chapter 39 is devoted to distributed and cellular robots and provides other examples of such reconfigurable robots.

60.3 Bio-inspired Sensors

60.3.1 Vision

Bio-inspired visual sensors in robotics range from very simple photosensitive devices, which mostly serve to implement phototaxis, to complex binocular devices used for more cognitive tasks like object recognition.

Phototaxis is seldom the focus of dedicated research. It is rather usually implemented merely to force a robot to move and exhibit other capacities such as obstacle avoidance or inter-robot communication.

Several visual systems calling upon optic-flow monitoring are particularly useful in the context of navigation tasks and are implemented in a variety of robots. This is the case with the work done in Marseilles' Biorobotics Laboratory that serves to understand how the organization of the compound eye of the housefly, and how the neural processing of visual information obtained during flight, endow this insect with various reflexes mandatory for its survival. The biological knowledge thus acquired

was exploited to implement optoelectronic devices allowing a terrestrial robot to wander in its environments while avoiding obstacles [60.8], or tethered aerial robots to track a contrasting target [60.9] or to automatically perform terrain-following, take-off, or landing [60.10] (Fig. 60.4).

The desert ant *Cataglyphis*, while probably merging optic-flow and odometry monitoring to evaluate its travel distances, is able to use its compound eyes to perceive the polarization pattern of the sky and infer its orientation. This affords it with accurate navigation capacities that make it possible to explore its desert habitat for hundreds of meters while foraging, and return back to its nest on an almost straight line, despite the absence of conspicuous landmarks and despite the impossibility of laying pheromones on the ground that would not almost immediately evaporate. Inspired by the insect's navigation system, mechanisms for path integration and visual piloting have been successfully

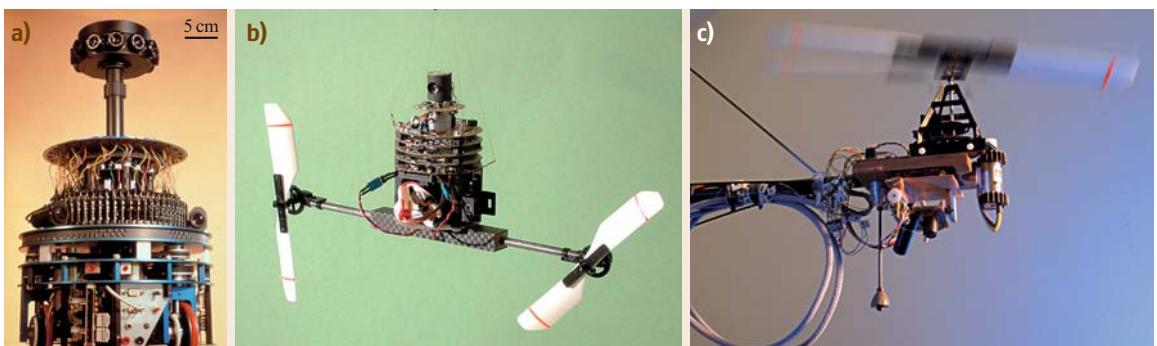

Fig. 60.4a–c Optoelectronic devices inspired by the housefly's compound eye. **(a)** Device for obstacle avoidance. **(b)** Device for target tracking. **(c)** Device for terrain following, take-off, and landing. ©CNRS Photothèque, Nicolas Franceschini, UMR6152 - Mouvement et Perception - Marseille

employed on mobile robot navigation in the Sahara desert [60.11].

Among the robotic realizations that are targeted at humanoid vision, some aim at integrating information provided by foveal and peripheral cameras. *Ude* et al. [60.12], in particular, describe a system that uses shape and color to detect and pursue objects through peripheral vision and then recognizes the object through a more detailed analysis of higher-resolution foveal images. The classification is inferred from a video stream rather than from a single image and, when a desired object is recognized, the robot reaches for it and ignores other objects (Fig. 60.5). Common alternatives to the use of two cameras per eye consist of using space-variant vision and, in particular, log-polar images. As an example, *Metta* [60.13] describes an attentional system that should be extended with modules for object recognition, trajectory tracking, and naive physics understanding during the natural interaction of a robot with the environment.

Other examples of robotic applications of perceptual processes underlying human vision are provided in Chap. 63 on perceptual robotics.

Vision-based simultaneous localization and mapping (**SLAM**) systems have also been implemented on humanoid robots, with the aim of increasing the autonomy of these machines. In particular, *Davison* et al. [60.14] used the HRP2 robot (Fig. 60.5) to demonstrate real-time **SLAM** capacities during agile combinations of walking and turning motions, using the robot's internal inertial sensors to monitor a type of three-dimensional odometry that reduced the local rate of increase in uncertainty within the **SLAM** map. The authors speculate that the availability of traditional odometry on all of the robot's degrees of freedom will allow more long-term motion constraints to be imposed and exploited by the **SLAM** algorithm, based on knowledge of possible robot configurations. Additional references to **SLAM** techniques are to be found in Chap. 37.

As another step towards autonomy in humanoid robots, mapping and planning capacities may be combined. *Michel* et al. [60.15], for instance, demonstrate that a real-time vision-based sensing system and an adaptive footstep planner allow a Honda ASIMO robot to autonomously traverse dynamic environments containing unpredictably moving obstacles.

60.3.2 Audition

Like vision, the sense of hearing in animals has been implemented on several robots to exhibit mere phono-

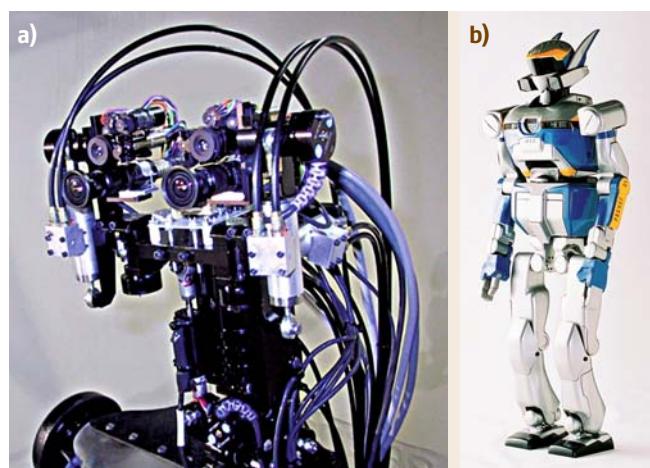

Fig. 60.5 (a) Four cameras implement foveal and peripheral vision in the head of the humanoid robot DB. Foveal cameras are above peripheral cameras. ©JST, ATR Robot developed by SARCOS. taxis behavior or more complex capacities such as object recognition.

At the University of Edinburgh, numerous research efforts are devoted to understanding the sensory-motor pathways and mechanisms that underlie positive or negative phonotaxis behavior in crickets through the implementation of various models on diverse robots such as the Khepera shown on Fig. 60.6. In particular, an analogue very-large-scale integrated (**VLSI**) circuit models the auditory mechanism that enables a female cricket to meet a conspecific male or to evade a bat (by the calling song or the echolocation calls they produce, respectively). The results suggest that the mechanism outputs a directional signal to sounds ahead at calling song frequency and to sound behind at echolocation frequencies, and that this combination of responses simplifies later neural processing in the cricket [60.16]. This processing is the subject of complementary modeling efforts in which spiking neuron controllers are also tested on robots, thus allowing the exploration of the functionality of the identified neurons in the insect, including the possible roles of multiple sensory fibers, mutually inhibitory connections, and brain neurons with pattern-filtering properties. Such robotic implementations also make the investigation of multimodal influences on the behavior possible, via the inclusion of an optomotor stabilization response and the demonstration that this may improve auditory tracking, particularly under conditions of random disturbance [60.17].

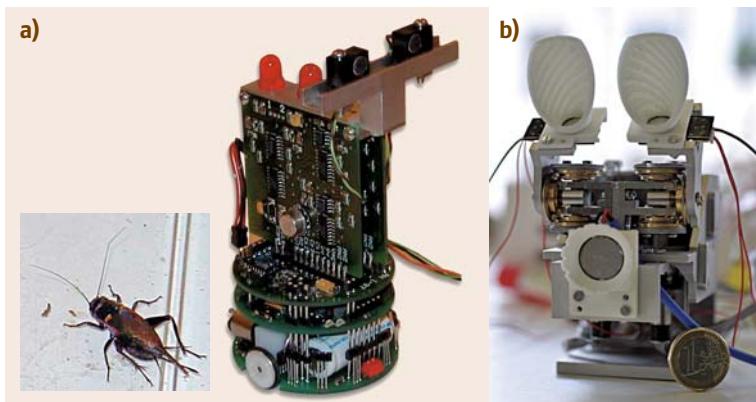

Fig. 60.6 (a) A Khepera robot equipped with a cricket-like auditory system. ©Barbara Webb, Institute for Perception, Action and Behaviour, University of Edinburgh. (b) The CIRCE robotic bat head ©Herbert Peremans, Active Perception Lab, Universiteit Antwerpen

Concerning more cognitive capacities, within the framework of the European Community (EC) project chiroptera-inspired robotic cephaloid (CIRCE), a bat head (Fig. 60.6) is used to investigate how the world is not just perceived, but actively explored, by bats. In particular, the work aims at identifying how various shapes, sizes, and movements influence the signals that the animal receives from its environment [60.18]. It is hoped that the principles gleaned from such work will prove useful in developing better antennas, particularly for wireless devices that are in motion and need to pick up complex signals from different directions.

Likewise, the Yale Sonar Robot, which is modeled after bat and dolphin echolocation behavior, is said to be so sensitive that it can tell whether a tossed coin has come up heads or tails. Called Rodolph – short for robotic dolphin – the robot is equipped with electrostatic transducers that can act either as transmitters or receivers to serve as the robot's mouth and ears. The design is inspired by bats, whose ears react by rotating in the direction of an echo source, and by dolphins, which appear to move around in order to place an object at a standard distance, thus reducing the complexity of object recognition [60.19]. Additional references to bio-inspired sonars are to be found in Chap. 21, dedicated to sonar sensing.

Nakadai et al. [60.20] describe a system that allows a humanoid robot to listen to a specific sound in under noisy environments (the human capability known as the *cocktail-party effect*) and to listen to several sources of speeches simultaneously, thus allowing it to cope with situations where someone or something playing sounds interrupts conversation (known as *barge-in* in spoken dialog systems). This system calls upon active motions directed at the sound source to improve localization by exploiting an *auditory fovea*. It also capitalizes on audio-

visual integration, thus making localization, separation, and recognition of three simultaneous speech sources possible.

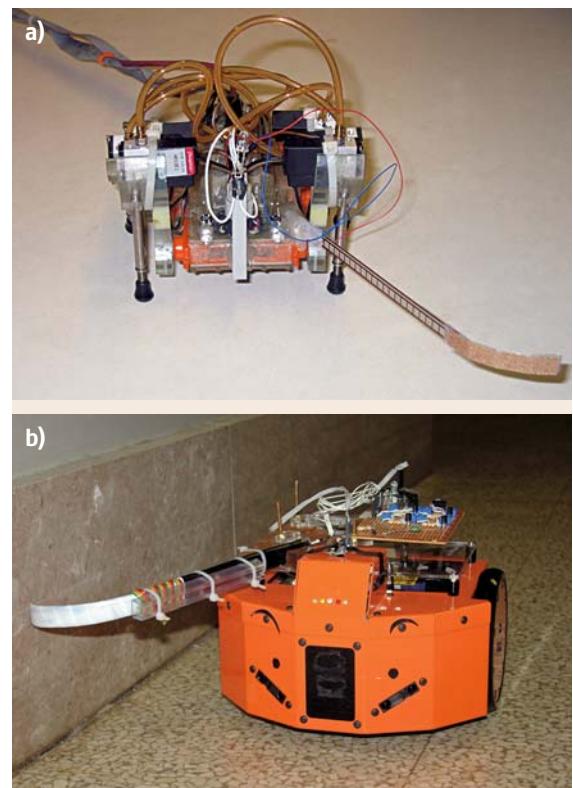

Fig. 60.7 (a) A simple antenna mounted on a Sprawlette robot ©Mark R. Cutkosky, Center for Design Research, Stanford University. (b) A more advanced tactile device ©Noah J. Cowan, Department of Mechanical Engineering, Johns Hopkins University

60.3.3 Touch

It is often asserted that, of all the five senses, touch is the most difficult to replicate in mechanical form. Be that as it may, a passive, highly compliant tactile sensor has been designed for the hexapedal running robot Sprawlette at Stanford, drawing inspiration from how the cockroach *Periplaneta americana* uses antenna feedback to control its orientation during a rapid wall-following behavior. Results on the stabilization of the robot suggest that the cockroach uses, at least in part, the rate of convergence to the wall – or *tactile flow* – to control its body orientation [60.21]. To make it possible to detect the point of greatest strain, or to differentiate between different shapes the sensor is bent into, more advanced versions of the antenna are currently under development (Fig. 60.7).

While a cockroach's antenna consists of multiple rigid segments and is covered along its length with

sensory receptors, a rat's whisker consists of a single, flexible, tapered hair and has tactile sensors located only at its base. The way in which two arrays of such sensors afford capacities of obstacle avoidance, texture discrimination, and object recognition has inspired several robotic realizations, notably that described by Russel and Wijaya [60.22] in which the whiskers are passive and rely upon the motion of the robot in order to scan the surface profile of touched objects. The robot is able to recognize a few objects formed from plane, cylindrical, and spherical surfaces. By using its simple manipulator, it can pick up and retrieve small objects.

Conversely, Pearson et al. [60.23] describe a touch system based on computational models of whisker-related neural circuitry in the rat brain, in which the whiskers will be actively scanning the surroundings. This work will contribute to the EC ICEA (integrating cognition, emotion, and autonomy – <http://www2.his.se/icea/>) project whose primary aim is to develop a cognitive systems architecture based on the anatomy and physiology of the mammalian brain.

In the field of humanoid robotics, investigations on touch sensors are being conducted at the University of Tokyo, where a robotic hand calling upon organic transistors as pressure sensors (Fig. 60.8a) has been produced. The same technology served to make a flexible artificial skin that can sense both pressure and temperature (Fig. 60.8b), thus more closely imitating the human sense of touch [60.24].

Another step in this direction has been made at the University of Nebraska [60.25], where a thin-film tactile sensor, which is as sensitive as the human finger in some ways, has been designed. When pressed against a textured object, the film creates a topographical map of the surface, by sending out both an electrical signal

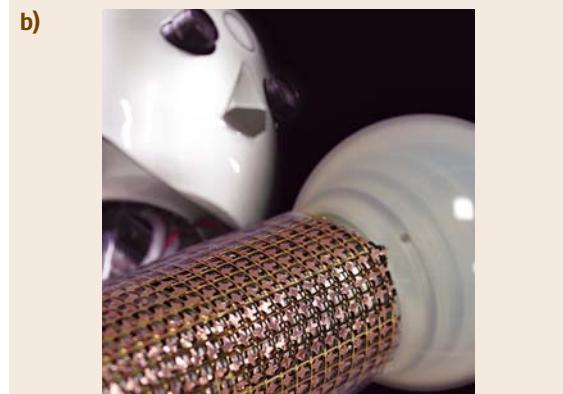

Fig. 60.8a,b Artificial skin devices at Tokyo University. (a) Pressure detection. (b) Pressure and temperature detection ©Takao Someya, Quantum-Phase Electronics Center, The University of Tokyo

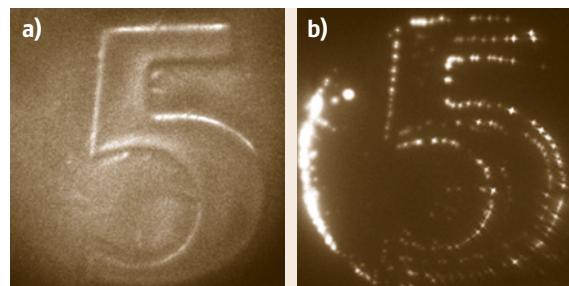

Fig. 60.9 (a) The optical image of a coin (b) The corresponding pressure image from the tactile sensor ©Ravi Saraf, Department of Chemical Engineering, University of Nebraska

and a visual signal that can be read with a small camera. The spatial resolution of these *maps* is as good as that achieved by human touch, as demonstrated by the image obtained when placing a coin on this mechanical fingertip (Fig. 60.9).

Although such sensors deal with texture in a way that is not at all like a fingertip, it has a high enough resolution to *feel* single cells, and therefore could help surgeons find the perimeter of a tumor during surgical procedures. Cancer cells, in particular breast cancer cells, have levels of pressure that are different from normal cells, and should feel *harder* to the sensor.

60.3.4 Smell

The way the nematod *Caenorhabditis elegans* uses chemotaxis – probably the most widespread form of goal-seeking behavior – to find bacterial food sources by following their odors has been investigated at the University of Oregon. This worm has a small nervous system (302 neurons), whose neurons and connectivity pattern have been completely characterized, so the neural circuit controlling chemotaxis is well known and, when implemented in a robot, proves to be able to cope with environmental variability and noise in sensory inputs [60.26]. The long-term objective of such work is to design a cheap, artificial eel that could locate explosive mines at sea. Among the research efforts that tackle the related and highly challenging issue of reproducing the odor-plume-tracking behavior in marine animals, results obtained on the RoboLobster are put in perspective in [60.27].

Other bio-inspired systems for odor recognition are under development in several places. For instance, the

chest of the humanoid WE-4RII robot of Waseda University (Fig. 60.2) is equipped with two mechanical lungs, each consisting of a cylinder and a piston, thanks to which the robot breathes air. Being also equipped with four semiconductor gas sensors, it recognizes the smells of alcohol, ammonia, and cigarette smoke [60.28].

60.3.5 Taste

A first robot with a sense of taste has recently been developed by NEC System Technologies, Ltd. Using infrared spectroscopic technology, this robot is capable of examining the taste of food and giving its name as well as its ingredients. Furthermore, it can give advice on the food and health issues based on the information gathered. The latest developments afford the robot with the capacity to distinguish good wine from bad wine, and Camembert from Gouda (<http://www.necst.co.jp/english/news/20061801/index.htm>).

60.3.6 Internal Sensors

Whereas the previous *external* sensors all provide information about an animal's or a robot's external world, *internal* sensors provide information about a creature's internal state. Although such so-called idiothetic sensors are widespread in robotic applications, measuring variables such as temperature, pressure, voltage, accelerations, etc., they are seldom biologically inspired, but in the implementation of a variety of visual–motor routines (smooth-pursuit tracking, saccades, binocular vergence, and vestibular-ocular and optokinetic reflexes), like those that are at work in the humanoid Cog robot mentioned later.

60.4 Bio-inspired Actuators

60.4.1 Locomotion

Crawling

Because they are able to move in environments inaccessible to humans, such as pipes or collapsed buildings, numerous snake-like robots have been developed for exploration and inspection tasks, as well as for participation in search-and-rescue missions. The Salamandra Robotica (Fig. 60.10) developed at the Ecole Polytechnique Fédérale de Lausanne (EPFL) in Switzerland extends these approaches because it is the first robot that combines the three modes of locomotion – serpentine

crawling, swimming, and walking – in a single robot. Being inspired by central pattern generators (CPG) found in vertebrate spinal cords, this work demonstrates how a primitive neural circuit for swimming, like the one found in the lamprey, can be extended by phylogenetically more recent limb oscillatory centers to explain the ability of salamanders to switch between swimming and walking. It also suggests a mechanism that explains how gait transition between swimming and walking can be obtained by simply varying the level of stimulation of the brainstem, and provides a potential explanation of how salamanders control their speed and direction

of locomotion, by modulating the level and the asymmetry, respectively, of the drive applied to the spinal cord [60.29].

Other applications are sought within the framework of the EC biomimetic structures for locomotion in the human body (BIOLOCH) project. In the perspective of helping doctors diagnose disease by carrying tiny cameras through patients' bodies, a robot designed to crawl through the human gut by mimicking the wriggling motion of an undersea worm has been developed by the project partners [60.30]. Drawing inspiration from the way polychaetes, or *paddle worms*, use tiny paddles on their body segments to push through sand, mud or water, they tackled the issue of supplying traditional forms of robotic locomotion that would not work in the peculiar environment of the gut (Fig. 60.10). The device is expected to lessen the chance of damaging a patient's internal organs with a colonic endoscope, and to enhance the exploration capacities afforded by *camera pills*.

Walking

Eight Legs. Joseph Ayers has developed a biomimetic robot based on the American lobster at the Marine Science Center of North Eastern University (Fig. 60.11). Capitalizing on recent advances in microcontrollers, smart materials, and microelectronic devices, this eight-legged ambulatory robot is intended for autonomous mine countermeasure operations in rivers, harbors, and/or the littoral zone of the ocean floor. Its control architecture supports a library of action patterns and reflexes – reverse-engineered from movies of lobsters behaving under the target conditions – that mediates tactile navigation, obstacle negotiation, and adaptation to surge.

The robot will have the overlying motivation to navigate on a specified compass heading. When encountering an obstacle, it will attempt to ascertain whether it is a mine candidate or not through dedicated sensors like an electronic nose, an acoustic hardness tester, or an active electric field perturbator. If the robot determines that the obstacle is not a mine candidate, it will decide whether to climb over the obstacle or to go around it using information supplied by its antennal sensors and claw-like surfaces. If climbing appears to be unfeasible, the robot will use a wall-following algorithm to go around the obstacle until it can resume its predetermined heading. This basic scenario will apply to almost all seafloor types because tactile queues from leg sensors will be used to determine whether the bottom is cobble, sand or hard, and because attitude reflexes will help with pitch and roll control [60.31].

Six Legs. In the performance energetics and dynamics of animal locomotion (PolyPEDAL) Laboratory at Berkeley, the observation that many animals self-stabilize to perturbations without a brain or its equivalent because control algorithms are embedded in their physical structure is widely exploited. Shape deposition manufacturing has allowed engineers to tune the legs of the SPRawl family of hand-sized hexapedal robots inspired by the cockroach that are very fast (up to five body lengths per second), robust (hip-height obstacles), and that self-stabilize to perturbations without any active sensing [60.32]. One such robot is shown on Fig. 60.7. Capitalizing on previous work [60.33], a cricket-inspired robot, approximately 8 cm long, designed for both walking and jumping is under development at Case Western Reserve University, and is shown in Fig. 60.11. McKibben artificial muscles will actuate the legs, compressed air will be generated by an onboard power plant, and a continuous-time recurrent neural network will be used for control. Additionally, front legs will enable climbing over larger obstacles and will also be used to control the pitch of the body before a jump and, therefore, aim the jump for distance or height.

Water strider insects are able to walk on water because, instead of using buoyancy-like macroscale bodies, these very light and small creatures balance their weight using repulsive surface tension forces produced by the hydrophobic microhairs that cover their legs. In the NanoRobotics Laboratory of Carnegie Mellon University, Water Strider, a miniature microrobot, walks on water with legs made from hydrophobic Teflon®-coated wires and a body made of carbon fiber for minimal weight (Fig. 60.11). This tethered robot can successfully

move forward and backward, and can also make turns. Its maximum speed in forward motion is 2.3 cm/s. In the future, environmental monitoring applications on dams, lakes, sea, etc. would become possible using a network of these robots with miniature sensors and an onboard power source and electronics [60.34].

Four Legs. Engineers from Boston Dynamics claim to have developed *the most advanced quadruped robot on Earth* for the US Army. Called BigDog, it walks, runs, and climbs on rough terrain, and carries heavy loads. Being the size of a large dog or a small mule, measuring 1 m long and 0.7 m tall, and weighing 75 kg, BigDog has trotted at 5 km/h, climbed a 35° slope, and carried a 50 kg load so far. BigDog is powered by a gasoline engine that drives a hydraulic actuation system. Its legs are articulated like an animal's, and have compliant elements that absorb shock and recycle energy from one step to the next (Fig. 60.11). Another quadruped with amazing locomotion capabilities is Scout II, presumably

the world's first galloping robot, developed at McGill University [60.35]. Using a single actuator per leg – the hip joint providing leg rotation in the sagittal plane – and each leg having two degrees of freedom (DOF) – the actuated revolute hip DOF, and the passive linear compliant leg DOF – the system exhibits passively generated bounding cycles and can stabilize itself without the need of any control action. This feature makes simple open-loop control of complex running behaviors such as bounding and galloping possible.

Two Legs. Developed at Stirling University, RunBot is probably the world's fastest biped robot for its size. Being 30 cm high, it can walk at a speed of 3.5 leg-lengths per second, which is comparable to the fastest relative speed of human walking (Fig. 60.11). This robot has some special mechanical features, e.g., small curved feet allowing rolling action and a properly positioned center of mass, which facilitate fast walking through exploitation of its natural dynamics. It also calls upon

a sensor-driven controller that is built with biologically inspired sensor and motor-neuron models, the parameters of which can be tuned by a policy gradient reinforcement learning algorithm in real time during walking. The robot does not employ any kind of position or trajectory-tracking control algorithm. Instead, it exploits its own natural dynamics during critical stages of its walking gait cycle [60.36].

Additional references to legged robots can be found in Chap. 16.

Wall-Climbing

In the Biomimetic Dextrous Manipulation Laboratory at Stanford University, researchers are working on a gecko-like robot, called Stickybot, designed to climb smooth surfaces like glass without using suction or adhesives (Fig. 60.12). Geckos can climb up walls and across ceilings thanks to roughly half a million tiny hairs, or setae, on the surface of each of their feet and to the hundreds to thousands of tiny pads, or spatulae, at the tip of each hair. Each of these pads is attracted to the wall by intermolecular van der Waals forces, which allow the gecko's feet to adhere. Conversely, if the hair is levered upward at a 30° angle, the spatulae at the end of the hair easily detach. The gecko does this simply by peeling its toes off the surface. Inspired by such structures and mechanisms, the Stickybot's feet are covered with thousands of synthetic setae made of an elastomer. These tiny polymer pads ensure a large area of contact between the feet and the wall, thus maximizing the expression of intermolecular forces. In the same laboratory, a six-legged robot called Spinybot climbs vertical surfaces according to similar principles. Spinybot's feet and toes are made from several different polymers, which range from flexible to rigid, thus enabling the robot to absorb jolts and bumps, much as animals' feet do [60.37].

The robots in scansorial environments (RiSE) project funded by the Defense Advanced Research Projects Agency ([DARPA](#)) Biodynamis program constitutes an extension of these research efforts that aims at building a bio-inspired climbing robot with the unique ability to walk on land and climb on trees, fences, walls, as well as other vertical surfaces. It calls upon novel robot kinematics, precision-manufactured compliant feet and appendages, and advanced robot behaviors [60.38, 39].

Jumping

In the perspective of environment exploration and monitoring, *Scarfogliero et al.* [60.40] describe a lightweight microrobot that demonstrates that jumping can be more

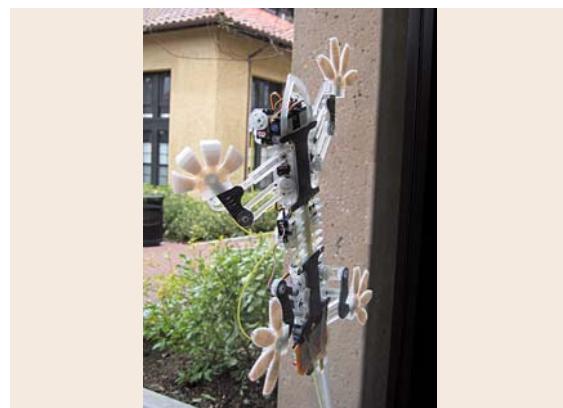

Fig. 60.12 Stickybot, the artificial gecko ©Mark R. Cutkosky, Stanford University Center for Design Research

energetically efficient than just walking or climbing, and can be used to overcome obstacles and uneven terrains. During the flight phase, energy from an electric micro-motor is collected in the robot's springs, and is released by a click mechanism during take-off. In this way the instantaneous power delivered by the rear legs is much higher than that provided by the motor.

Swimming

Several biomimetic robots are being produced that emulate the propulsive systems of fish, dolphins, or seals, and exploit the complex fluid mechanics these animals use to propel themselves. A primary goal of these projects is to build machines that can maneuver by taking advantage of flows and body positions, leading to huge energy savings, and substantially increasing the length of swimming time. For instance, the group at MIT Towing Tank designed two robotic fish, *RoboTuna*

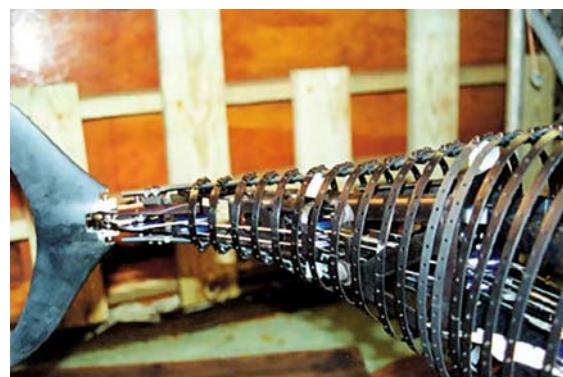

Fig. 60.13 The tail of RoboTuna at MIT ©Michael Triantafyllou, MIT Towing Tank

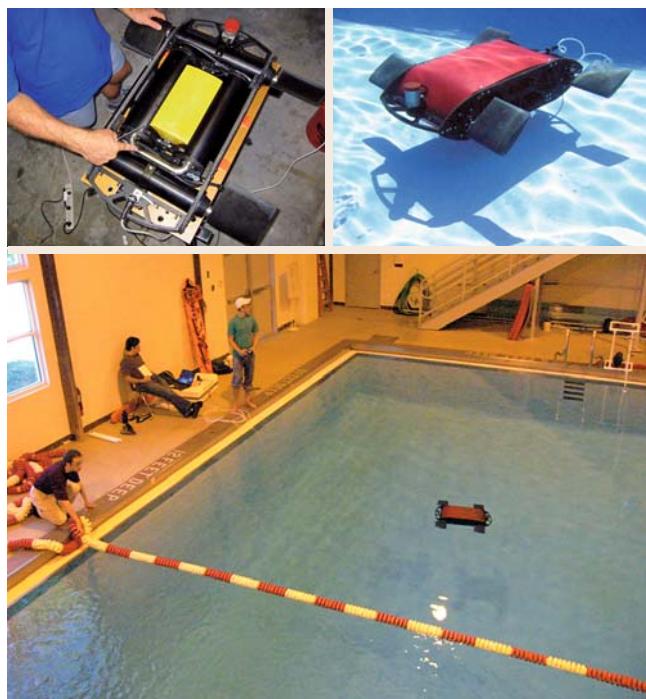

Fig. 60.14 The robot Madeleine ©John H. Long, Jr, Interdisciplinary Robotics Research Laboratory, Vassar College

and *RoboPike*, which use servo motors and spring element spines (Fig. 60.13), and serve to demonstrate the advantages of flapping foil propulsion. It has thus been shown that RoboTuna can reduce its drag by more than 70% compared to the same body towed straight and

rigid [60.41]. Likewise, it appears that biomimetic fish can turn at a maximum rate of $75^\circ/\text{s}$, whereas conventional rigid-bodied robots and submarines turn at approximately $3\text{--}5^\circ/\text{s}$ [60.42].

The robot Madeleine of Vassar College imitates the design of a turtle. Measuring $80 \times 30 \text{ cm}$ and weighing 24 kg, it has a comparable power output, and its polyurethane flippers have the same stiffness as a real turtle's, but the latter are operated by electric motors connected to an onboard computer (Fig. 60.14). Because it can swim underwater using four flippers, like many extinct animals, or with two flippers, like modern animals, this robot has been used to investigate theories of locomotion in existing and extinct animals. It thus appears that having four flippers does not improve the top speed – apparently because the front flippers create turbulence that interferes with the rear flippers' ability to generate forward propulsion – but does increase energy use. This may explain why natural selection favored two-flipper over four-flipper creatures like the plesiosaurs, and why four-flipper animals such as penguins, sea turtles, and seals use only two of their limbs for propulsion [60.43].

Flying

Flapping wings offer several advantages over the fixed wings of today's reconnaissance drones, like flying at low speeds, hovering, making sharp turns, and even flying backward. Like in animals, the vortex created beneath each wing is exploited to create the push necessary for robots to take to the sky.

The goal of the Micromechanical Flying Insect (MFI) project at Berkeley is to develop a 25 mm robot capable of sustained autonomous flight, which could be used in search, rescue, monitoring, and reconnaissance. Such tiny robots will be based on biomimetic principles that capture some of the exceptional flight performance achieved by true flies, i.e., large forces generated by non-steady-state aerodynamics, a high power-to-weight ratio motor system, and a high-speed control system with tightly integrated visual and inertial sensors. Design analysis suggests that piezoelectric actuators and flexible thorax structures can provide the necessary power density and wing stroke, and that adequate power can be supplied by lithium batteries charged by solar cells. Likewise, mathematical models capitalizing on wing–thorax dynamics, flapping flight aerodynamics in a low-Reynolds-number regime, body dynamics, as well as on a biomimetic sensory system consisting of ocelli, halteres, magnetic compass, and optical flow sensors, have been used to generate realistic simulations for MFI

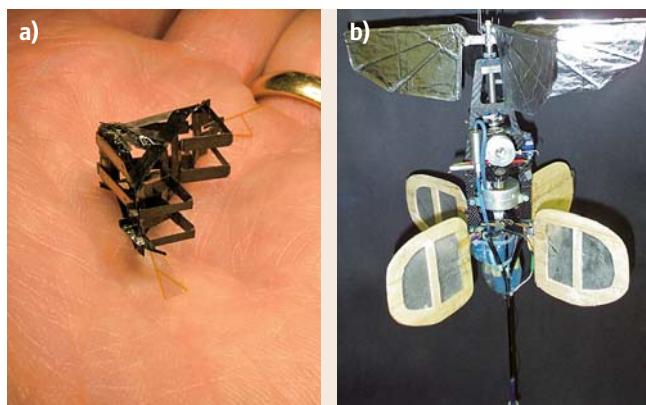

Fig. 60.15a,b Flapping-wing robots. **(a)** MFI ©Ronald Fearing, Berkeley's Electrical Engineering and Computer Science Department. **(b)** Mentor ©James DeLaurier, Institute for Aerospace Studies, University of Toronto

and insect flight. In turn, such simulations served to design a flight control algorithm maintaining stable flight in hovering mode [60.44, 45]. A first MFI platform, which flaps its two wings and is the right size, has already been produced (Fig. 60.15).

The four-winged ornithopter Mentor (Fig. 60.15), which is being developed at the University of Toronto as part of a general research effort targeted at flapping-wing flight [60.46, 47], is said to be the first artificial flapping-wing device that successfully hovered, doing so with the agility of a hummingbird. In particular, it exhibited the *clap-fling* behavior that the animal uses to enhance lift by clapping its wings together, then flinging them apart at high speeds. This augments the lift-producing bound vorticity on the wings. Likewise, the aircraft demonstrated the capability to shift from hovering to horizontal flight, which inspires current research. Mentor is about 30 cm long and weighs about 0.5 kg, but engineers eventually hope to shrink it to hummingbird size and weight. Other comparable micro aerial vehicle (MAV) devices are reported in [60.48, 49].

On a much larger scale, a few manned flapping-wing robots have also been designed. In Votkinsk in the

Fig. 60.16 The OCTARM robot ©Ian Walker, Department of Electrical and Computer Engineering, Clemson University

1990s, Toporov built a tow-launched biplane ornithopter that could reportedly be made to climb and fly for 200 m as a result of the pilot's muscular effort [60.50]. More recently, within the Ornithopter project of SRI International and the University of Toronto [60.51], the two-winged Flapper plane has flown for 14 s at an average speed of 88 km/h. It has a 12 m wingspan and weighs 350 kg with pilot and fuel. The wings are made of carbon fiber and Kevlar, and are moved by a gas-powered engine. A description of previous attempts at making such a platform fly is available in [60.52].

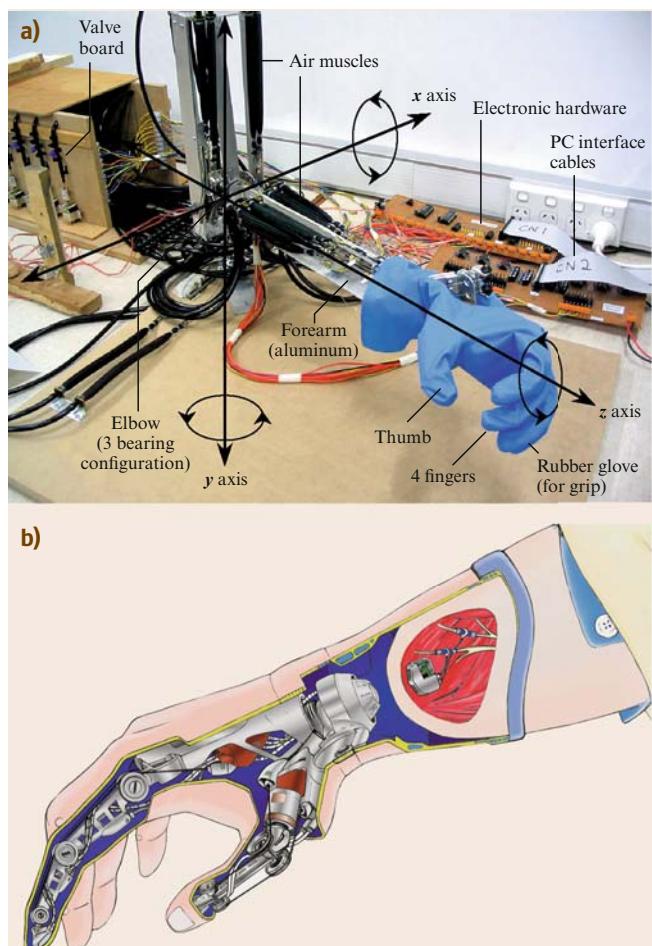

Fig. 60.17 (a) The humanoid hand of Curtin University of Technology. ©Euan Lindsay and Peter Scarfe, Mechatronic Engineering, Curtin University of Technology (b) The Cyberhand project ©Project Cyberhand (IST-2001-35094) and Scuola Superiore Santa Anna, Pisa

60.4.2 Grasping

When hunting and grabbing food, the octopus uses all the flexibility its arms are capable of. However, when feeding, the animal is able to bend its flexible arms to form *joints* like those in human arms. Inspired by such dexterous appendages found in cephalopods – particularly the arms and suckers of octopus, and the arms and tentacles of squid – Walker et al. [60.53] describe recent results in the development of a new class of soft, continuous-backbone robot manipulators. Fed by fundamental research into the manipulation tactics, sensory biology, and neural control of octopuses, this work in turn is leading to the development of artificial devices based on both electroactive polymers and pneumatic McKibben muscles, as well as to novel approaches to motion planning and operator interfaces for the so-called OCTARM robot (Fig. 60.16). Likewise, inspired by biological trunks and tentacles, a multisection continuum robot, Air-Octo, in which the extension of each section can be independently controlled, exhibits both bending and extension capacities, and demonstrates superior performance arising from the additional degrees of freedom than arms with comparable total degrees of freedom [60.54].

Human grasping has inspired the humanoid hand developed at Curtin University of Technology by Scarfe and Lindsay [60.55]. The corresponding system presents ten individually controllable degrees of freedom ranging from the elbow to the fingers, and is actuated through 20 McKibben air muscles, each supplied by a pneumatic pressure-balancing valve that allows for proportional control to be achieved with simple and inexpensive components. The hand is able to perform a number of

human-equivalent tasks, such as grasping and relocating objects (Fig. 60.17). A similar research is funded by the EC CYBERHAND project that aims at developing a cybernetic prosthetic hand [60.56]. It is hoped that the device will recreate the *lifelike* perception of the natural hand, and thus increase its acceptability. To this end, biomimetic sensors replicating the natural sensors are to be developed, and dedicated electrodes – capable of delivering sensory feedback to the amputee's central nervous system and extracting his intentions – are to be designed (Fig. 60.17).

Chapter 15 provides additional references to robot hands.

60.4.3 Drilling

Due to the ultraviolet flux in the surface layers of most bodies in the solar system, future astrobiological research is increasingly seeking to conduct subsurface penetration and drilling to detect the chemical signature for extant or extinct life. To address this issue, Gao et al. [60.57] present a bio-inspired micropenetrator implementing a novel concept of two-valve-reciprocating motion that is inspired by the way a wood wasp uses its ovipositor to drill holes into trees in order to lay its eggs. Indeed, such ovipositors can be split into two longitudinal halves, one side being equipped with cutting teeth and the other with pockets that serve to carry the sawdust away from the hole. The cutting teeth are used to cut the wood in compression and avoid buckling. The sawdust they produce is deposited into the pockets and carried to the surface on the upstroke. The two sides repeat this process in a reciprocating motion. The corresponding artificial system is lightweight (0.5 kg), driven at low power (3 W), and able to drill deep (1–2 m).

60.5 Bio-inspired Control Architectures

Attempts at tackling the *whole iguana* challenge [60.58], i.e., that of integrating sensors, actuators and control in the design of a simple but complete artificial animal, are abundant in the literature and several of the aforementioned realizations come under this objective. However, the corresponding controllers usually implement mere reflexes that serve to cope with present circumstances only. In this paragraph, more cognitive architectures, able to deal with past and future events as well, and in which adaptive mechanisms such as learning, evolution, and development may be incorporated, will be mentioned.

60.5.1 Behavior-Based Robotics

Under the aegis of so-called *behavior-based* robotics – to which Chap. 38 is dedicated – many systems with minimally cognitive architectures have been developed. For instance, the series of robots designed by Brooks and his students at MIT demonstrate that the *subsumption architecture* [60.59] may endow artificial animals with adaptive capacities that do not necessitate high-level reasoning [60.60]. Moreover, there are some indications that such control architecture may be at work in real animals, such as the coastal snail *Littorina* [60.61].

Likewise, the *schemas* that are used by Arkin and his students at the Georgia Institute of Technology to control numerous other robots [60.62] have roots in psychology [60.63] and neuroscience [60.64].

60.5.2 Learning Robots

Different bio-inspired learning mechanisms – like those implementing associative, reinforcement, or imitation learning schemes – are currently at work in robotic applications.

For instance, in the robotics laboratory at Nagoya University, the robot Brachiator is able to swing from handhold to handhold like a gibbon (Fig. 60.18). The robot is equipped with legs that generate initial momentum, and with a computer vision system to figure out where to place its hand-like grippers. A standard reinforcement learning algorithm is used to learn the right sensory-motor coordination required to move along a horizontal scale while hanging on successive rungs: it provides a punishment signal when the robot misses the next handhold, and a reward signal when it succeeds. Thus, after a number of failed trials, the robot eventually succeeds in safely moving from one extremity of the scale to the other [60.65].

Bio-inspired associative learning mechanisms are used in applications that capitalize upon the place cells and head-direction cells found in hippocampal and para-hippocampal structures in the brain to implement map-building, localization, and navigation capacities in robots (see [60.66–68] for reviews). Likewise, reinforcement learning mechanisms inspired by the presumed function of dopaminergic neurons [60.69] may be associated with models based on the anatomy and physiology of basal ganglia and related structures [60.70, 71], which endow a robot with a motivational system and action-selection capacities – i.e., those of deciding when to shift from one activity to another, according to the various subgoals the unexpected events encountered during the fulfillment of a given mission generate. Such controllers and capacities are currently combined in the Psikharpax artificial rat that will be able to explore an unknown environment, to build a topological map of it, and to plan trajectories to places where it will fulfill various internal needs, like *eating, resting, exploring* or *avoiding danger* [60.72] (Fig. 60.18) – as a contribution to the EC project ICEA mentioned before.

MirrorBot, another EC project [60.73], capitalizes on the discovery of mirror neurons in the frontal lobes of monkeys, and on their potential relevance to human brain evolution. Indeed, mirror neuron areas correspond

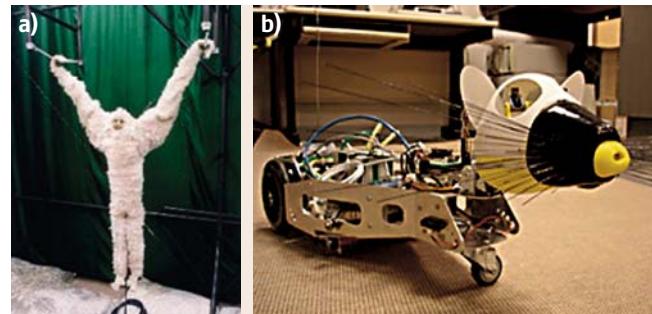

Fig. 60.18 (a) Brachiator, the artificial gibbon ©Toshio Fukuda, Department of Micro-Nano Systems Engineering, Nagoya University. (b) Psikharpax, the artificial rat ©Christophe Grand, Steve N'Guyen, Patrick Pirim, Bruno Gas, Ryad Benosman, ISIR, Université Paris 6

to cortical areas that are related to human language centers, and it seems that these neurons play a critical role in cortical networks establishing links between perception, action, and language [60.74]. The project has developed an approach of biomimetic multimodal learning, including imitation learning, using a mirror-neuron-based robot, and has investigated the task of foraging for objects that are designated by their names [60.75].

At the Neuroscience Institute in San Diego, a series of brain-based devices (BBDs) – i.e., physical devices with simulated nervous systems that guide behavior, to serve as a heuristic for understanding brain function – have been constructed. These BBDs are based on biological principles and alter their behavior to the environment through self-learning. The resulting systems autonomously generalize signals from the environment into perceptual categories and become increasingly successful in coping with the environment. Among these devices, the robot Darwin VII is equipped with a charge-coupled device (CCD) camera for vision, microphones for hearing, conductivity sensors for taste, and effectors to move its base and its head, and with a gripping manipulator having one degree of freedom. Its control architecture is made of 20 000 neurons, and it is endowed with a few instincts, like an interest in bright objects, a predilection for tasting things, and an innate notion of what tastes good. Thus, the robot explores its environment and quickly learns that striped blocks are yummy and that spotted ones taste bad. Based on the same robotic platform, Darwin VIII is equipped with a simulated nervous system containing 28 neural areas, 53 450 neuronal units, and approximately 1.7 million synaptic connections. It demonstrates that different brain areas and modalities can yield a coherent perceptual re-

sponse in the absence of any superordinate control, thus solving the so-called *binding* problem. In particular, the robot binds features such as colors and line segments into objects and discriminates between these objects in a visual scene [60.76]. Darwin IX is a mobile physical device equipped with artificial whiskers and a neural simulation based on the rat somatosensory system. Neuronal units with time-lagged response properties, together with the selective modulation of neural connection strengths, provide a plausible neural mechanism for the spatiotemporal transformations of sensory input necessary for both texture discrimination and selective conditioning to textures. Having an innate tendency to avoid *foot-shock* pads made of reflective construction paper deposited on the ground of its experimental arena, the

robot may be conditioned to avoid specific textures encountered near these aversive stimuli [60.77]. Darwin X incorporates a large-scale simulation of the hippocampus and surrounding areas, thus making it possible to solve a dry version of the Morris *water-maze* task, in which the robot must find a hidden platform in its environment using only visual landmarks and self-movement cues to navigate to the platform from any starting position [60.78]. Besides its ability to learn to run mazes like rats, Darwin X has been thrown into a soccer match, and turned out to be victorious in the 2005 RoboCup US Open. Finally, Darwin XI combines the main characteristics of several previous versions, including a whisker system, and serves to demonstrate the robot's capacity to learn the reward structure of the environment, as well as the reversal of behavior when this structure changes.

In the perspective of exploring the role that chaotic dynamics may play in self-organizing behavior, researchers involved in the [NASA](#)-funded self-organizing dynamically adaptable systems (SODAS) project are using a nonlinear dynamics approach to model how the brain, which is usually in a high-dimensional, disorderly *basal* state, instantly shifts from a chaotic state to an attractor four or five times a second in order to recognize something familiar, or to make a decision. Such phase transitions and attractors in one area of the brain affect attractors in other areas, and are considered to produce intentional behavior. Focused on the way the brain orients the body in space and uses positive and negative reinforcement from the environment to navigate autonomously to a destination, the goal of the SODAS project is to enable robots to do the same on future National Aeronautics and Space Administration ([NASA](#)) missions. In particular, it has produced the KIV architecture that models the brain's limbic system, the simplest neurological structure capable of acting intentionally in an inherently self-consistent manner. *Kozma et al.* [60.79] describe how, in a two-dimensional computer simulation of a Martian landscape, KIV uses positive and negative reinforcement to learn the most effective path to a goal, and uses habituation to reduce the distraction of ambient noise and other irrelevant sensory inputs.

Other bio-inspired approaches to the design of control architectures are to be found in Chap. 62, which is dedicated to neurorobotics.

60.5.3 Evolving Robots

Using appropriate evolutionary algorithms and artificial selection processes to adapt from generation to genera-

ation the code that describes a robot's controller has become current practice. Usually, an efficient code is sought in simulation and then implemented on a real robot [60.80].

At Chalmers University of Technology, for example, such an approach has been used to coordinate the visual information acquired through the two eyes of the humanoid robot Elvis (Fig. 60.19a) with the motor orders sent to its effectors. Thus the robot is able to track and point a visual target [60.81]. In a similar manner, at the Paris VI University, an incremental approach capitalizing upon solutions to simpler problems to devise solutions to more complex ones has been applied to the evolution of neural controllers for locomotion and obstacle avoidance in the six-legged SECT robot (Fig. 60.19b) [60.82]. At the same university, simulated artificial evolution has been applied to the control of horizontal flight in an artificial bird, or to slope-soaring in a glider [60.83]. The corresponding controllers will be implemented on real platforms as a contribution to the Robur project [60.84].

For the genetically organized lifelike electromechanics (Golem) project at Brandeis University, *Lipson* and *Pollack* [60.85] went beyond the evolution of hardware controllers and demonstrated for the first time a path that allows the transfer of virtual diversity of morphology into reality. They thus conducted a set of experiments in which simple electromechanical systems composed of thermoplastic, linear actuators, and neurons evolved from scratch to yield physical locomoting machines (Fig. 60.20).

Additional references to evolutionary robotics can be found in Chap. 61.

60.5.4 Developing Robots

Two varieties of developmental processes are currently applied to robotics. The first is related to evolution and aims at designing indirect coding schemes which, instead of directly specifying a robot's behavior and/or shape, describe developmental rules according to which complex neural controllers and/or morphologies can be derived from simple programs (see [60.86] for a review). This is done in the hope that the approach will scale up with the complexity of the control problems to be solved. Such a methodology has been applied at the Paris VI University to evolve neural controllers for diverse rolling, walking, swimming, and flying animals or robots [60.87].

The second series of developmental process (see [60.88] for a review) are related to learning and aim

at reproducing the successive sensory-motor and cognitive stages exhibited by developing animals, especially children [60.89]. As an example of such an endeavor, the upper-torso humanoid robot called Cog [60.90] (Fig. 60.21a), developed at MIT, has 22 DOFs and a variety of external and internal sensory systems, including visual, auditory, vestibular, kinesthetic, and tactile senses [60.91]. It has been endowed with various basic drives provided by its primary designers and, like a human baby, it has gone through a series of parallel developmental stages in its sensory-motor and cognitive capabilities. Among the results already acquired are the development of mechanisms for reaching and grasping, for rhythmic movement control, for

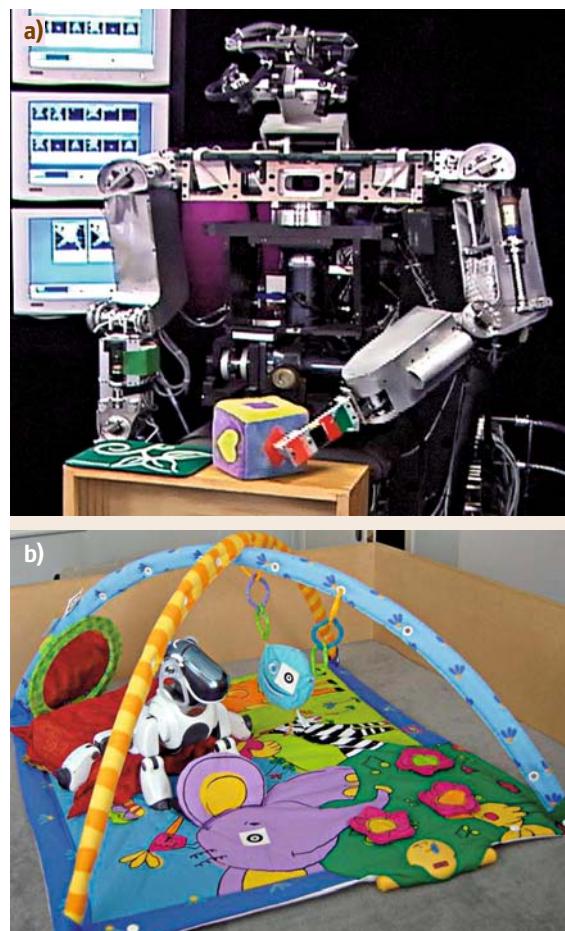

Fig. 60.21 (a) The Cog robot. ©Rodney Brooks, Computer Science and Artificial Intelligence Lab, MIT. (b) An Aibo robot in a playground environment ©Frédéric Kaplan, Sony Computer Science Laboratory, Paris

visual search and attention, for imitation learning, for emotional regulation of social dynamics, for saliency identification through shared attention, and for the emergence of a theory of mind [60.92]. The latter expression is commonly used to design the set of cognitive skills that make it possible to attribute beliefs, goals, and desires to other individuals. In a similar perspective, at Sony Computer Science Laboratory (CSL) in Paris, a mechanism of so-called *intelligent adaptive curiosity* serves as a source of self-development for an Aibo

robot placed in a playground environment (Fig. 60.21b) that tries to maximize its learning progress. According to this mechanism, the robot focuses on situations which are neither too predictable nor too unpredictable, and the complexity of its activity autonomously increases with time. In particular, it first spends time in situations which are easy to learn, then progressively shifts its attention to situations of increasing difficulty, avoiding situations in which nothing new can be learned [60.93].

60.6 Energetic Autonomy

The majority of bio-inspired systems described so far were targeted at increasing the robots' behavioral autonomy. However, a second, even more challenging, issue remains to be tackled, that of reproducing the energetic autonomy of animals, and the way they manage to discover and exploit resources to supply their energy needs. Very few attempts have been made in this direction yet. As a notable exception, Chew Chew was a 12-wheeled, train-like robot developed at the University of South Florida, which derived power through a microbial fuel cell (MFC) stomach (Fig. 60.22a). The stomach broke down refined sugar using *Escherichia coli* bacteria and then converted the chemical energy from that digestion process into electricity. The microbes from the bacteria fed on the sugar, which released electrons. These electrons, in turn, supplied a charge to the battery through a redox reaction. Moreover, the sugar cubes being completely dissolved by the microbes, the system produced very little waste [60.94].

Slugbot (Fig. 60.22b) was a robotic slug catcher developed at the Bristol Robotics Laboratory that was

equipped with a long articulated arm at the end of which were located a camera used for detecting slugs and a gripper used for catching them. The robot shined red light on the ground and used the camera to identify a shiny, sluglike object, which it picked up and dropped in a hopper [60.95]. Unfortunately, funding of the project ran out before researchers succeeded in refueling the robot's batteries through slug fermentation and methane production.

Although praiseworthy, these attempts did not provide convincing evidence that they could supply enough electricity to generate useful work and they have been abandoned. However, EcoBot II, a new robot that gets closer to true energetic autonomy, is under development at the Bristol Robotics Laboratory and benefits from previous experience. EcoBot II is equipped with an array of eight MFCs, in the anodes of which bacteria found in sludge act as catalysts to generate energy from dead flies supplied by a human operator or, more precisely, from sugar contained in their exoskeleton. Later on, the robot will be made predatory, using sewage or a pheromone

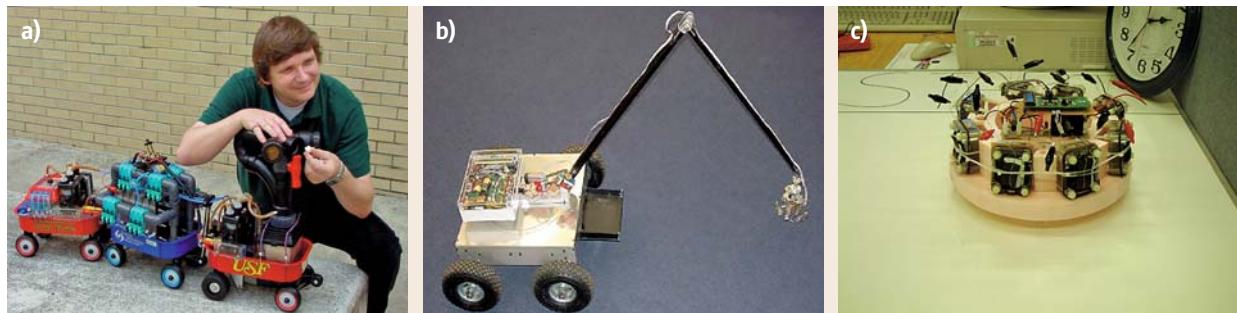

Fig. 60.22a–c Towards energetically autonomous robots: (a) Chew Chew ©Stuart Wilkinson, Mechanical Engineering Dept., University of South Florida, (b) Slugbot, and (c) EcoBot II ©Chris Melhuish, Bristol Robotics Laboratory, University of Bristol and University of the West of England

as a bait to catch the flies, and some form of pump to suck them into the digestion chambers. In the MFCs' cathodes, O₂ from free air acts as the oxidizing agent to take up the electrons and protons to produce H₂O. This closes the circuit and keeps the system balanced (Fig. 60.22c). Right now, EcoBot II can crawl along at a top speed of about 2–4 cm every 15 min and obtains

enough power to perform phototaxis while remotely reporting temperature measurements via radio at the same time [60.96]. This makes it the world's first robot to be performing four different types of behavior – sensing, processing, actuation, and communication – from unrefined biomass. These research efforts contribute to the EC project ICEA already mentioned.

60.7 Collective Robotics

Numerous research efforts contribute to the field of bio-inspired collective robotics [60.97] and several of them are described in Chap. 40, which is devoted to multiple mobile robot systems. Indeed, the collaboration of two or more workers is mandatory as soon as a given task cannot be accomplished by a single individual. This is the case, for instance, in several species of ants when workers co-operate to retrieve large preys. When one ant finds a prey item, it usually tries to move it, and, when unsuccessful for some time, recruits nestmates through direct contact or chemical marking. Within the group thus formed, ants change position and alignment until the prey can be moved toward the nest. A robotic implementation of this phenomenon is described in [60.98] and illustrates how decentralized problem solving may be implemented in a group of robots. Other demonstrations of robots that collaborate to solve a given task were produced within the framework of the SWARM-BOTS project that was funded by the EC and was focused on the design and implementation of self-organizing and self-assembling biologically inspired robots. A swarmbot is an aggregate of s-bots – i. e., a collection of mobile robots able to self-

assemble by connecting/disconnecting from each other. It can explore, navigate, and transport heavy objects on rough terrains in situations in which a single s-bot would have major problems achieving the task alone, like collectively passing over a gap too big for a single robot (Fig. 60.23) [60.99].

The coordination of a swarm of underwater glider robots in Monterey Bay is at the core of the adaptive sampling and prediction (ASAP) program, which is funded by the Office of Naval Research, and aims at measuring physicochemical parameters, and at tracking currents and upwellings [60.100]. Ultimately, the project may lead to the development of robot fleets that forecast ocean conditions and better protect endangered marine animals, track oil spills, and guide military operations at sea. Inspired by the behavior of schools of fish, the coordination policy of the robots allows them to capture the dynamic nature of the ocean while staying in organized patterns even as they are buffeted by strong currents. In particular, the paths that they follow are optimized as the ocean changes so that the measurements they take are permanently as information-rich as possible.

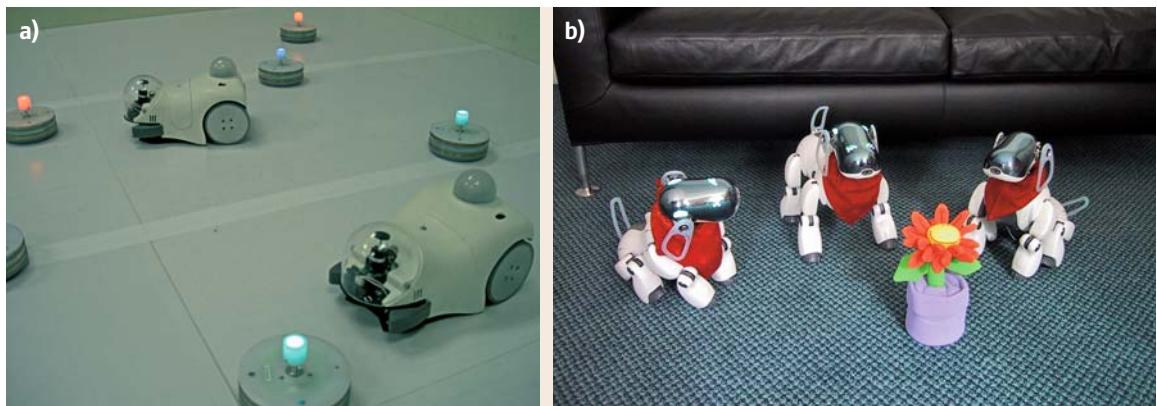

Fig. 60.25 (a) Cyber Rodents seeking battery packs ©Kenji Doya, Okinawa Institute of Science and Technology. (b) Three Sony Aibos paying attention to an object and possibly agreeing on a common word designating it ©Frédéric Kaplan, Sony Computer Science Laboratory, Paris

The NASA Institute for Advanced Concepts in Atlanta supports a project aiming at coordinating a fleet of refuelable Entomopter robots deployed from their *mothership*, a Pathfinder-like rover (Fig. 60.24), and flapping smartly through the thin, carbon-dioxide-laden atmosphere of Mars. With a 1 m wing span, each such robot could haul up to 15 kg of payload. A chemical muscle would generate autonomic wing beating from a liquid fuel source and provide a small amount of electricity to run onboard systems. Waste gas produced by the chemical muscle would be tapped for steering the robot while in flight, thereby making obstacle avoidance possible. Once airborne, the robots would flap at low altitude over Mars, sniffing atmospheric samples, looking for minerals, and even collecting rock and soil specimens. They could also provide the rover with essential navigation instructions. Finally, returning to home base, the Entomopters would suckle up to the rover, refueling themselves for another round of aerial maneuvers. Mini prototypes of such a flying robot have already been produced [60.101, 102] for terrestrial applications. In the same overall perspective, *Huntsberger* [60.103] describes the map-making memory and action-selection mechanism of the biologically inspired system for map-based autonomous rover control (BISMARC), an integrated control system for long-duration missions involving robots performing cooperative tasks, which is currently under development at the Jet Propulsion Laboratory (**JPL**) in Pasadena.

Besides cooperation, another variety of interaction is put to work in experiments that involve robots in artificial ecosystems, in which they usually compete for the acquisition of spare resources. This is, for example, the

case with the Cyber Rodent project at the Okinawa Institute of Science and Technology, a project that seeks to understand the origins of our reward and affective systems by building artificial agents that share the same intrinsic constraints as animals, i.e., self-preservation and self-reproduction. A Cyber Rodent is a robot that can search for and recharge from battery packs on the floor (Fig. 60.25a). It can also *mate* with a nearby agent, a process that entails the transfer of control programs through the robots' infrared communication ports. In particular, Cyber Rodents are used to study how evolution can help in the learning of battery-capturing behaviors, through the transfer of *genes* coding learning parameters such as the speed of memory update and the width of random exploration [60.104].

Finally, communication is at the heart of several projects that have been undertaken in the line of the so-called *talking heads* experiments [60.105] that studied the evolution of a shared lexicon in a population of embodied software agents. The agents developed their vocabulary by observing a scene through digital cameras and communicating about what they had seen together (Fig. 60.25b). Among such research efforts, the ECAgents project, which is sponsored by the EC, is developing a new generation of embodied agents that are able to interact directly with the physical world and to communicate between them and with other agents, including humans. For example, *Hafner* and *Kaplan* [60.106] studied how nonverbal communication in robots, like pointing gestures, can serve to bootstrap their shared communication systems by influencing the attention of one another. More generally, the ECAgents project investigates basic properties of

different communication systems – from simple communication systems in animals to human language and technology-supported human communication – to clarify the nature of existing communications systems and to provide ideas for designing new technologies based on collections of embodied and communicating de-

vices. This will be achieved through the development of new design principles, algorithms, and mechanisms that can extend the functionality of existing technological artefacts (mobile phone, WI-FI devices, robots and robot-like artefacts, etc.) or lead to the development of entirely new ones.

60.8 Biohybrid Robots

The solutions that nature has evolved to difficult engineering problems are, in many cases, far beyond present-day engineering capability. Therefore, when engineers are unable to reproduce the functionalities of some sensor, actuator or controller embodied in a living creature, they may try to integrate the corresponding biological component into a so-called *biohybrid* robot, thus physically using biology to augment technology. This has been done by *Kuwana et al.* [60.107], who equipped a mobile robot with living silk-moth antennas, the electroantennogram signals they produced being sent to an external computer that translated them into

actuator signals. In a pheromone plume, this robot exhibited a locomotion pattern similar to that of a male silk moth and succeeded in locating a pheromone source. Likewise, *Herr and Dennis* [60.108] built a swimming robot actuated by two explanted frog semitendinous muscles and controlled by an embedded microcontroller. The muscles got their energy from the glucose solution that the fish was swimming in. Using open-loop stimulation protocols, the robot performed basic maneuvers such as starting, stopping, turning, and straight-line swimming at a maximum speed of 1/3 body-lengths/second.

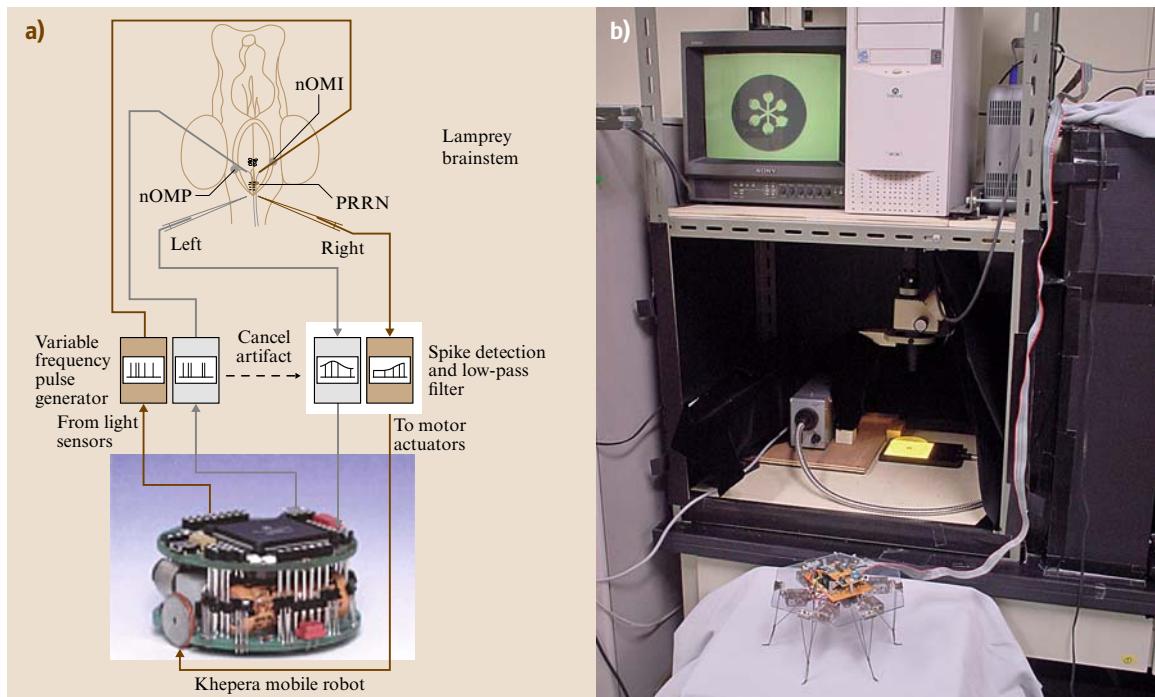

Fig. 60.26 (a) A robot controlled by a lamprey brainstem ©Sandro Mussa-Ivaldi, Depts. of Physiology, Physical Medicine & Rehabilitation and Biomedical Engineering, Northwestern University. **(b)** A robot controlled by a slime mold ©Soichiro Tsuda, Graduate School of Science and Technology, Kobe University

Bakkum et al. [60.109] review a series of experiences in which cultures of real neurons are used to control robots. At Northwestern University, for instance, the part of the lamprey's brain that works to keep the animal's body balanced has been connected to a two-wheeled Khepera robot. In normal circumstances, the corresponding circuit receives vestibular and other sensory signals and issues motor commands to stabilize the orientation of the body during swimming. In the experimental setup that was used, light receptors on the robot sensed the surroundings, and a computer translated that information into electrical impulses that were fed into the lamprey's neurons. The latter interpreted the impulses as they would if they were trying to keep the animal swimming upright. The computer then translated the cells' signals back into electrical commands instructing the robot how to turn its wheels in response to a light (Fig. 60.26a). Such experiments have provided useful hints about the adaptive capacities of the neuronal circuit, demonstrating that different behaviors can be generated with different electrode locations, and that the prolonged suppression of one input channel leads to altered responsiveness long after it has been restored [60.110].

A similar approach has been undertaken at the University of Southampton where, instead of calling upon numerous interconnected neurons, a single-celled organism – *Physarum polycephalum*, a bright yellow slime mold that can grow to several meters in diameter and naturally shies away from light – has been used to control the movement of a hexapod robot so that it kept out of light and sought dark places in which to hide itself. The experimenters grew the slime in a six-pointed star shape on top of a circuit and connected it remotely, via a computer, to the robot. Any light shone on sensors mounted on top of the robot was used to control light shone onto one of the six points of the circuit-mounted mold, each corresponding to a leg of the robot (Fig. 60.26b). As the slime tried to get away from the light its movement was sensed by the circuit and used to control one of the robot's six legs. The robot then scrabbled away from bright lights as a mechanical embodiment of the mold [60.111].

Finally, entire brains may be used to control robotic devices, as done at Duke University, where a rhesus monkey was taught to intentionally control the movement of a robot arm in real time, using only signals from his brain and visual feedback on a video screen. A neuronal model, which was developed by monitoring normal brain and muscle activity as a monkey moved

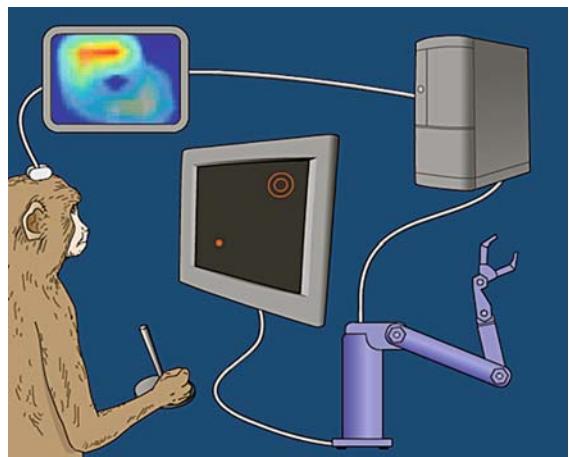

Fig. 60.27 A monkey brain controlling a robotic arm. After <http://www.biotele.com/>

his own arm, served to translate the brain signals from the monkey into movements of the robot arm. While the monkey was using a joystick to move a cursor on a computer screen, readings were taken from a few hundred neurons in the frontal and parietal regions of his brain. The activation of the biceps and wrist muscles was monitored, as were the velocity of the arms and the force of the grip. Once the neuronal model had developed an accurate level of prediction, the control of the cursor was switched from the joystick to the robotic arm, which in turn was controlled by the monkey's brain signals. At first the monkey continued moving his own arm whilst carrying out the task, but in time he learned that this was no longer necessary and stopped doing so [60.112] (Fig. 60.27).

Obviously, such technology affords great perspectives in the rehabilitation of people with brain and spinal cord damage, on the one side, while raising ethical issues, on the other side [60.113]. ETHICBOTS, an EC-sponsored project [60.114] is devoted to the identification and analysis of techno-ethical issues concerning the integration of human beings and artificial devices. Obviously, such concerns need to be extended to other animals as well, in cases where, for example, a living Madagascar hissing cockroach is placed atop a modified trackball to control a three-wheeled robot as part of an artistic project [60.115].

Finally, Chap. 33 on exoskeletons provides other examples of the integration of human beings and artificial devices, while Chap. 64 insists on the social and ethical implications of robotics.

60.9 Discussion

It appears that almost all the continuum previously evoked has been covered by the numerous realizations described in this review. In particular, it should be clear that a kangaroo-shaped toy robot has almost nothing to do with a real kangaroo, and that some of the devices that afford a robot a sense of touch or smell do reproduce a natural functionality, but certainly not in the exact way in which it is implemented in a living creature. Such realizations are clearly bio-inspired, but definitely not biomimetic, and they must be placed near the continuum's first extremity. Towards the other extremity, the optoelectronic circuits that copy the mechanisms implementing visual reflexes in the fly, or the artificial neural networks that copy the brain structures involved in navigation, action-selection and planning in mammals capitalize on almost all the relevant and currently available biological knowledge. They are clearly biomimetic even if their degree of realism may certainly be improved, if only because there are still a lot of discoveries to be made regarding the inner workings of these mechanisms and structures *in vivo*.

Noticing that important recent achievements in robotics have been inspired by living systems does not mean that purely engineering approaches to the field have not also lead to spectacular advances, as evidenced by numerous chapters in this handbook. Conversely, under the pretext that nature never invented the wheel, the jet plane or the laser range-finder, denying any usefulness to bio-inspired approaches to robotics would sound like rear-guard action. In fact, microscopic wheels do exist in nature such as in Adenosine 5'-triphosphate (ATP) synthase and bacterial flagellum. Additionally, the wheel-like locomotion of tumbleweed balls across the desert has inspired the [JPL Tumbleweed rover](#), i. e., a quasi-spherical vehicle intended to traverse a planetary surface with a rolling and/or bouncing motion driven by the wind [60.116]. Instead, the interesting issue is that of delineating the applications for which such approaches are most likely to be useful to robotics. In this regard, although we repeatedly deplored several years ago [60.117, 118] that the field of robotics did not favor a profusion of comparisons that would allow us to understand which architectures and working principles allow an animal or a robot to solve a given kind of problem in a particular environment, we are compelled to observe that the situation has not improved since that time. Considering, for instance, the profusion of models, working principles, physical realizations, and the like that characterize the robotic applications to navigation [60.66, 67],

nothing would be more useful than systematic comparisons in which different robots would be confronted with the same problem, and different problems would be tackled by the same robot.

Be that as it may, the main lesson to be drawn from this review is probably that, if human inventions may be irreplaceable for optimizing a given functionality in rather predictable circumstances, drawing inspiration from the solutions discovered via natural tinkering [60.119] may be particularly useful for finding operational compromises to multi-optimization problems raised by survival issues in unpredictable environments, i. e., to issues that engineers have carefully postponed as much as possible up to now. Indeed, probably few people would deny that the capacities of autonomy and adaptation exhibited by living creatures far exceed those of current robots, which are seldom confronted with the necessity of coping with permanent changes in their external environment or in their inner needs, motivations or emotions, nor at the constraint of freeing themselves from human-delivered energy resources.

Besides the fact that numerous sensors, actuators or control architectures in animals are often still more efficient than the artificial devices they have inspired – either for reasons tied to technological limitations or to lack of biological knowledge – perhaps the principal reason for the superiority of animals over robots lies in their greater degree of integration. In fact, in the 3.5 billion years since the appearance of life on Earth, natural sensors, effectors, and control architectures have been offered enough time to coevolve and produce coherent wholes, a process that contrasts strongly with the current practice of engineers, who often independently design and produce the various components that they later assemble into a given artifact. Unfortunately, the laws governing natural evolution and integration are far from being deciphered and exploited in a more efficient manner than in current evolutionary robotics applications.

This last remark is related to the observation that biologists too, in their tendency to favor reductionist over holistic approaches, often postpone the consideration of integrative mechanisms and processes that future robotics will mostly need. Indeed, in its endeavor to unravel the mysteries of natural life, traditional biology usually seeks to decompose a system into its constituent subsystems and then to study these in isolation from one another, according to a top-down, analytical, and reductionist approach. On the contrary, people involved in

artificial life or robotics research attempt to reproduce given characteristics of living systems with man-made artifacts such as computers or robots. Ideally, their approach is bottom-up and starts with a collection of entities or modules exhibiting properties or behaviors that are simple and well understood, and organizes them into more complex systems in which internal interac-

tions generate emergent lifelike properties. Obviously, fruitful interactions are to be expected between these people and biologists who will devote their research efforts to the kind of integrative considerations advocated here. Many such interactions are already in place, as demonstrated in this chapter and several others in this handbook.

60.10 Conclusion

This chapter has reviewed numerous recent applications of bio-inspired solutions to robotics. It seems likely that such solutions will prove to be even more useful as future robots are confronted with similar survival issues to those experienced by animals in unpredictable environments. This will require subsequent progress in the corresponding biological knowledge, a process to which tight collaboration between numerous disciplines, including robotics, may well critically contribute.

Evolutionary

61. Evolutionary Robotics

Dario Floreano, Phil Husbands, Stefano Nolfi

Evolutionary Robotics is a method for automatically generating artificial brains and morphologies of autonomous robots. This approach is useful both for investigating the design space of robotic applications and for testing scientific hypotheses of biological mechanisms and processes. In this chapter we provide an overview of methods and results of Evolutionary Robotics with robots of different shapes, dimensions, and operation features. We consider both simulated and physical robots with special consideration to the transfer between the two worlds.

61.1 Method

Evolutionary robotics is a method for the automatic creation of autonomous robots [61.1]. It is inspired by the Darwinian principle of selective reproduction of the fittest, captured by evolutionary algorithms [61.2]. In evolutionary robotics, robots are considered as autonomous artificial organisms that develop their own control system and body configuration in close interaction with the environment without human intervention. Drawing inspiration from principles of biological self-organization, evolutionary robotics includes elements of evolutionary, neural, developmental, and morphological systems. The idea that an evolutionary process could drive the generation of control systems dates back to

at least the 1950s [61.3] with a more explicit form appearing in the mid 1980s with the ingenious thought experiments by neuroscientist *Valentino Braitenberg* on neurally driven vehicles [61.4]. In the early 1990s, the first generation of simulated artificial organisms with a genetic code describing the neural circuitry and morphology of a sensory motor system began evolving on computer screens [61.5–8]. At that time, real robots were still complicated and expensive machines that required specialized programming techniques and skillful manipulation. Towards the end of that period, a new generation of robots started to emerge that shared important characteristics with simple biological systems:

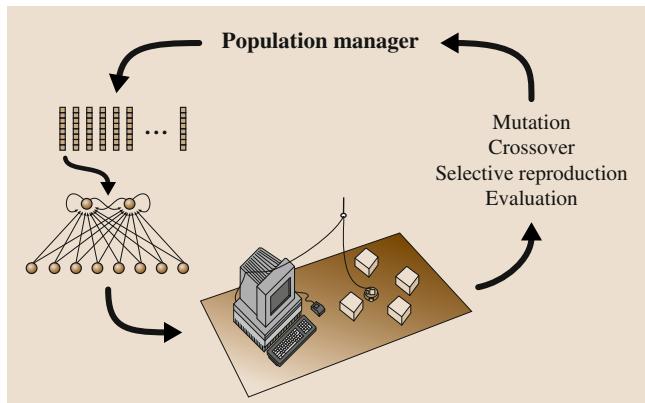

Fig. 61.1 Evolutionary experiments on a single robot. Each individual of the population is decoded into a corresponding neurocontroller which reads sensory information and sends motor commands to the robot every 300 ms while its fitness is automatically evaluated and stored away for reproductive selection

robustness, simplicity, small size, flexibility, and modularity [61.9, 10]. Above all, those robots were designed so that they could be programmed and manipulated by people without engineering training. Those technological achievements, together with the growing influence of biological inspiration in artificial intelligence [61.11], coincided with the first evolutionary experiments on real robots [61.12–14], and the term evolutionary robotics was coined [61.15].

The major methodological steps in evolutionary robotics proceed as follows (Fig. 61.1). An initial population of different artificial chromosomes, each encoding the control system (and possibly the morphology) of a robot, is randomly created. Each of these chromosomes is then decoded into a corresponding controller, for example a neural network, and downloaded into the processor of the robot. The robot is then let free to act (move, look around, manipulate the environment) according to a genetically specified controller while its performance for a given task is automatically evaluated. Performance evaluation is done by a fitness function that measures how fast and straight the robot moves, how frequently it collides with obstacles, etc. This procedure is repeated for all chromosomes of the population. The fittest individuals (those that have received more fitness points) are allowed to reproduce by generating copies of their chromosomes with the addition of random modifications introduced by genetic operators (e.g., mutations and exchange of genetic material). The newly obtained population is then tested again on the same robot. This process is repeated for a number of generations until an individual is born which satisfies the fitness function set by the user. The control system of evolved robots, encoded in an artificial genome, is therefore generated by a repeated process of selective reproduction, random mutation, and genetic recombination, similarly to what happens in natural evolution.

61.2 First Steps

In an early experiment on robot evolution without human intervention, carried out at Ecole Polytechnique Fédérale de Lausanne (EPFL) [61.12], a small wheeled robot was evolved for navigation in a looping maze (Fig. 61.2). The Khepera robot has a diameter of 55 mm and two wheels with controllable velocities in both directions of rotation. It also has eight infrared sensors, six on one side and two on the other side, that can function either in active mode to measure distance from obstacles or in passive mode to measure the amount of (infrared) light in the environment. The robot was connected to a desktop computer through rotating contacts that provided both power supply and data exchange through a serial port.

A simple genetic algorithm [61.16] was used to evolve the synaptic strengths of a neural network composed of eight sensory neurons and two motor neurons.

Each sensory unit was clamped to one of the eight active infrared sensors whose value was updated every 300 ms. Each motor unit received weighted signals from the sensory units and from the other motor unit, plus a recurrent connection with itself with a 300 ms delay. The net input of the motor units was offset by a modifiable threshold and passed through a logistic squashing function. The resulting outputs, in the range [0, 1], were used to control the two motors so that an output of 1 generated maximum rotation speed in one direction, an output of 0 generated maximum rotation speed in the opposite direction, and an output of 0.5 did not generate any motion in the corresponding wheel. A population of 80 individuals, each coding the synaptic strengths and threshold values of the neural controllers, was initialized with all weights set to small random values centered around zero. Each individual was tested on the phys-

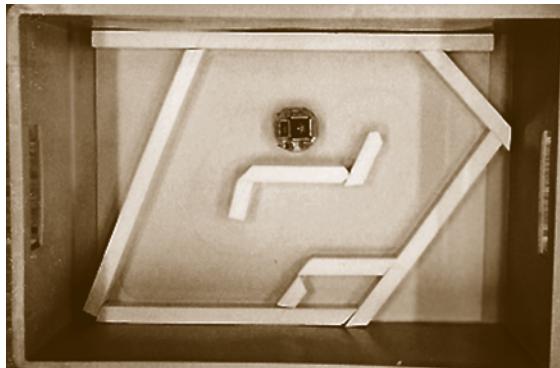

Fig. 61.2 Bird's-eye view of the desktop Khepera robot in the looping maze

ical robot for 80 sensorimotor cycles (approximately 24 s) and evaluated at every cycle according to a fitness function with three components measured onboard the robot:

$$\phi = V(1 - \sqrt{\Delta v})(1 - i), \quad (61.1)$$

where V is the average rotation speed of the two wheels, Δv is the absolute value of the algebraic difference between the signed speed values of the wheels (positive is one direction, negative the other), and i is the normalized activation value of the infrared sensor with the highest activity. The first component is maximized by speed, the second by straight motion, and the third by distance from objects.

During the first 100 generations, both average and best fitness values grew steadily, as shown in Fig. 61.3. A fitness value of 1.0 would correspond to a robot moving straight at maximum speed in an open space and therefore was not attainable in the looping maze shown in Fig. 61.2, where some of the sensors were often active and where several turns were necessary to navigate. Figure 61.4 shows the trajectory of the best individual of the last generation.

Although the fitness function did not specify in what direction the robot should navigate (given that it was perfectly circular and that the wheels could rotate in both directions), after a few generations all the best individuals moved in the direction corresponding to the side with the highest number of sensors. Individuals moving in the other direction had a higher probability of colliding into corners without detecting them and thus disappeared from the population. Furthermore, the cruising speed of the best evolved robots was approximately half of the maximum speed that could be technically achieved and did not increase even when the evolution-

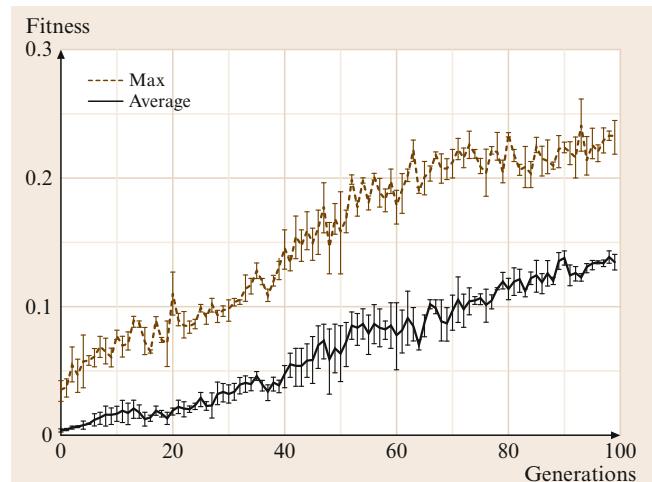

Fig. 61.3 Average fitness of the population and fitness of the best individual at each generation (error bars show standard error over three runs from different initial populations)

ary experiment was continued up to 200 generations. Further analysis revealed that this self-limitation of the navigation speed had an adaptive function because, considering the sensory and motor refresh rate together with the response profile of the distance sensors, robots that traveled faster had a higher risk of colliding with walls before detecting them; they gradually disappeared from the population.

Despite its simplicity, this experiments shows that evolution can discover solutions that match not only

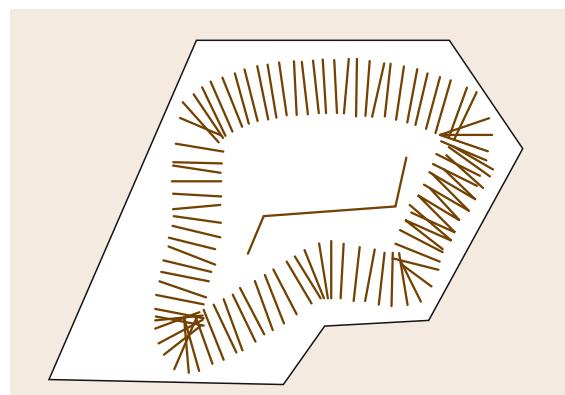

Fig. 61.4 Trajectory of the robot with the best neural controller of the last generation. Segments represent the axis between the two wheels. Data were recorded and plotted every 300 ms using an external laser positioning device

the computational requirements of the task to be solved, but also the morphological and mechanical properties of the robot in relation to its physical environment.

61.2.1 Evolution of Neural Controllers for Walking

Over the past 15 years or so, there has been a growing body of work on evolving controllers for various kinds of walking robots – a nontrivial sensorimotor coordination task. Early work in this area concentrated on evolving dynamical network controllers for simple (abstract) simulated insects (often inspired by cockroach studies) which were required to walk in simple environments [61.18, 19]. Earlier, *Beer* had introduced a neural architecture for locomotion based on studies of cockroaches [61.17], which is shown in Fig. 61.5. The promise of this work soon led to versions of this methodology being used on real robots. Probably the first success in this direction was by *Lewis* et al. [61.14, 20] who evolved a neural controller for a simple hexapod robot using coupled oscillators built from continuous-time, leaky-integrator, artificial neurons. All evaluations were done on the actual robot with each leg connected to its own pair of coupled neurons, leg swing being driven by one neuron and leg elevation by the other. These pairs of neurons were cross connected, in a manner similar to that used by *Beer* and *Gallagher* [61.19] (Fig. 61.5), to allow coordination between the legs. In order to speed up the process, they employed staged evolution where first an oscillator capable of moving a leg was evolved and then an architecture based on these oscillators was further evolved to develop walking. The robot was able to execute an efficient tripod gait on flat surfaces.

Gallagher et al. [61.21] described experiments where neural networks controlling locomotion in an artificial insect were evolved in simulation and then successfully downloaded onto a real hexapod robot. This machine was more complex than *Lewis* et al.'s, with a greater number of degrees of freedom per leg. In this approach, each leg was controlled by a fully connected network of five continuous-time, leaky-integrator neurons, each receiving a weighted sensory input from that leg's angle sensor. Initially the architecture shown in Fig. 61.5 was used, with the connection weights and neuron time constants and biases under genetic control. This produced efficient tripod gaits for walking on flat surfaces. In order to produce a wider range of gaits operating at a number of

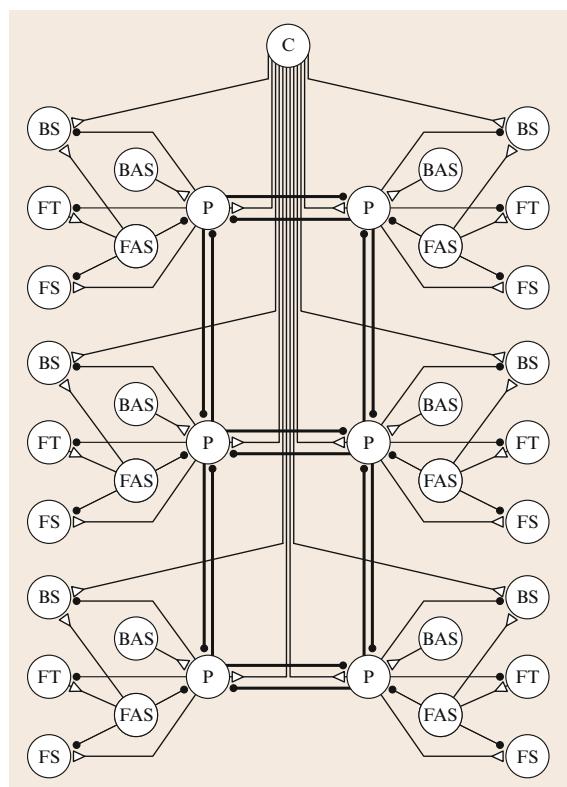

Fig. 61.5 Schematic diagram of a distributed neural network for the control of locomotion as used by *Beer* et al. [61.17]. Excitatory connections are denoted by open triangles and inhibitory connections are denoted by filled circles. C, command neuron; P, pacemaker neuron; FT, foot motor neuron; FS and BS, forward swing and backward swing motor neurons; FAS and BAS, forward and backward angle sensors

speeds such that rougher terrain could be successfully negotiated, a different distributed architecture, more inspired by stick insect studies, was found to be more effective [61.22].

Galt et al. [61.23] used a genetic algorithm to derive the optimal gait parameters for a Robug III robot, an eight-legged, pneumatically powered walking and climbing robot. The individual genotypes represented parameters defining each leg's support period and the timing relationships between leg movements. These parameters were used as inputs to a mechanistic finite-state machine pattern-generating algorithm that drove the locomotion. Such algorithms, which are often used in conventional walking machines, rely on relatively simple control dynamics and do not have the

same potential for the kind of sophisticated multigait coordination that complex dynamical neural network architectures, such as those described in this section, have been shown to produce. However, controllers were successfully evolved for a wide range of environments and to cope with damage and systems failure (although an individual controller had to be tuned to each environment; they were not able to self-adapt across a wide range of conditions). *Gomi and Ide* [61.24] evolved the gaits of an eight-legged robot (Fig. 61.6) using genotypes made of eight similarly organized sets of genes, each gene coding for leg motion characteristics such as the amount of delay after which the leg begins to move, the direction of the leg's motion, the end positions of both vertical and horizontal swings of the leg, and the vertical and horizontal angular speed of the leg. After a few dozen generations, where evaluation was on the robot, a mixture of tetrapod and wave gaits was obtained. Using the cellular encoding [61.25] developmental approach – which genetically encodes a grammar-tree program that controls the division of cells growing into a dynamical recurrent neural network of the kind used by Beer and colleagues – *Gruau* [61.26] evolved a single-leg neural controller for the same eight-legged robot used by Gomi and Ide. This generated a smooth and fast quadrupod locomotion gait. *Kodjabachian and Meyer* [61.27] extended this work to develop more sophisticated locomotion behaviors. *Jakobi* [61.28] successfully used his minimal simulation techniques (described in Sect. 61.3) to evolve controllers for the same eight-legged robot as

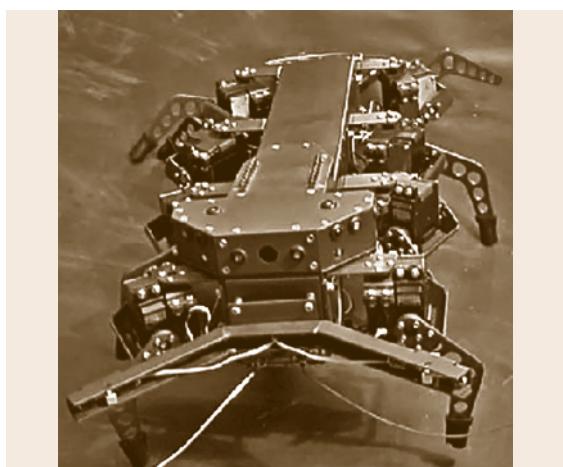

Fig. 61.6 The octopod robot built by Applied AI Systems Inc.

Gruau. Evolution in simulation took less than 2 h on what would today be regarded as a very slow computer, and was then successfully transferred to the real robot. *Jakobi* evolved modular controllers based on Beer's continuous recurrent networks to control the robot as it engaged in walking about its environment, avoiding obstacles and seeking out goals depending on the sensory input. The robot could smoothly change gait, move backward and forward, and even turn on the spot. More recent work has used similar architectures to those explored by the researchers mentioned above, to control more mechanically sophisticated robots such as the Sony Aibo [61.29].

Recently there has been successful work on evolving coupled oscillator style neural controllers for the highly unstable dynamic problem of biped walking. *Reil and Husbands* [61.30] showed that accurate physics based simulations using physics-engine software could be used to develop controllers able to generate successful bipedal gaits. Reil and colleagues have now significantly developed this technology to exploit its commercial possibilities, in the animation and games industries, for the real-time control of physically simulated three-dimensional (3-D) humanoid characters engaged in a variety of motor behaviors (see [61.31] for further details). Coupled neural oscillators have been evolved also to control the swimming pattern of articulated, snake-like, underwater robots using physics-based simulations [61.32].

Vaughan has taken related work in another direction. He has successfully applied evolutionary robotics techniques to evolve a simulation of a 3-D ten-degree-of-freedom bipedal robot. This machine demonstrates many of the properties of human locomotion. By using passive dynamics and compliant tendons, it conserves energy while walking on a flat surface. Its speed and gait can be dynamically adjusted and it is capable of adapting to discrepancies in both its environment and its body's construction [61.33]. The parameters of the body and continuous dynamical neural network controller were under genetic control. The machine started out as a passive dynamic walker [61.34] on a slope, and then throughout the evolutionary process the slope was gradually lowered to a flat surface. The machine demonstrated resistance to disturbance while retaining passive dynamic features such as a passive swing leg. This machine did not have a torso, but Vaughan has also successfully applied the method to a simplified two-dimensional (2-D) machine with a torso above the hips. When pushed, this dynamically stable bipedal machine

walks either forward or backwards just enough to release the pressure placed on it. It is also able to adapt to external and internal perturbations as well as variations in body size and mass [61.35].

McHale and Husbands [61.36, 37] have compared many forms of evolved neural controllers for bipedal and quadrupedal walking machines. Recurrent dynamical continuous time networks and GasNets (described in Sect. 61.6.3) were shown to have advantages in most circumstances. The vast majority of the studies

mentioned above were conducted for relatively benign environments. Notwithstanding this observation, we can conclude that the more complex dynamical neural network architectures, with their intricate dynamics, generally produce a wider range of gaits and generate smoother, more adaptive locomotion than the more standard use of systems based on finite-state machines employing parameterized rules governing the timing and coordination of individual leg movements [61.38].

61.3 Simulation and Reality

Few of the experiments in the previous section were carried out entirely on physical robots because

1. evolution may take a long time, especially if it is carried out on a single robot that incarnates the bodies of all the individuals of the evolving population;
2. the physical robot can be damaged because populations always contain a certain number of poorly performing individuals (for example, colliding against walls) by effect of random mutations;
3. restoring the environment to initial conditions between trials of different individuals or populations (for example, replenishing the arena with objects) may not always be feasible without human intervention;
4. evolution of morphologies and evolution of robots that can grow during their lifetime is almost impossible with today's technology without some level of human intervention.

For those reasons, researchers often resort to evolution in simulation and transfer the evolved controllers to the physical robot. In the case of morphology evolution, the physical robot is manually assembled according to the evolved specifications. However, it is well known that programs that work well in simulations may not function properly in the real world because of differences in sensing, actuation, and in the dynamic interactions between robot and environment [61.39]. This *reality gap* is even more evident in adaptive approaches, such as evolutionary robotics, where the control system and morphology are gradually crafted through the repeated interactions between the robot and the environment. Therefore, robots will evolve to match the specificities of the simulation, which differ from the real world. Al-

though these issues clearly rule out any simulation based on grid worlds or pure kinematics, over the last 10 years simulation techniques have dramatically improved and resulted in software libraries that model reasonably well dynamical properties such as friction, collision, mass, gravity, and inertia [61.40]. These software tools allow one to simulate articulated robots of variable morphology and their environment as fast as, or faster than, real time in a desktop computer. Today, those physics-based simulations are widely used by most researchers in evolutionary robotics and indeed most of the work with highly articulated robots is carried out with those simulations.

Nonetheless, even physics-based simulations include small discrepancies that can accumulate over time and result in very different behavior from reality (for example, a robot may get stuck against a wall in simulation whereas it can get free in reality, or vice versa). Also, physics-based simulations cannot account for diversity of response profiles of the individual sensors, motors, and gears of a physical robot. There are at least four methods to cope with these problems and improve the quality of the transfer from simulation to reality.

A widely used method consists of adding independent noise to the values of the sensors provided by the model and to the end position of the robot computed by the simulator [61.41]. Some software libraries allow the introduction of noise at several levels of the simulation. This solution prevents evolution from finding solutions that rely on the specificities of the simulation model. One may also sample the actual sensor values of the real robot positioned at several angles and distances from objects of different texture. Those values are then stored in a look-up table and retrieved with the addition of noise according to the position of the

robot in the environment [61.42]. This method proved to be very effective for generating controllers that transfer smoothly from simulation to reality. A drawback of this sampling method is that it does not scale up well to high-dimensional sensors (e.g., vision) or geometrically complicated objects.

Another method, also known as minimal simulations, consists of modeling only those characteristics of the robot and environment that are relevant for the emergence of desired behaviors [61.43]. These characteristics, which are referred to as base-set features, should be accurately modeled in simulation. Instead, all the other characteristics, which are referred to as implementation aspects, should be randomly varied across several trials of the same individual in order to ensure that evolving individuals do not rely on implementation aspects, but rely on base-set features only. Base-set features must also be varied to some extent across trials in order to ensure some degree of robustness of the individual with respect to base-set features, but this variation should not be so large that reliably fit controllers fail to evolve at all. This method allows very fast evolution of complex robot–environment situations, as in the example of the hexapod walk described in Sect. 61.2.1. A drawback of minimal simulations is that it is not always easy to tell in advance which are the base-set features that are relevant for the desired behavior.

Yet another method consists of the coevolution of the robot (control and/or morphology) and of the simulator parameters that are most likely to differ from the real world and that may affect the quality of the transfer [61.44]. This method consists of coevolving two populations, one encoding the properties of the robot and one encoding the parameters of the simulator. Coevolution happens in several passes through a two-stage

process. In stage one, a randomly generated population of robots are evolved in the default simulator and the best individual is tested on the real robot while the time series of sensory values are recorded. In stage two, the population of simulators is evolved to reduce the difference between the time series recorded on the real robot and the time series obtained by testing evolved robots within the simulator. The best evolved simulator is then used for stage one where a new randomly generated population is evolved and the best individual is tested on the real robot to generate the time series for stage two of simulator evolution. This two-stage coevolution is repeated several times until the error between simulated and real robot behavior is the smallest possible. It has been shown that approximately 20 passes of the two-stage process are sufficient to evolve a good control system that could be transferred to an articulated robot. In that case, the real robot was used to test only 20 individuals.

Finally, another method consists of genetically encoding and evolving the learning rules of the control system, rather than its parameters (e.g., connection strengths). The parameters of the decoded control system are always initialized to small random values at the beginning of an individual lifetime and must self-organize using the learning rules [61.45]. This method prevents evolution from finding a set of control parameters that fit the specificities of the simulation model, and encourages emergence of control systems that remain adaptive to partially unknown environments. When such an evolved individual is transferred to the real robot, it will develop online its control parameters according to the genetically evolved learning rules and taking into account the specificities of the physical world. This method is described in more detail in Sect. 61.7.2 on evolution of learning.

61.4 Simple Controllers, Complex Behaviors

Behavior is a dynamical process resulting from nonlinear interactions (occurring at a fast time rate) between the agent’s control system, its body, and the environment [61.46, 47]. At any time step, the environment and the agent–environment relation influence the body and the motor reaction of the agent, which in turn influences the environment and/or the agent–environmental relation (Fig. 61.7). Sequences of these interactions lead to a dynamical process where the contributions of the different aspects (i.e., the robot’s control system, the

robot’s body, and the environment) cannot be separated. This implies that even complete knowledge of the elements governing the interactions provides little insight into the behavior emerging from these interactions [61.48, 49].

An important advantage of evolutionary robotics is that it is not necessary to identify the relations between the rules governing the interactions and the resulting behavior [61.1, 49]. Evolutionary robotics is an adaptation process where the free parameters of the robots that

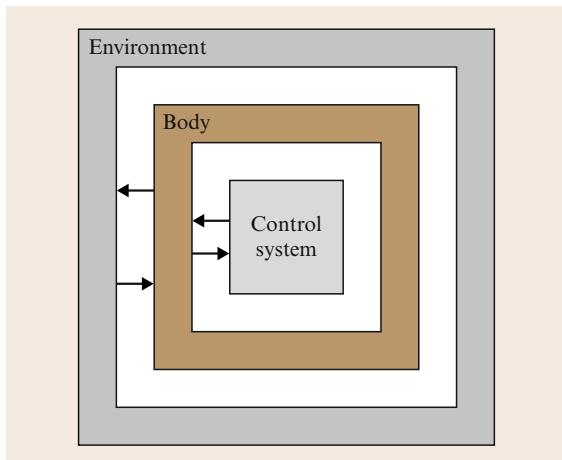

Fig. 61.7 Robot behavior results from nonlinear interactions, occurring at fast time rates, between the agent's control system, its body, and the environment

regulate the interactions, initially randomly assigned, are modified through a process of random variation and are selected and/or discarded on the basis of their effects at the behavioral level. These characteristics allow evolving robots to discover useful behavioral properties emerging from the interactions without the need to identify the relations between the rules governing the interaction and the resulting behavior. An emergent behavioral property or behavior is a form of behavior that can hardly be predicted or inferred by an external observer even when they have complete knowledge of the interacting elements and of the rules governing those interactions. The possibility of developing robots that exploit emergent behavior, in turn, allows evolutionary methods to come up with simple solutions to problems that are complex from an observer's perspective.

As an example (Fig. 61.8), consider the case of a Khepera robot placed in an arena surrounded by walls and containing a food object (i.e., a cylindrical object) that the robot should find and remain close to [61.50]. The robot is provided with eight infrared sensors and two motors controlling the two corresponding wheels. From the point of view of an external observer, solving this problem requires robots able to:

1. explore the environment until an obstacle is detected
2. discriminate whether the obstacle detected is a wall or a cylindrical object

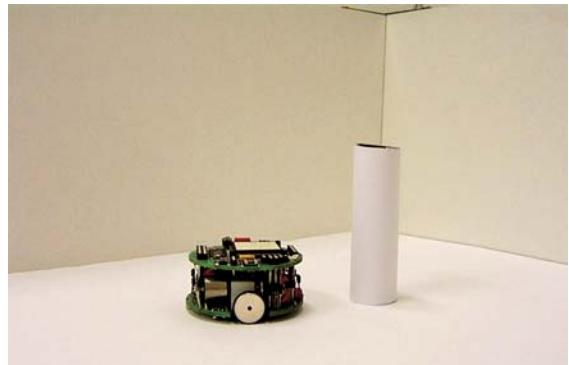

Fig. 61.8 The environment and the robot. The environment consists of an arena of 60×35 cm and contains a cylindrical objects placed at a randomly selected location

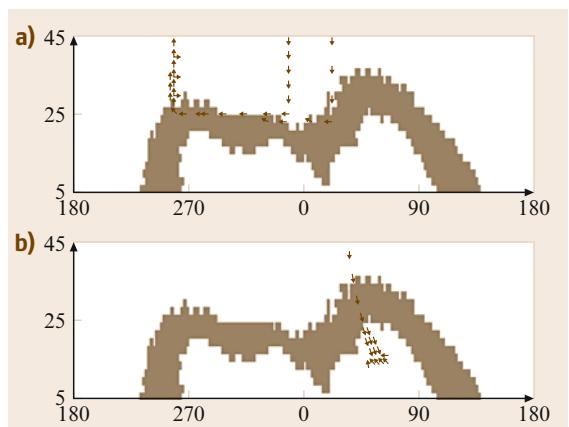

Fig. 61.9a,b Angular trajectories of an evolved robot close to a wall (a) and to a cylinder (b). The picture was obtained by placing the robot at a random position in the environment, leaving it free to move for 500 cycles, and recording its relative movements with respect to the two types of objects for distances smaller than 45 mm. For sake of clarity, arrows are used to indicate the relative direction, but not the amplitude of movements

3. approach or avoid the object depending on the object type

A detailed analysis of the sensory patterns experienced by the robot indicated that the task of discriminating the two objects is far from trivial since the two classes of sensory patterns experienced by

robots close to a wall and close to cylindrical objects overlap significantly. However, robots evolved for the ability to solve this task resorted to a strategy that does not require explicit discrimination of the two types of objects [61.50].

In all replications of the experiment, the evolved robot moved away from walls, but when they encountered the food object tended to oscillate back and forth or left and right in its proximity (Fig. 61.9). This solution consists of producing a behavioral attractor near the cylindrical object. A behavioral attractor is a series of sensorimotor sequences that maintain the robot close to the object. In this case, the forward movement in front of the cylindrical object generates a variation of the sensory

pattern experienced by the robot that, in turn, triggers a backward movement.

Therefore, evolved robots do not solve the problem by discriminating the two type of objects (cylinder and wall) and displaying an approaching or avoiding behavior, but rather exploit behaviors that emerge from the interaction between the robot's control system, the robots' body, and the environment. The possibility to discover and rely on these forms of emergent behavior allows evolving robots to find computationally simple solutions to apparently complex problems. Indeed, the problem described in this section only requires a simple reactive neural controller with one layer of feedforward connections between sensors and motors.

61.5 Seeing the Light

The experiments described so far rely mainly on relatively simple distance sensors, such as active infrared or sonar. Pioneering experiments on evolving visually guided behaviors were performed at Sussex University [61.51] on a specially designed gantry robot (Fig. 61.10). Discrete-time dynamical recurrent neural networks and visual sampling morphologies were concurrently evolved: the brain was developed in tandem with the visual sensor [61.13, 52, 53]. The robot was designed to allow real-world evolution by having *off-board* power and processing so that the robot could be run for long periods while being monitored by automatic

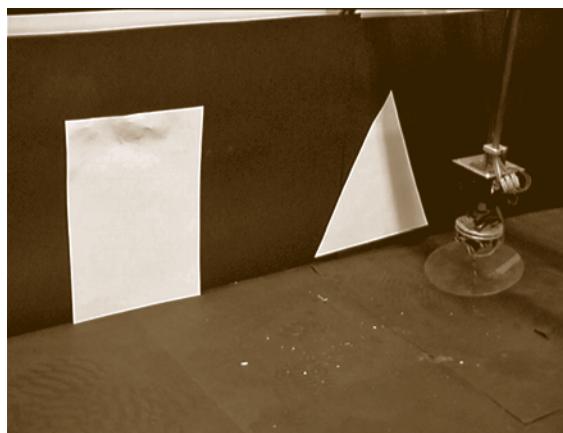

Fig. 61.10 The gantry robot used in the visual discrimination task. The camera inside the top box points down at the inclined mirror, which can be turned by the stepper motor beneath. The lower plastic disk is suspended from a joystick to detect collisions with obstacles

fitness evaluation functions. A charge-coupled device (**CCD**) camera points down towards a mirror angled at 45° as shown in Fig. 61.10. The mirror can rotate around an axis perpendicular to the camera's image plane. The camera is suspended from the gantry, allowing motion in the X , Y , and Z dimensions. This effectively provides an equivalent to a wheeled robot with a forward-facing

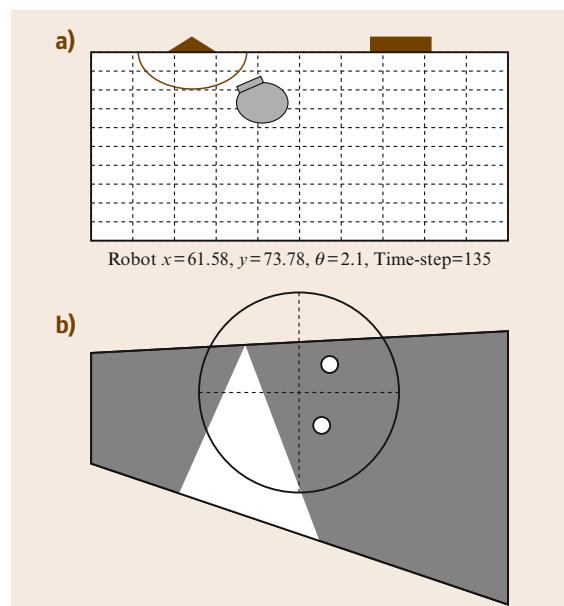

Fig. 61.11a,b The shape discrimination task. **(a)** The position of the robot in the arena, showing the target area in front of the triangle. **(b)** The robot camera's field of view showing the visual patches selected by evolution for sensory input

camera when only the X and Y dimensions of translation are used. The additional dimension allows flying behaviors to be studied.

The apparatus was initially used in a manner similar to the real-world experiments on navigation in the looping maze with the miniature mobile robot described in Sect. 61.2. A population of strings encoding robot controllers and visual sensing morphologies were stored on a computer to be downloaded one at a time onto the robot. The exact position and orientation of the camera head can be accurately tracked and used in the fitness evaluations. A number of visually guided navigation behaviors were successfully achieved, including navigating around obstacles, tracking moving targets, and discriminating between different objects [61.52]. The evolutionary process was incremental. The ability to distinguish between two different targets was evolved on top of the single target-finding behavior. The chromosome was of dynamic length so the neurocontroller was structurally further developed by evolution to achieve the new task (neurons and connections added). In the

experiment illustrated in Figs. 61.10 and 61.11, starting from a random position and orientation, the robot had to move to the triangle rather than the rectangle. This had to be achieved irrespective of the relative positions of the shapes and under very noisy lighting conditions. Recurrent neural network controllers were evolved in conjunction with visual sampling morphologies. Only genetically specified patches from the camera image were used (by being connected to input neurons according to the genetic specification). The rest of the image was thrown away. This resulted in extremely minimal systems using only two or three pixels of visual information, yet still able to perform the task reliably under highly variable lighting conditions [61.13, 52].

This was another example of staged, or incremental, evolution to obtain control systems capable of solving problems that are either too complex or may profit from an evolutionary methodology that discovers, preserves, and builds upon subcomponents of the solution. For an evolutionary method that incorporate strategies to explicitly address this issue, interested readers may refer to [61.54]. However, staged evolution remains a poorly explored area of evolutionary robotics that deserves further study and a more principled approach [61.55] in order to achieve increasingly complex robotic systems.

61.5.1 Coevolution of Active Vision and Feature Selection

Machine vision today can hardly compete with biological vision despite the enormous power of computers. One of the most remarkable – and often neglected – differences between machine vision and biological vision is that computers are often asked to process an entire image in one shot and produce an immediate answer whereas animals take time to explore the image over time, searching for features and dynamically integrating information over time.

Active vision is the sequential and interactive process of selecting and analyzing parts of a visual scene [61.56–58]. *Feature selection* instead is the development of sensitivity to relevant features in the visual scene to which the system selectively responds, e.g., [61.59]. Each of these processes has been investigated and adopted in machine vision. However, the combination of active vision and feature selection is still largely unexplored. An intriguing hypothesis is that coevolution of active vision and feature selection could greatly simplify the computational complexity of vision-based behavior by facilitating each other's task.

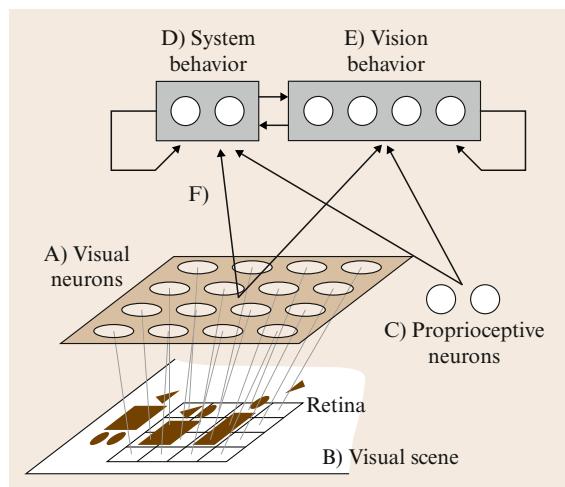

Fig. 61.12 The neural architecture of the active vision system is composed of: (A) a grid of visual neurons with nonoverlapping receptive fields whose activation is given by (B) the grey level of the corresponding pixels in the image; (C) a set of proprioceptive neurons that provide information about the movement of the vision system; (D) a set of output neurons that determine the behavior of the system (pattern recognition, car driving, robot navigation); (E) a set of output neurons that determine the behavior of the vision system; and (F) a set of evolvable synaptic connections. The number of neurons in each subsystem can vary according to the experimental settings

This hypothesis was investigated in a series of experiments [61.60] on coevolution of active vision and feature selection for behavioral systems equipped with a primitive moving retina and a deliberately simple neural architecture (Fig. 61.12). The neural architecture was composed of an artificial retina and two sets of output units. One set of output units determined the movement and zooming factor of the retina, and the other set of units determined the behavior of the system, such as the response of a pattern-recognition system, the control parameters of a robot, or the actions of a car driver. The neural network was embedded in a behavioral system and its input/output values were updated every 300 ms while its fitness was computed. Therefore, the synaptic weights of this network were responsible for both the visual features on which the system based its behavior and for the motor actions necessary to search for those features.

In a first set of experiments, the neural network was embedded in a simulated pan–tilt camera and asked to discriminate between triangles and squares of different size that could appear at any location of a screen (Fig. 61.13a), a perceptual task similar to that explored with the gantry robot described in Sect. 61.5. The visual system was free to explore the image for 60 s while continuously reporting whether the current screen showed a triangle or a square. The fitness was proportional to the amount of correct responses accumulated over the 60 s for several screenshots containing various instances of the two shapes. Evolved systems were capable of correctly identifying the type of shape with 100% accuracy after a few seconds despite the fact that this recognition problem is not linearly separable and that the neural network does not have hidden units, which in theory are necessary to solve nonlinearly separable tasks. Indeed, the same neural network presented with the same set of images and trained with supervised learning, but without the possibility to actively explore the scene, was not capable of solving the task. The evolved active vision system developed sensitivity to vertical edges, oriented edges and corners, and used its movement to search for these features in order to tell whether the shape was a triangle or a square. These features, which are also found in the early visual system of almost all animals, are invariant to size and location.

In a second set of experiments, the neural network was embedded in a simulated car and was asked to drive over several mountain circuits (Fig. 61.13b). The simulator was a modified version of a car race video game. The neural network could move the retina across the scene seen through the windscreens at the driver's seat

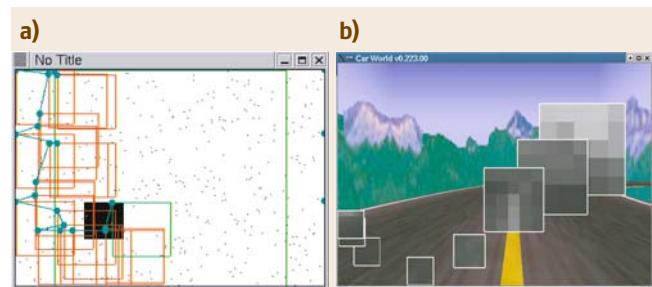

Fig. 61.13 (a) An evolved individual explores the screen searching for the shape and recognizes it by the presence of a vertical edge. (b) Search for the edge of the road at the beginning of a drive over a mountain road

Fig. 61.14 A mobile robot with a pan–tilt camera is asked to move within the walled arena in the office environment

and control the steering, acceleration, and braking of the car. The fitness was inversely proportional to the time taken to complete the circuits without exiting the road. Evolved networks completed all circuits with time laps competitive to those of well-trained students controlling the car with a joystick. The evolved network started by searching for the edge of the road and tracked its relative position with respect to the edge of the windscreens in order to control steering and acceleration. This behavior was supported by the development of sensitivity to oriented edges.

In a third set of experiments, the neural network was embedded in a real mobile robot with a pan–tilt camera that was asked to navigate in a square arena with low walls located in an office (Fig. 61.14). The fitness was proportional to the amount of straight motion measured over two minutes. Robots that hit the walls because they watched people or other irrelevant features of the office had lower fitness than robots that could perform long

straight paths and avoid walls of the arena. Evolved robots tended to fixate the edge between the floor and the walls of the arena, and turned away from the wall when the size of its retinal projection became larger than a threshold. This combination of sensitivity to oriented edges and looming is also found in the visual circuits of several insects and birds.

In a further set of experiments [61.61], the visual pathway of the neural network was augmented by an intermediate set of neurons whose synaptic weights could be modified by Hebbian learning [61.62] while the robot moved in the environment. All the other synaptic weights were genetically encoded and evolved. The results showed that lifelong development of the recep-

tive fields improved the performance of evolved robots and allowed robust transfer of evolved neural controllers from simulated to real robots, because the receptive fields developed sensitivity to features encountered in the environment where they happen to be born (see also the section above on simulation and reality). Furthermore, the results showed that the development of visual receptive fields was significantly and consistently affected by active vision as compared to the development of receptive fields passively exposed to the same set of sample images. In other words, robots evolved with active vision developed sensitivity to a smaller subset of features in the environment and actively tracked those features to maintain a stable behavior.

61.6 Computational Neuroethology

Evolutionary robotics is also used to investigate open questions in neuroscience and cognitive science [61.65] because it offers the vantage point of a behavioral system that interacts with its environment [61.66]. Although the results should be carefully considered when drawing analogies with biological organisms, evolutionary

robotics can generate and test hypotheses that could be further investigated with mainstream neuroscience methods.

For example, the active vision system with Hebbian plasticity described in the previous section was used to answer a question raised by *Held* and *Hein* [61.63] in the 1960s. The authors devised the apparatus shown in Fig. 61.15 where the free movements of a kitten (*active kitten*) were transmitted to a second kitten that was carried in a gondola (*passive kitten*). The second kitten could move its head, but its feet did not touch the ground. Consequently, the two kitten received almost identical visual stimulation, but only one of them received that stimulation as a result of body self-movement. After a few days in that environment, only the active kitten displayed normal behavior in several visually guided tasks. The authors suggested the hypothesis that proprioceptive motor information resulting from generation of actions was necessary for the development of normal, visually guided behavior.

The kitten experiments were replicated by cloning an evolved robot controller and randomly initializing the synaptic values of the adaptive visual pathways in both clones. One cloned robot was then left free to move in a square environment while the other cloned robot was forced to move along imposed trajectories, but was free to control its camera position, just like the passive kitten [61.67]. The results indicated that the visual receptive fields and behaviors of passive robots differ significantly from those of active robots. Furthermore, passive robots that were later left free to move were no longer capable of properly avoiding walls. A thorough analysis of neural activation correlated with behavior of the robot

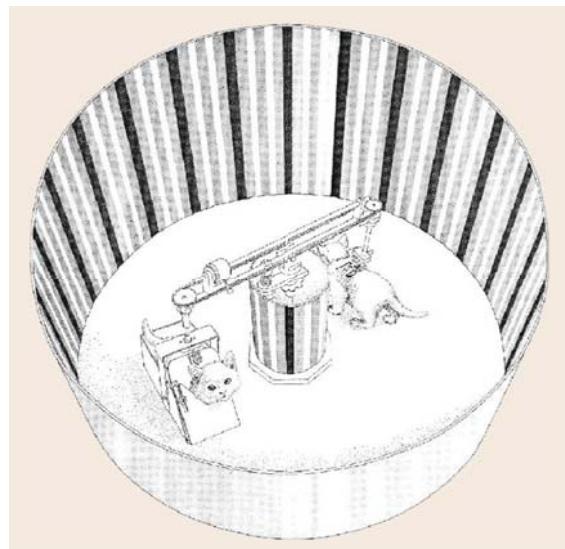

Fig. 61.15 The original apparatus in [61.63], where the gross movements of a kitten moving almost freely were transmitted to a second kitten that was carried in a gondola. Both kittens were allowed to move their head. They received essentially the same visual stimulation because of the unvarying pattern on the walls and the center post of the apparatus (after [61.64], with permission)

and even transplantation of neurons across active and passive robots revealed that the poor performance was due to the fact that passive robots could not completely select the visual features they were exposed to. Consequently, passive robots developed sensitivity to features that were not functional to their normal behavior and interfered with other dominant features in the visual field. Whether this explanation also hold for living animals remains to be further investigated, but at least these experiments indicated that motor feedback is not necessary to explain the pattern of pathological behavior observed in animals and robots.

61.6.1 Emergence of Place Cells

Let us now consider the case of an animal exploring an environment and periodically returning to its nest to feed. It has been speculated that this type of situation requires the formation of spatial representations of the environment that allow the animal to find its way home [61.68]. Different neural models with various degrees of complexity and biological detail that could provide such functionality have been proposed [61.69, 70].

Would a robot evolved under similar survival conditions develop a spatial representation of the environment and, if so, what type of representation would that be? These questions were explored using the same Khepera robot and evolutionary methodology described in Sect. 61.2 for reactive navigation in the looping maze. The environment was a square arena with a small patch on the floor in a corner where the robot could instantaneously recharge its (simulated) battery (Fig. 61.16). The environment was located in a dark room with a small light tower over the *recharging station*.

The sensory system of the robot was composed of eight distance sensors, two ambient-light sensors (one on each side), one floor-color sensor, and a sensor for battery charge level. The battery lasted only 20 s and had a linear discharge. The evolutionary neural network included five fully connected internal neurons between sensory and motor neurons. The same fitness function described in Sect. 61.2 for navigation in the looping maze was used, except for the middle term which had been used to encourage straight navigation in the looping maze. The fitness value was computed every 300 ms and accumulated over the life span of the individual. Therefore, individuals who discovered where the charger was could live longer and accumulate more fitness by exploring the environment (individuals were killed if they survived longer than 60 s to limit the experimentation time).

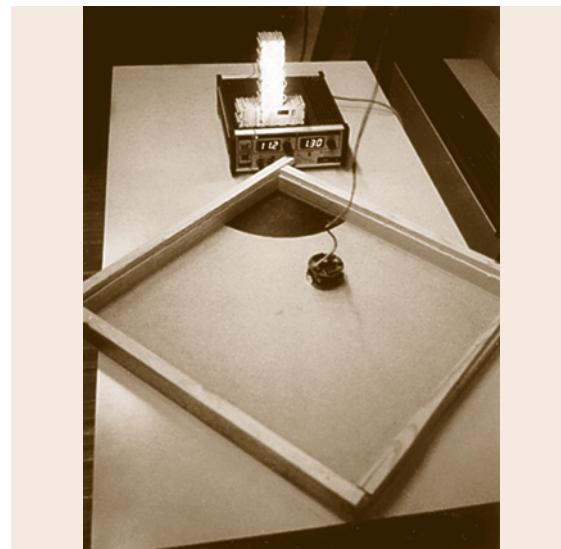

Fig. 61.16 Bird's eye view of the arena with the light tower over the recharging station and the Khepera robot

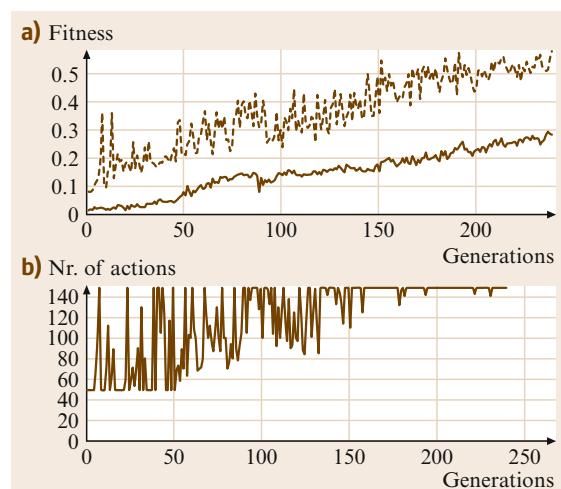

Fig. 61.17 (a) Average population fitness (*continuous line*) and fitness of the best individual (*dotted line*). **(b)** Life span of the best individuals measured as number of sensorimotor cycles, or actions. Individuals start with a full battery which lasts 50 actions (20 s), if not recharged. The maximum life span is 150 actions

The same physical robot evolved for 10 days and nights as both the fitness and life span of individuals continued to increase (Fig. 61.17). After approximately 200 generations, the robot was capable of navigating around the environment, covering long trajectories while avoid-

ing both walls and the recharging area. When the battery was almost discharged it initiated a straight navigation towards the recharging area and exited immediately after battery recharge to resume navigation. Best evolved individuals always entered the recharging area one or two seconds before full discharge of the battery. That implies that robots must somehow calibrate the timing and trajectory of their homing behavior depending on where they happened to be in the environment.

In order to understand how that behavior could possibly be generated, a set of neuroethological measures were performed using a laser positioning device that provided exact position and orientation of the robot every 300 ms. By correlating the robot position and behavior with the activation of the internal neurons in real time while the evolved individual freely moved in the environment, it was possible to see that some neurons specialized for reactive behaviors, such as obstacle avoidance, forward motion, and battery monitoring. Other neurons instead displayed more complex activation patterns. One of them revealed a pattern of activation levels that depended on whether the robot was oriented facing the light tower or facing the opposite direction (Fig. 61.18). In the former case, the activation pattern

reflected zones of the environment and paths typically followed by the robot during exploration and homing. For example, the robot trajectory towards the recharging area never crossed the two *gate walls* visible in the activation maps around the recharging station. When the robot faced the opposite direction, the same neuron displayed a gradient field orthogonally aligned with the recharging area. This gradient provides an indication of the distance from the recharging area. Interestingly, this pattern of activity is not significantly affected by the charge level of the battery.

The functioning of this neuron reminds of the classic findings on the hippocampus of the rat brain where some neurons (also known as *place cells*) selectively fire when the rat is in specific areas of the environment [61.71]. Also, the orientation-specific pattern of neural activation measured on the evolved robot is reminiscent of the so-called *head-direction neurons* in the rat hippocampus, which are positioned nearby place cells, whose firing patterns depend on the rat heading direction with respect to an environmental landmark [61.72]. Although the analogy between brains of evolved robots and of biological organisms should not be taken too literally, these results indicate that the two organisms converge towards a functionally similar neural strategy, which may be more efficient to address this type of situation than a strategy that does not rely on representations (but only on reactive strategies such as random motion, light following, or dead reckoning).

61.6.2 Spiking Neurons

The great majority of biological neurons communicate using self-propagating electrical pulses called *spikes*, but from an information-theoretic perspective it is not yet clear how information is encoded in the spike train. Connectionist models [61.73], by far the most widespread, assume that what matters is the *firing rate* of a neuron, that is, the average quantity of spikes emitted by the neuron within a relatively long time window (for example, over 100 ms). Alternatively, what matters is the average number of spikes of a small population of neurons at a give point. In these models the real-valued output of an artificial neuron represents the firing rate, possibly normalized relatively to the maximum attainable value. Pulsed models [61.74], instead, are based on the assumption that the *firing time*, that is, the precise time of emission of a single spike, may convey important information [61.75]. Spiking neuron models have slightly more complicated dynamics of synaptic and membrane integration. Depending on one's theory

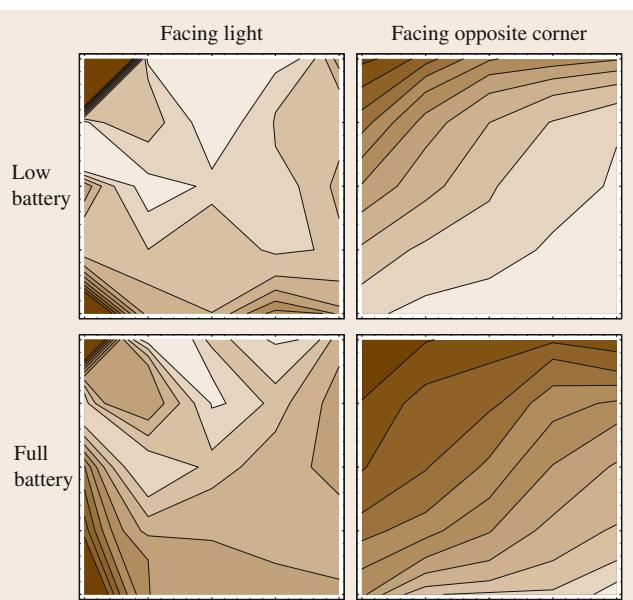

Fig. 61.18 Activation levels (brightness proportional to activation) of an internal neuron plotted over the environment while the robot was positioned at various locations in each of the four conditions (facing recharging area or not, discharged battery or not). The recharging area is located at the *top left corner* of each map

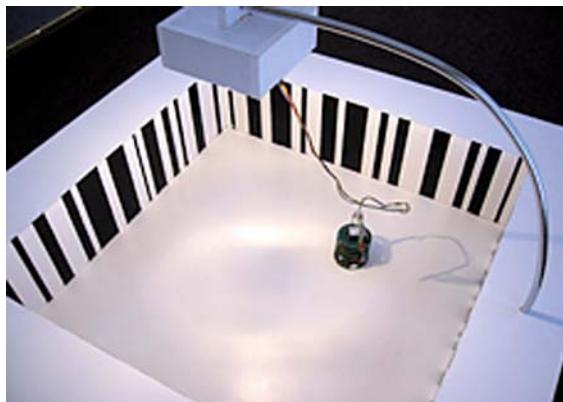

Fig. 61.19 A network of spiking neurons is evolved to drive the vision-based robot in the arena. The light below the rotating contacts allows continuous evolution also overnight

of what really matters, connectionist or spiking models are used.

However, designing circuits of spiking neurons that display a desired functionality is still a challenging task. The most successful results in the field of robotics obtained so far focused on the first stages of sensory processing and on relatively simple motor control [61.76, 77]. Despite these implementations, there are not yet methods for developing complex spiking circuits that could display minimally cognitive functions or learn behavioral abilities through autonomous interaction with a physical environment.

Artificial evolution represents a promising methodology to generate networks of spiking circuits with desired functionalities expressed as behavioral criteria (fitness function). Evolved networks could then be examined to detect what communication modality is used and how that correlates with observed behavior of the robot.

Floreano and colleagues [61.78] evolved a fully connected network of spiking neurons for driving a vision-based robot in an arena painted with black stripes of variable size against a white background (Fig. 61.19). The Khepera robot used in these experiments was equipped with a vision turret composed of one linear array of grayscale photoreceptors spanning a visual field of 36°. The output values of a bank of local contrast detection filters were converted in spikes (the stronger the contrast, the larger the number of spikes per second) sent to ten fully connected spiking neurons implemented according to the spike response model [61.79]. The spike series of a subset of these neurons was translated into motor commands (more spikes per second corresponded

to faster rotation of the wheel). The fitness function was the amount of forward translation of the robot measured over 2 min. Consequently robots that turned in place or hit the walls had comparatively lower fitness than robots that could move straight and turn only to avoid walls. The genome of these robots was a bit string that encoded only the sign of the neurons and the presence of synaptic connections. Existing connections were set to 1 and could not change during the lifetime of the robot.

Evolution reliably discovered very robust spiking controllers in approximately 20 generations (approximately 30 h of evolution on the real robot). Evolved robots could avoid not only the walls, but any object positioned in front of them. Detailed analysis of the best evolved controllers revealed that neurons did not exploit time differences between spikes, which one would have expected if optic flow was used to detect distance from walls. Instead, they simply used the number of incoming spikes (firing rate) as an indication of when to turn. When the robot perceived a lot of contrast it would go straight, but when the contrast decreased below a certain threshold (indicating that it approached an object), it started to turn away. This extremely efficient and simple result seems to be in contrast with theories of optic flow detection in insects and may be worth considering as an alternative hypothesis for vision-based behavior.

Spiking neural networks turned out to be more evolvable than connectionist models (at least for this task). One possible explanation is that spiking neurons have subthreshold dynamics that, to some extent, can be affected by mutations without immediately affecting the output of the network.

The robust results and compact genetic encoding encouraged the authors to use an even simpler model of spiking neuron so that the entire neural network could be mapped in less than 50 bytes of memory. The evolutionary algorithm was also reduced to a few lines of code and the entire system was implemented within

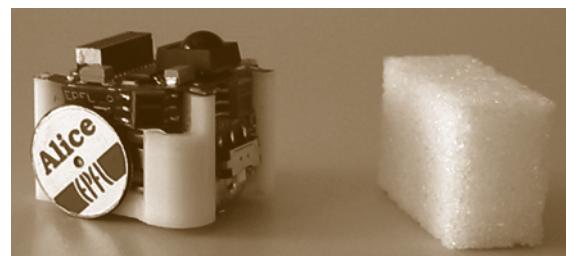

Fig. 61.20 The Alice sugar-cube robot equipped with the evolutionary spiking neural network implemented within its PIC microcontroller

a programmable intelligent computer (**PIC**) microcontroller without the need for any external computer for data storage. The system was used for a sugar-cube robot (Fig. 61.20) that autonomously and reliably developed the ability to navigate around a maze in less than an hour [61.80]. Interestingly, evolved spiking controllers developed a pattern of connections where spiking neurons received connections from a small patch of neighboring sensors, but not from other sensors, and were connected only to neighboring spiking neurons. This pattern of connectivity is also observed in biological systems and encourages specialization of neurons to sensory features.

61.6.3 GasNets

This section describes another style of artificial neural network strongly inspired by those parts of contemporary neuroscience that emphasize the complex electrochemical nature of real nervous systems. In particular, they make use of an analogue of *volume signaling*, whereby neurotransmitters freely diffuse into a relatively large volume around a nerve cell, potentially affecting many other neurons [61.81, 82]. This exotic form of neural signaling does not sit easily with classical pictures of brain mechanisms and is forcing a radical rethink of existing theory [61.83–86]. The class of artificial neural networks developed to explore artificial volume signaling are known as GasNets [61.87]. These are essentially standard neural networks augmented by a chemical signaling system comprising a diffusing *virtual gas* which can modulate the response of other neurons. A number of GasNet variants, inspired by different aspects of real nervous systems, have been explored in an evolutionary robotics context as artificial nervous systems for mobile autonomous robots. They have been shown to be significantly more evolvable, in terms of speed to a good solution, than other forms of neural networks for a variety of robot tasks and behaviors [61.36, 87–89]. They are being investigated as potentially useful engineering tools and as a way of gaining helpful insights into biological systems [61.85, 90, 91].

By analogy with biological neuronal networks, GasNets incorporate two distinct signaling mechanisms, one *electrical* and one *chemical*. The underlying *electrical* network is a discrete-time-step recurrent neural network with a variable number of nodes. These nodes are connected by either excitatory or inhibitory links.

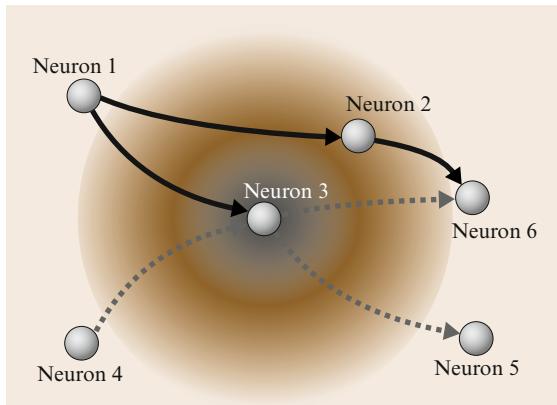

In addition to this underlying network in which positive and negative *signals* flow between units, an abstract

process loosely analogous to the diffusion of gaseous modulators is at play. Some units can emit virtual *gases* which diffuse and are capable of modulating the behavior of other units by changing the profile of their output functions. The networks occupy a 2-D space; the diffusion processes mean that the relative positioning of nodes is crucial to the functioning of the network. Spatially, the gas concentration varies as an inverse exponential of the distance from the emitting node with a spread governed by a parameter r with the concentration set to zero for all distances greater than r . The total concentration of gas at a node is determined by summing the contributions from all other emitting nodes.

For mathematical convenience, in the original GasNet there are two *gases*, one whose modulatory effect is to increase the transfer function gain parameter and one whose effect is to decrease it. Thus the gas does not alter the electrical activity in the network directly but rather acts by continuously changing the mapping between input and output for individual nodes, either directly or by stimulating the production of further virtual gas. The general form of the diffusion is based on the properties of a (real) single-source neuron as modeled in detail by Philippides et al. [61.85, 90]. The modulation chosen is motivated by what is known of NO modulatory effects at synapses [61.92]. For full details see [61.87].

Various extensions of the basic GasNet have been produced. Two in particular are strongly inspired by contemporary neuroscience. The *plexus model* is directly inspired by a type of signaling seen in the mammalian cerebral cortex in which the NO signal is generated by the combined action of many fine NO-producing fibers, giving a targeted *cloud* which is distant from the neurons from which the fiber plexus emanates [61.91]. In the plexus GasNet, which models this form of signaling at an abstract level, the spatial distribution of gas concentration has been modified to be uniform over the area of affect. The center of this gas diffusion cloud is under genetic control and can be distant from the controlling node (which, by analogy, is the source of the *plexus*) [61.89]. All other details of the models are identical to the original GasNet model, as described earlier. The *receptor* GasNet incorporates an aspect of biological neuronal networks that has no analog in the vast majority of ANNs: the role of receptor molecules. Although neuroscience is a long way from a full understanding of receptor mechanisms, a number of powerful systems level ideas can be abstracted.

Details of the receptor variant are similar to the basic GasNet except there is now *only one* virtual gas and each node in the network can have one of three discrete quan-

A GasNet. Neuron 3 is emitting gas, and modulating neuron 2 despite there being no synaptic connection.

Fig. 61.21 A basic GasNet showing positive (*solid*) and negative (*dashed*) electrical connections and a diffusing virtual gas creating a *chemical gradient*

ties (zero, medium, maximum) of a number of possible receptors. The modulation the diffusing neurotransmitter affects at a neuron depends on which receptors are present. The strength of a modulation at a node is proportional to the product of the gas concentration at the node and the relevant receptor quantity. In the original GasNet, any node that was in the path of a diffusing transmitter would be modulated in a fixed way. The receptor model allows site-specific modulations, including no modulation (no receptors) and multiple modulations at a single site (see [61.89] for further details).

Although most of the GasNet variants described in this section have been successfully used in a number of robotic tasks, their evolvability and other properties were thoroughly compared on a version of the (gantry) robot visual discrimination task described in Sect. 61.5. All aspects of the networks were under genetic control: the number of nodes, the connectivity and, in the case of the GasNets, all parameters governing volume signaling (including the position of the nodes and whether or not they were *virtual gas* emitters). The visual sampling morphology was also under evolutionary control. The original basic GasNet was found to be significantly more

evolvable than a variety of other styles of connectionist neural networks as well as a GasNet with the volume signaling disabled. Successful GasNet controllers for this task tended to be rather minimal, in terms of numbers of nodes and connections, while possessing complex dynamics [61.87]. Later experiments comparing the basic GasNet with the plexus and receptor variants showed the latter two to be considerably more evolvable than the former, with the receptor GasNet being particularly successful [61.89].

The GasNet experiments mentioned above demonstrated that the intricate network dynamics made possible by the artificial volume signaling mechanisms can be readily harnessed to generate adaptive behaviors in autonomous agents. They also throw up such questions as why GasNets are more evolvable than many other forms of ANN and why there is a difference in evolvability between GasNet variants. Investigations of this question indicate that the interaction between the two GasNet signaling mechanisms, *electrical* and *chemical*, plays a crucial role [61.88, 89]. Evolutionary theory led to the hypothesis that systems involving distinct yet coupled processes are highly evolvable when the coupling is flexible (i.e., it is relatively easy for evolution to change the degree of coupling in the system) with a bias towards a loose coupling; this allows the possibility of *tuning* one process against the other without destructive interference [61.88, 89, 93]. This may also be the case for subthreshold dynamics of spiking neural networks, which although not yet compared to GasNets, were shown to be more evolvable than connectionist networks. Measurements of the degree of coupling in the GasNets variants versus speed of evolution supported this view [61.89]; the receptor GasNet, for which the evolutionary search process has the most direct control over the degree of coupling between the signaling processes, and which has a bias towards a loose coupling, was by far the most evolvable [61.89]. These and ongoing investigations indicate that explicitly dealing with the electrochemical nature of nervous systems is likely to be an increasingly fruitful area of research, both for evolutionary robotics and for neuroscience, that will likely force us to broaden our notions of what behavior-generating mechanisms might look like.

61.7 Evolution and Learning

Evolution and learning (or phylogenetic and ontogenetic adaptation) are two forms of biological adaptation that

differ in space and time. Evolution is a process of selective reproduction and substitution based on the existence

of a population of individuals displaying variability at the genetic level. Learning, instead, is a set of modifications taking place within each single individual during its own life time. Evolution and learning operate on different time scales. Evolution is a form of adaptation capable of capturing relatively slow environmental changes that might encompass several generations (e.g., the perceptual characteristics of food sources for a given species). Learning, instead, allows an individual to adapt to environmental modifications that are unpredictable at the generational level. Learning might include a variety of mechanisms that produce adaptive changes in an individual during its lifetime, such as physical development, neural maturation, variation of the connectivity between neurons, and synaptic plasticity. Finally, whereas evolution operates on the genotype, learning affects only the phenotype, and phenotypic modifications cannot directly modify the genotype.

Researchers have combined evolutionary techniques and learning techniques (supervised or unsupervised learning algorithm such us reinforcement learning or Hebbian learning; for a review see [61.94]). These studies have been conducted with two different purposes:

1. identifying the potential advantage of combining these two methods from the point of view of developing robust and effective robots
2. understanding the role of the interaction between learning and evolution in nature

Within an evolutionary perspective, learning has several different adaptive functions. First, it might allows individuals to adapt to changes that occur too quickly to be tracked by evolution [61.95]. Secondly, learning might allows robots to use information extracted during their interaction with environment to develop adaptive characters ontogenetically without necessarily discovering these characters through genetic variations and without encoding these characters in their genome. To understand the importance of this aspect, we should consider that evolutionary adaptation is based on an explicit but concise indication of how well an individual robot coped with its environment – the fitness value of a robot. Ontogenetic adaptation, on the contrary, is based on extremely rich information – the state of the sensors while the robot interacts with its environment. This huge amount of information encodes very indirectly how well an individual is doing in different phases of its lifetime or how it should modify its behavior to increase its fitness. However, evolving robots that have acquired a predisposition to exploit this information to produce adaptive changes during their lifetime might be able to

develop adaptive characteristics on the fly, thus leading to the possibility to produce *complex* phenotypes on the basis of parsimonious genotypes. Finally, learning can help and guide evolution. Although physical changes of the phenotype, such as strengthening of synapses during learning, cannot be written back into the genotype, *Baldwin* [61.96] and *Waddington* [61.97] suggested that learning might indeed affect the evolutionary course in subtle but effective ways. Baldwin's argument was that learning accelerates evolution because suboptimal individuals can reproduce by acquiring during life necessary features for survival. However, variation occurring during successive generation might lead to the discovery of genetic traits that lead to the establishment of the same characteristics that were previously acquired thorough lifetime learning. This latter aspect of Baldwin's effect, namely indirect genetic assimilation of learned traits, has been later supported by scientific evidence and defined by *Waddington* [61.97] as a canalization effect.

Learning however, also has costs such as: (1) a delay in the ability to acquire fitness (due to the need to develop fit behavior ontogenetically), and (2) increased unreliability due to the fact that the possibility to develop certain abilities ontogenetically is subjected to partially unpredictable characteristics of the robot–environment interaction [61.98]. In the next two subsections we describe two experiments that show some of the potential advantages of combining evolution and learning.

61.7.1 Learning to Adapt to Fast Environmental Variations

Consider the case of a Khepera robot that should explore an arena surrounded by black or white walls to reach a target placed in a randomly selected location [61.95]. Evolving robots are provided with eight sensory neurons that encode the state of the four corresponding infrared sensors and two motor neurons that control the desired speed of the two wheels. Since the color of the walls change every generation and since the color significantly affects the intensity of the response of the infrared sensors, evolving robots should develop an ability to *infer* whether they are currently located in an environment with white or black walls and learn to modify their behavior during lifetime. That is, robots should avoid walls only when the infrared sensors are almost fully activated in the case of arenas with white walls, while they should avoid walls even when the infrared sensors are slightly activated in the case of arenas with black walls.

Robots were provided with a neural controller (Fig. 61.22) including four sensory neurons that encoded

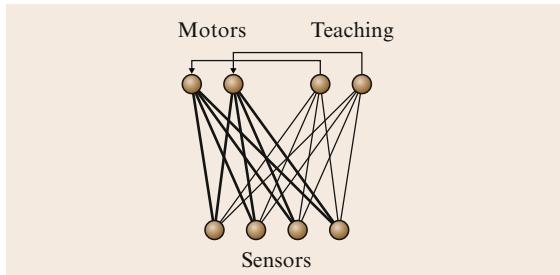

Fig. 61.22 A self-teaching network. The output of the two teaching neurons is used as a teaching value for the two motor neurons. The weights that connect the sensory neurons to the teaching neurons do not vary during the robots' lifetime while the weights that connect the sensory neurons to the motor neurons are modified with an error-correction algorithm

the state of four corresponding infrared sensors; two motors neurons that encoded the desired speed of the two wheels; and two teaching neurons that encoded the teaching values used to modify the connection weights from the sensory neurons to the motor neurons during the robots' lifetime. This special architecture allows evolving robots to transform the sensory states experienced by the robots during their lifetime into teaching signals that might potentially lead to adaptive variations during lifetime. Analysis of evolved robots revealed that they developed two different behaviors that are adapted to the particular arena where they happen to be *born* (surrounded by white or black walls). Evolving robots did not inherit an ability to behave effectively, but rather a predisposition to learn to behave. This predisposition to learn involves several aspects such as a tendency to experience useful learning experiences, a tendency to acquire useful adaptive characters through learning, and a tendency to channel variations toward different directions in different environmental conditions [61.95].

61.7.2 Evolution of Learning

In the previous example, the evolutionary neural network learned using a standard learning rule that was applied to all synaptic connections. Floreano and collaborators [61.99] explored the possibility of genetically encoding and evolving the learning rules associated to the different synaptic connections of a neural network embedded in a real robot. The main motivation of this line of work was to evolve robots capable of adapting to a partially unknown environment, rather than robots adapted to the environment(s) seen during evolution. In

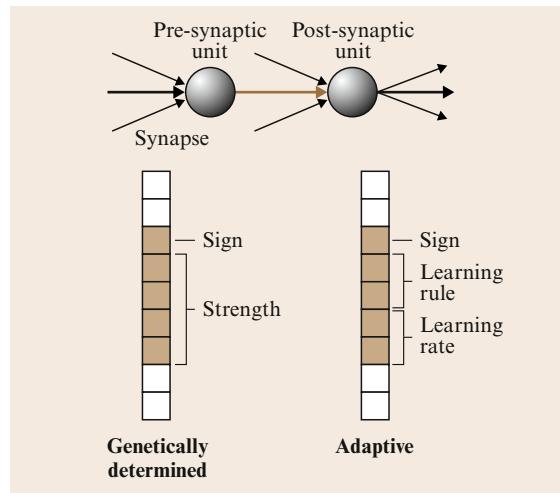

Fig. 61.23 Two methods for genetically encoding a synaptic connection. Genetically determined synapses cannot change during the lifetime of the robot. Adaptive synapses instead are randomly initialized and can change during lifetime of the robot according to the learning rules and rates specified in the genome

order to prevent evolutionary tuning of the neural network to the specificities of the evolutionary environment (which would limit transfer to different environments or transfer from simulation to reality), the synaptic weight values were not genetically encoded. Instead, each synaptic connection in the network was described by three genes that defined its sign, its learning rule, and its learning rate (Fig. 61.23). Every time a genome was decoded into a neural network and downloaded onto the robot, the synaptic strengths were initialized to small random values and could change according to the genetically specified rules and rates while the robot interacted with the environment. Variations of this methodology included a more compact genetic encoding where the learning properties were associated to a neuron instead of a synapse. All synapses afferent to a neuron used its genetically specified rules and rates. Genes could encode four types of Hebbian learning that were modeled upon neurophysiological data and were complementary to each other [61.100].

Experimental results in a nontrivial, multitask environment (Fig. 61.24) indicated that this methodology has a number of significant advantages with respect to the evolution of synaptic strengths without learning [61.45]. Robots evolved faster and obtained better fitness values. Furthermore, evolved behaviors were qualitatively different, notably in that they did not exploit minimal

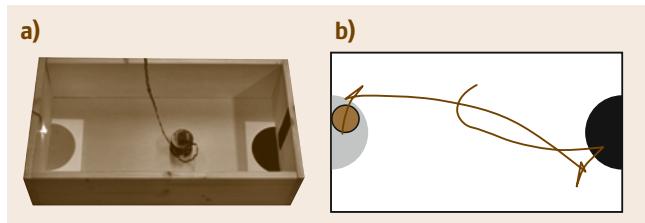

Fig. 61.24 (a) A mobile robot Khepera equipped with a vision module can gain fitness points by staying on the gray area only when the light is on. The light is normally off, but it can be switched on if the robot passes over the black area positioned on the other side of the arena. The robot can detect ambient light and wall color, but not the color of the floor. (b) Behavior of an individual evolved in simulation with genetic encoding of learning rules

solutions tuned to the environment (such as turning only on one side, or turning in circles tuned to the dimensions of the evolutionary arena). Most important, these robots displayed remarkable adaptive properties after evolution. Best evolved individuals: (1) transferred perfectly from simulated to physical robots, (2) accomplished the

task when the light and reflection properties of the environment were modified, (3) accomplished the task when key landmarks and target areas of the environment were displaced, and (4) transferred well across morphologically different robotic platforms. In other words, these robots were selected for their ability to solve a partially unknown problem by adapting on the fly, rather than for being a solution to the problem seen during evolution.

In further experiments where the genetic code for each synapse of the network included one gene whose value caused its remaining genes to be interpreted as connection strengths or learning rules and rates, 80% of the synapses *made the choice* of using learning, reinforcing the fact that this genetic strategy has a comparatively stronger adaptive power [61.100]. This methodology could also be used to evolve the morphology of neural controllers were synapses are created at runtime and therefore their strengths cannot be genetically specified [61.101]. Recently, the adaptive properties of this type of adaptive genetic encoding were confirmed also in the context of evolutionary spiking neurons for robot control [61.102].

61.8 Competition and Cooperation

In the previous sections, we limited our analysis to individual behaviors, i. e., to the evolution of robots placed in an environment that does not include other robots. The evolutionary method, however, can also be applied to develop collective behaviors in which evolving robots are placed in an environment that also contains other individual robots and are selected for the ability to display competitive or cooperative behavior.

In this section we briefly review two examples involving competitive and cooperative behaviors. As we see, the evolution of collective behavior is particularly interesting from the point of view of synthesizing progressively more complex behaviors and from the point of view of developing solutions that are robust with respect to environmental variations.

61.8.1 Coevolving Predator and Prey Robots

Competitive coevolution, for example the coevolution of two populations of predator and prey robots that are evolved for the ability to catch prey and to escape predators, respectively, has two characteristics that are particularly interesting from an evolutionary robotics perspective. The first aspect is that the competition

between populations with different interests might spontaneously lead to a sort of incremental evolutionary process where evolving individuals are faced with progressively more complex challenges (although this is not necessarily the case). Indeed, in initial generations the task of the two populations is relatively simple because opponents have simple and poorly developed abilities on average. After a few generations, however, the abilities of the two populations increase and, consequently, the challenges for each population become more difficult. The second aspect consists of the fact that the environment varies across generations because it includes other coevolving individuals. This implies that coevolving individuals should be able to adapt to ever-changing environments and to develop behaviors that are robust with respect to environmental variations.

The potential advantages of competitive coevolution for evolutionary robotics have been demonstrated by a set of experiments conducted by Floreano and Nolfi [61.94, 103] where two populations of robots were evolved for the ability to catch prey and escape predators, respectively (Fig. 61.25).

The results indicated that both predator and prey robots tended to vary their behavior throughout gen-

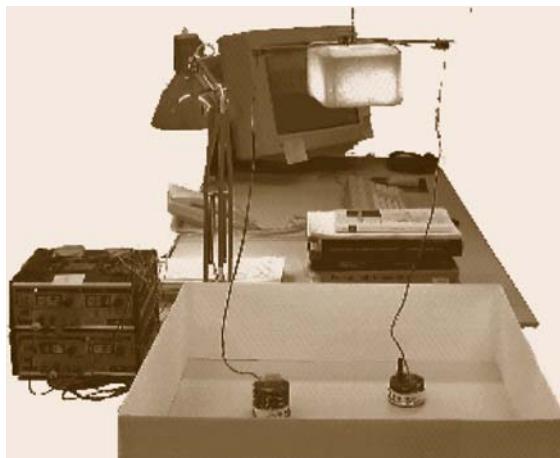

Fig. 61.25 Experimental setup. The predator and prey robot (*from left to right*) are placed in an arena surrounded by walls and are allowed to interact for several trials starting at different randomly generated orientations. Predators are selected on the basis of the percentage of trials in which they are able to catch (i. e., to touch) the prey, and prey on the basis of the percentage of trials in which they were able to escape (i. e., to not be touched by) predators. Predators have a vision system, whereas the prey have only short-range distance sensors, but can go twice as fast as the predator. Collision between the robots is detected by a conductive belt at the base of the robots

erations without converging on a stable strategy. The behavior displayed by individuals at each generation tended to be tightly adapted to the counter-strategy exhibited by the opponent of the same generation. This evolutionary dynamic however does not really lead to long-lasting progress because, after an initial evolutionary phase, the coevolutionary process led to a limit cycle dynamic where the same small set of behavioral strategies recycled over and over again along generations [61.94]. This limit cycle dynamic can be explained by considering that prey robots tended to vary their behavior in order to disorient predators as soon as predators become effective against the current behavioral strategies exhibited by prey robots.

However, experiments [61.103] where robots were allowed to change their behavior on the fly on the basis of unsupervised Hebbian learning rules showed that the evolutionary phase where coevolving robots were able to produce real progress was significantly longer, and evolved predators displayed an ability to effectively cope with prey exhibiting different behavioral strategies by adapting their behavior on the fly to the prey's behavior.

Prey instead tended to display behavior that changed in unpredictable ways.

Further experiments showed that competitive coevolution can solve problem that the evolution of a single population cannot. *Nolfi and Floreano* [61.94] demonstrated that the attempt to evolve predators robot for the ability to catch a fixed pre-evolved prey produced lower performance with respect to control experiments where predators and prey were coevolved at the same time.

61.8.2 Evolving Cooperative Behavior

Cooperative behavior refers to the situation where a group of robots sharing the same environment coordinate and help each other to solve a problem that cannot be solved by a single robot [61.104]. Although the synthesis of cooperative robots through evolutionary methods is a rather recent enterprise, obtained results are very promising. When it comes to evolving a population of robots for cooperative behaviors, it is necessary to decide the genetic relation among members of a team and the method for selective reproduction. Robots in a team can be genetically homogeneous (clones) or heterogeneous (they differ from each other). Furthermore, the fitness can be computed at the level of the team (in which case, the entire team of robots is reproduced) or at the level of the individual (in which case, only individuals of the team are selected for reproduction). The combination of two variables, genetic relatedness and level of selection, generates at least four different conditions, with a variety of mixed conditions in between. It has been shown experimentally that the choice of homogeneous teams with team-level selection is the most efficient for generating robots that display altruistic cooperation where individual robots are willing to pay a cost for the benefit of the entire team [61.105, 106].

Recent research showed that teams of evolved robots can:

1. develop robust and effective behavior [61.107–109]
2. display an ability to differentiate their behavior in order to better cooperate [61.107, 109]
3. develop communication capabilities and a shared communication system [61.110, 111]

Here we briefly review one of these experiments where swarm-bots [61.112], i. e., teams of autonomous robots capable of dynamically assembling by physically connecting together, were evolved for displaying coordinated motion, navigation on rough terrains, collective negotiation of obstacles and holes, and dynamical shape reorganization in order to go through narrow passages.

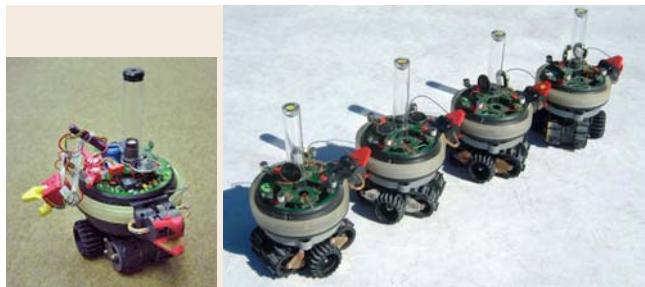

Fig. 61.26 An s-bot and a simulated swarm-bot consisting of four s-bots assembled in chain formation

Each s-bot consisted of a main platform (chassis) and turret that could actively rotate with respect to each other (Fig. 61.26). The chassis included tracks with teethed wheels for navigation on both rough and flat terrain, and four infrared sensors pointing to the ground. The turret included a gripper, a loudspeaker, 16 infrared sensors, three microphones, and a traction sensor placed between

the turret and the chassis to detect the direction and the intensity of the traction force that the turret exerts on the chassis. Each s-bot was provided with a simple neural controller where sensory neurons were directly connected to the motors neurons that controlled the desired speed of the tracks and whether or not a sound signal was produced. The team of s-bots forming a swarm-bot was homogeneous and evolved with team-level selection.

Swarm-bots of four s-bots assembled in chain formation (Fig. 61.26) were evolved for the ability to move coordinately on a flat terrain. Evolved neural controllers were also capable of producing coordinated movements when the swarm-bot was augmented by additional s-bots and reorganized in different shapes. Swarm-bots also dynamically rearranged their shape in order to effectively negotiate narrow passages and were capable of moving on rough terrains by negotiating situations that could not be handled by a single robot. Such robots also collectively avoided obstacles and coordinated to transport heavy objects [61.107, 108, 113].

61.9 Evolutionary Hardware

The work described so far was mainly conducted on robots that did not change shape during evolution, with the exception of self-assembling robots where several

individuals can connect to become a superorganism of variable shape. In recent years, technology advancements have allowed researchers to explore evolution of electronic circuits and morphologies. In this section, we briefly summarize some foundational work in this direction.

61.9.1 Evolvable Hardware Robot Controllers

In most of the work discussed so far some form of genetically specified neural network, implemented in software, has been at the center of the robot control system. Work on a related approach of evolving control systems directly onto hardware dates back to *Thompson's* work in the mid 1990s [61.114]. In contrast to hardware controllers that are designed or programmed to follow a well-defined sequence of instructions, evolved hardware controllers are directly configured by evolution and then allowed to behave in real time according to semiconductor physics. By removing standard electronics design constraints, the physics can be exploited to produce highly nonstandard and often very efficient and minimal systems [61.115].

Thompson [61.114] used artificial evolution to design an onboard hardware controller for a two-wheeled

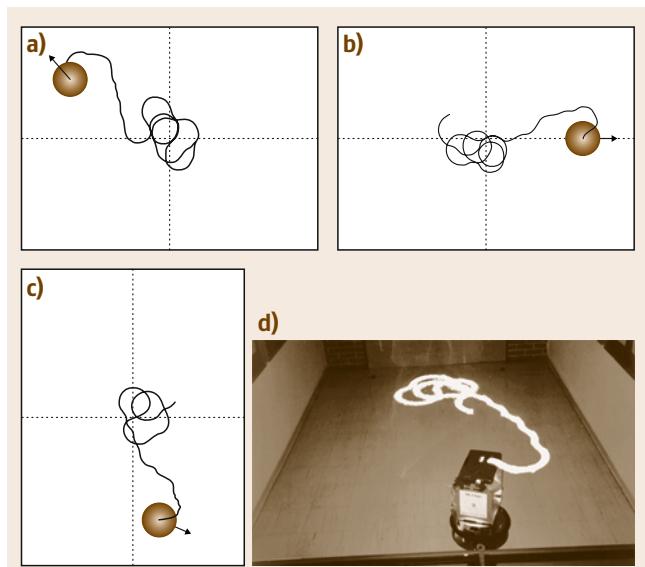

Fig. 61.27a–d Wall-avoidance behavior of a robot with an evolved hardware controller in virtual reality and (d) the real world

autonomous mobile robot engaged in simple wall-avoidance behavior in an empty arena. Starting from a random orientation, and position near the wall, the robot had to move to the center of the arena and stay there using limited sensory input (Fig. 61.27). The DC motors driving the wheels were not allowed to run in reverse and the robot's only sensors were a pair of time-of-flight sonars rigidly mounted on the robot, pointing left and right.

Thompson's approach made use of a so-called dynamic state machine (**DSM**) – a kind of generalized read-only memory (**ROM**) implementation of a finite-state machine where the usual constraint of strict synchronization of input signals and state transitions are relaxed (in fact put under evolutionary control). The system had access to a global clock whose frequency was also under genetic control. Thus evolution determined whether each signal was synchronized to the clock or allowed to flow asynchronously. This allowed the evolving **DSM** to be tightly coupled to the dynamics of interaction between the robot and environment and for evolution to explore a wide range of systems dynamics. The process took place within the robot in a kind of *virtual reality* in the sense that the real evolving hardware controlled the real motors, but the wheels were just spinning in the air. The movements that the robot would have actually performed if the wheels had been supporting it were then simulated and the sonar echo signals that the robot was expected to receive were supplied in real time to the hardware **DSM**. Excellent performance was attained after 35 generations, with good transfer from the virtual environment to the real world (Fig. 61.27).

Shortly after this research was performed, particular types of field programmable gate arrays (**FPGAs**) which were appropriate for evolutionary applications became available. **FPGAs** are reconfigurable systems allowing the construction of circuits built from basic logic elements. Thompson exploited their properties to demonstrate evolution directly in the chip. By again relaxing standard constraints, such as synchronizing all elements with a central clock, he was able to develop very novel forms of functional circuits, including a controller for a Khepera robot using infrared sensors to avoid obstacles [61.115, 116].

Following Thompson's pioneering work, *Keymeulen* evolved a robot control system using a Boolean function approach implemented on gate-level evolvable hardware [61.117]. This system acted as a navigation system for a mobile robot capable of locating and reaching a colored ball while avoiding obstacles. The robot was equipped with infrared sensors and an vision system

giving the direction and distance to the target. A programmable logic device (**PLD**) was used to implement a Boolean function in its disjunctive form. This work demonstrated that such gate-level evolvable hardware was able to take advantage of the correlations in the input states and to exhibit useful generalization abilities, thus allowing the evolution of robust behavior in simulation followed by a good transfer into the real world.

In a rather different approach, *Ritter* et al. used an FPGA implementation of an onboard evolutionary algorithm to develop a controller for a hexapod robot [61.118]. *Floreano* and collaborators devised a multicellular reconfigurable circuit capable of evolution, self-repair, and adaptation [61.119], and used it as a substrate for evolving spiking controllers of a wheeled robot [61.120]. Although evolved hardware controllers are not widely used in evolutionary robotics, they still hold out the promise of some very useful properties, such as robustness to faults, which make them interesting for extreme condition applications such as space robotics.

61.9.2 Evolving Bodies

In the work described so far there has been an overwhelming tendency to evolve control system for pre-existing robots: the brain is constrained to fit a particular body and set of sensors. Of course in nature the nervous system evolved simultaneously with the rest of the organism. As a result, the nervous system is highly integrated with the sensory apparatus and the rest of the body: the whole operates in a harmonious and balanced way – there are no distinct boundaries between control system, sensors and body. From the start, work at Sussex University incorporated the evolution of sensor properties, including positions, but other aspects of the physical robot were fixed [61.15]. Although the limitations of not being able to control body morphology genetically were acknowledged at this stage, there were severe technical difficulties in overcoming them, so this issue was somewhat sidelined.

Karl Sims started to unlock these possibilities in his highly imaginative work on evolving simulated 3-D *creatures* in an environment with realistic physics [61.121]. In this work, the creatures coevolved under a competitive scenario in which they were required to try and gain control of a resource (a cube) placed in the center of an arena. Both the morphology of the creatures and the neural system controlling their actuators were under evolutionary control. Their bodies were built from rigid 3-D primitives with the overall morphology being

determined by a developmental process encoded as a directed graph. Various kinds of genetically determined joints were allowed between body parts. A variety of sensors could be specified for a specific body part. The simulated world included realistic modeling of gravity, frictions, collisions, and other dynamics such that behaviors were restricted to be physically plausible. Many different styles of locomotion evolved along with a variety of interesting, and often entertaining, strategies to capture the resource, including pushing the opponent away and covering up the cube.

With the later developments of sophisticated physics engines for modeling a variety of physical bodies, Sims' work inspired a rash of evolved virtual creatures, including realistic humanoid figures capable of a variety of behaviors [61.30].

In what might be regarded as a step towards evolving robot bodies, *Funes* and *Pollack* explored the use of evolutionary algorithms in the design of physical structures taking account of stresses and torques [61.122]. They experimented with evolving structures assembled from elementary components (LEGO bricks). Evolution took place in simulation and the designs were verified in the real world. Stable 3-D brick structures such as tables, cranes, bridges, and scaffolds were evolved within the restrictions of maximum stress torques at each joint between brick pairs. Each brick was modeled as exerting an external load with a lever arm from its center of mass to the supporting joint, resulting in a network of masses and forces representing the structure. A genetic programming approach was taken using tree structures to represent the 3-D LEGO structures. A mutation operator acted on individual brick parameters while subtree crossover allowed more radical changes to the structure. As well as fitness functions designed to encourage particular types of structures, an additional low-level fitness factor favoring the fewest bricks successfully weeded out many of the redundant bricks that inevitably arose. LEGO proved to be a predictable building tool with modes of breakage and linkage that could be relatively easily modeled. While this work was successful, producing very strong designs, it focused on static structures, so was limited in terms of its relevance to functional robotic body parts. However, it did demonstrate a viable approach to evolving physical structures.

While various researchers advocated the use of fully evolvable hardware to develop not only a robot's control circuits, but also its body plan, which might include the types, numbers, and positions of the sensors, the body size, the wheel radius, actuator properties and so on [61.123], this was still largely confined to theoretical

discussion until *Lipson* and *Pollack*'s work on the Golem project [61.124], which was a significant step on from the earlier LEGO work [61.122].

Lipson and *Pollack*, working at Brandeis University, pushed the idea of fully evolvable robot hardware about as far as is reasonably technologically feasible at present. In an important piece of research, directly inspired by Sims' earlier simulation work, autonomous *creatures* were evolved in simulation out of basic building blocks (neurons, plastic bars, actuators) [61.124]. The bars could connect together to form arbitrary truss structures with the possibility of both rigid and articulated substructures. Neurons could be connected to each other and to bars whose length they would then control via a linear actuator. Machines defined in this way were required to move as far as possible in a limited time. The fittest individuals were then fabricated robotically using rapid manufacturing technology (plastic extrusion 3-D printing) to produce results such as that shown in Fig. 61.28. They thus achieved autonomy of design and construction using evolution in a limited-universe physical simulation coupled to automatic fabrication. The fitness function employed was simply the Euclidean distance moved by the center of mass of a machine over a fixed small number of cycles of its neural controller. A number of different mutation operator acted in concert: small changes to bar or neuron properties, additions and deletions of bars or neurons, changes to connections between neurons and bars, and the creation of new vertices. The highly unconventional designs thus performed as well in reality as in simulation. The success of this work points the way to new possibilities in developing energy-efficient fault-tolerant machines.

Pfeifer and colleagues at Zurich University have explored issues central to the key motivation for fully

Fig. 61.28 A locomoting *creature* evolved by *Lipson* and *Pollack* in research which achieved an autonomous design and fabrication process

evolvable robot hardware: the balanced interplay between body morphology, neural processing, and the generation of adaptive behavior [61.125, 126]. Work from this group has involved a number of approaches, including evolutionary robotics. One focus is on studying how to exploit the dynamic interaction between the embodied agent and the environment. Pfeifer uses the term *morphological computation* to draw attention to the fact that some of the control of behavior can be

performed by the dynamic interaction derived from morphological properties (e.g., the passive forward swing of the leg in walking and the spring-like properties of muscles). By taking morphological computation into account, it is very likely that more robust, energy efficient robots can be developed. *Pfeifer* has developed a set of design principles for intelligent systems that take into account this balance between environment, morphology, and behavior [61.125].

61.10 Closing Remarks

Evolutionary robotics is a young and integrated approach to robot development without human intervention where machines change and adapt by capitalizing on the interactions with their environment. Despite initial skepticism by mainstream and applied robotics practitioners and even by pioneers of this approach [61.127], over the years the field has been constantly growing with new methods and approaches for evolving more complex, efficient, and sometimes surprising robotic systems. In some areas, such as morphology and self-

assembly, evolutionary robotics is still the most widely used and powerful approach.

Evolutionary robotics is not only a method for automatic robot development inspired by biology, but also a tool for investigating open questions in biology concerning evolutionary, developmental, and brain dynamics. Its richness and fecundity make us believe that this approach will continue to grow and progress towards the creation of a new species of machines capable of self-evolution.

62. Neurorobotics: From Vision to Action

Michael A. Arbib, Giorgio Metta, Patrick van der Smagt

The lay view of a robot is a mechanical human, and thus robotics has always been inspired by attempts to emulate biology. In this Chapter, we extend this biological motivation from humans to animals more generally, but with a focus on the central nervous systems rather than the bodies of these creatures. In particular, we investigate the sensorimotor loop in the execution of sophisticated behavior. Some of these sections concentrate on cases where vision provides key sensory data. Neuroethology is the study of the brain mechanisms underlying animal behavior, and Sect. 62.2 exemplifies the lessons it has to offer robotics by looking at optic flow in bees, visually guided behavior in frogs, and navigation in rats, turning then to the coordination of behaviors and the role of attention. Brains are composed of diverse subsystems, many of which are relevant to robotics, but we have chosen just two regions of the mammalian brain for detailed analysis. Section 62.3 presents the cerebellum. While we can plan and execute actions without a cerebellum, the actions are no longer graceful and become uncoordinated. We reveal how a cerebellum can provide a key ingredient in an adaptive control system, tuning parameters both within and between motor schemas. Section 62.4 turns to the mirror system, which provides shared representations which bridge between the execution of an action and the observation of that action when performed by others. We develop a neurobiological model of how learning may forge mirror neurons for hand

movements, provide a Bayesian view of a robot mirror system, and discuss what must be added to a mirror system to support robot imitation. We conclude by emphasizing that, while neuroscience can inspire novel robotic designs, it is also the case that robots can be used as embodied test beds for the analysis of brain models.

62.1 Definitions

Neurorobotics may be defined as *the design of computational structures for robots inspired by the study of the nervous systems of humans and other animals*.

We note the success of *artificial* neural networks – networks of simple computing elements whose connections change with *experience* – as providing a medium for par-

allel adaptive computation that has seen application in robot vision systems and controllers but here we emphasize neural networks derived from the study of specific *neurobiological* systems. Neurorobotics has a twofold aim: creating better machines which employ the principles of natural neural computation; and using the study of bio-inspired robots to improve understanding of the functioning of the brain. Chapter 60, *Biologically Inspired Robots*, complements our study of *brain design* with work on *body design*, the design of robotic control and actuator systems based on careful study of the relevant biology.

Walter [62.1] described two *biologically inspired* robots, the electromechanical tortoises *Machina speculatrix* and *M. docilis* (though each body has wheels not legs). *M. speculatrix* has a steerable photoelectric cell, which makes it sensitive to light, and an electrical contact, which allows it to respond when it bumps into obstacles. The photoreceptor rotates until a light of moderate intensity is registered, at which time the organism orients itself towards the light and approaches it. However, very bright lights, material obstacles, and steep gradients are repellent to the *tortoise*. The latter stimuli convert the photoamplifier into an oscillator, which causes alternating movements of butting and withdrawal, so that the robot pushes small objects out of its way, goes around heavy ones, and avoids slopes. The *tortoise* has a *hutch*, which contains a bright light. When the machine's batteries are charged, this bright light is repellent. When the batteries are low, the light becomes attractive to the machine and the light continues to exert an attraction until the tortoise enters the hutch, where the machine's circuitry is temporarily turned off until the batteries are recharged, at which time the bright hutch light again exerts a negative tropism. The second robot, *M. docilis* was produced by grafting onto *M. speculatrix* a circuit designed to form conditioned reflexes. In one experiment, Walter connected this circuit to the obstacle-avoiding device in *M. speculatrix*. Training consisted of blowing a whistle just before bumping the shell.

Although Walter's controllers are simple and not based on neural analysis, they do illustrate an attempt to gain inspiration from seeking the simplest mechanisms that will yield an interesting class of biologically

inspired robot behaviors, and then showing how different additional mechanisms yield a variety of enriched behaviors. Braitenberg's book [62.2] is very much in this spirit and has entered the canon of neurorobotics. While their work provides a historical background for the studies surveyed here, we instead emphasize studies inspired by the computational neuroscience of the mechanisms serving vision and action in the human and animal brain. We seek lessons from linking behavior to the analysis of the internal workings of the brain (1) at the relatively high level of characterizing the functional roles of specific brain regions (or the functional units of analysis called schemas Sect. 62.2.4), and the behaviors which emerge from the interactions between them, and (2) at the more detailed level of models of neural circuitry linked to the data of neuroanatomy and neurophysiology. There are lessons for neurorobotics to be learned from even finer-scale analysis of the biophysics of individual neurons and the neurochemistry of synaptic plasticity but these are beyond the scope of this chapter (see Segev and London [62.3] and Fregnac [62.4], respectively, for entry points into the relevant computational neuroscience).

The plan of this Chapter is as follows. After some selected examples from computational neuroethology, the computational analysis of neural mechanisms underlying animal behavior, we show how perceptual and motor schemas and visual attention provide the framework for our action-oriented view of perception, and show the relevance of the computational neuroscience to robotic implementations (Sect. 62.2). We then pay particular attention to two systems of the mammalian brain, the cerebellum and its role in tuning and coordinating actions (Sect. 62.3), and the mirror system and its roles in action recognition and imitation (Sect. 62.4). The extroduction will then invite readers to explore the many other areas in which neurorobotics offers lessons from neuroscience to the development of novel robot designs. What follows, then, can be seen as a contribution to the continuing dialogue between robot behavior and animal and human behavior in which particular emphasis is placed on the search for the neural underpinnings of vision, visually guided action, and cerebellar control.

62.2 Neuroethological Inspiration

Biological evolution has yielded a staggering variety of creatures, each with brains and bodies adapted to spe-

cific niches. One may thus turn to the neuroethology of specific creatures to gain inspiration for special-purpose

robots. In Sect. 62.2.1, we will see how researchers have studied bees and flies for inspiration for the design of flying robots, but have also learned lessons for the visual control of terrestrial robots. In Sect. 62.2.2, we introduce *Rana computatrix*, an evolving model of visuomotor coordination in frogs and toads. The name *the frog that computes*, was inspired by Walter's *M. speculatrix* and inspired in turn the names of a number of other species of neuroethologically inspired robots, including *Beer's* [62.5] computational cockroach *Periplaneta computatrix* and *Cliff's* [62.6] hoverfly *Syritta computatrix*.

Moreover, we learn not only from the brains of specific creatures but also from comparative analysis of the brains of diverse creatures, looking for homologous mechanisms as computational variants which may then be related to the different ecological niches of the creatures that utilize them. A basic theme of brain evolution is that new functions often emerge through modulation and coordination of existing structures. In other words, to the extent that new circuitry may be identified with the new function, it need not be as a module that computes the function autonomously, but rather as one that can deploy prior resources to achieve the novel functionality. Section 62.2.3 will introduce the role of the rat brain in navigation, while Sect. 62.2.4 will look at the general framework of perceptual schemas motor schemas and coordinated control programs for a high-level view of the neuroscience and neurorobotics of vision and action. Finally, Sect. 62.2.5 will look at the control of visual attention in mammals as a homolog of orienting behavior in frogs and toads. All this sets the stage for our emphasis on the roles of the cerebellum (Sect. 62.3) and mirror systems (Sect. 62.4) in the brains of mammals and their implications for neurorobotics. We stress that the choice of these two systems is conditioned by our own expertise, and that studies of many other brain systems also hold great importance for neurorobotics.

62.2.1 Optic Flow in Bees and Robots

Before we turn to vertebrate brains for much of our inspiration for neurorobotics, we briefly sample the rich literature on insect-inspired research. Among the founding studies in computational neuroethology were a series of reports from the laboratory of Werner Reichardt in Tübingen which linked the delicate anatomy of the fly's brain to the extraction of visual data needed for flight control. More than 40 years ago, *Reichardt* [62.7] published a model of motion detection inspired by this work that has long been central to discussions of visual motion

in both the neuroscience and robotics literatures. *Borst* and *Dickinson* [62.8] provide a recent study of continuing biological research on visual course control in flies. Such work has inspired a large number of robot studies, including those of *van der Smagt* and *Groen* [62.9], *van der Smagt* [62.10] *Liu* and *Usseglio-Viretta* [62.11], *Ruffier* et al. [62.12], and *Reiser* and *Dickinson* [62.13].

Here, however, we look in a little more detail at honeybees. *Srinivasan*, *Zhang*, and *Chahl* [62.14] continued the tradition of studying image motion cues in insects by investigating how optic flow (the flow of pattern across the eye induced by motion relative to the environment) is exploited by honeybees to guide locomotion and navigation. They analyzed how bees perform a smooth landing on a flat surface: image velocity is held constant as the surface is approached, thus automatically ensuring that flight speed is close to zero at touchdown. This obviates any need for explicit knowledge of flight speed or height above the ground. This landing strategy was then implemented in a robotic gantry to test its applicability to autonomous airborne vehicles. *Baron* and *Srinivasan* [62.15] investigated the extent to which ground speed is affected by headwinds. Honey

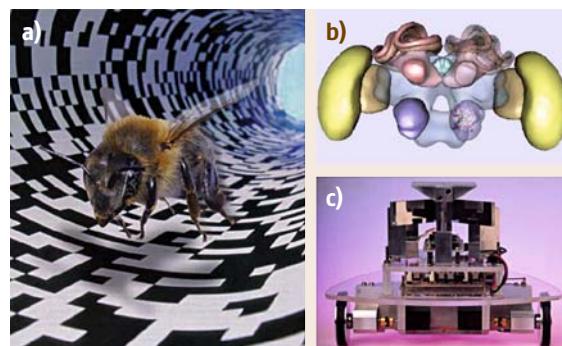

Fig. 62.1a–c Observation of the trajectories of honeybees flying in visually textured tunnels has provided insights into how bees use optic flow cues to regulate flight speed and estimate distance flown, and balance optic flow in the two eyes to fly safely through narrow gaps. This information has been used to build autonomously navigating robots. (b) schematic illustration of a honey-bee brain, carrying about a million neurons within about one cubic millimeter. (Images courtesy of M. Srinivasan: (a) *Science* **287**, 851–853 (2000); (b) *Virtual Atlas of the Honeybee Brain*, <http://www.neurobiologie.fu-berlin.de/beebrain/Bee/VRML/SnapshotCosmoall.jpg>. (c) (Research School of Biological Sciences, Australian National University) A mobile robot guided by an optic flow algorithm based on the studies exemplified in (a))

bees were trained to enter a tunnel to forage at a sucrose feeder placed at its far end (Fig. 62.1a). The bees used visual cues to maintain their ground speed by adjusting their airspeed to maintain a constant rate of optic flow, even against headwinds which were, at their strongest, 50% of a bee's maximum recorded forward velocity.

Vladusich et al. [62.16] studied the effect of adding goal-defining landmarks. Bees were trained to forage in an optic-flow-rich tunnel with a landmark positioned directly above the feeder. They searched much more accurately when both odometric and landmark cues were available than when only odometry was available. When the two cue sources were set in conflict, by shifting the position of the landmark in the tunnel during tests, bees overwhelmingly used landmark cues rather than odometry. This, together with other such experiments, suggests that bees can make use of odometric and landmark cues in a more flexible and dynamic way than previously envisaged. In earlier studies of bees flying down a tunnel, Srinivasan and Zhang [62.17] placed different patterns on the left and right walls. They found that bees balance the image velocities in the left and right visual fields. This strategy ensures that bees fly down the middle of the tunnel, without bumping into the side walls, enabling them to negotiate narrow passages or to fly between obstacles. This strategy has been applied to a corridor-following robot (Fig. 62.1c). By holding constant the average image velocity as seen by the two eyes during flight, the bee avoids potential collisions, slowing down when it flies through a narrow passage. The movement-sensitive mechanisms underlying these various behaviors differ qualitatively as well as quantitatively, from those that mediate the optomotor response (e.g., turning to track a pattern of moving stripes) that had been the initial target of investigation of the Reichardt laboratory. The lesson for robot control is that flight appears to be coordinated by a number of visuomotor systems acting in concert, and the same lesson can apply to a whole range of tasks which must convert vision to action. Of course, vision is but one of the sensory systems that play a vital role in insect behavior. Webb [62.18] uses her own work on robot design inspired by the auditory control of behavior in crickets to anchor a far-ranging assessment of the extent to which robotics can offer good models of animal behaviors.

62.2.2 Visually Guided Behavior in Frogs and Robots

Lettvin et al. [62.19] treated the frog's visual system from an ethological perspective, analyzing circuitry in relation

to the animal's ecological niche to show that different cells in the retina and the visual midbrain region known as the tectum were specialized for detecting predators and prey. However, in much visually guided behavior, the animal does not respond to a single stimulus, but rather to some property of the overall configuration. We thus turn to the question *what does the frog's eye tell the frog?*, stressing the embodied nervous system or, perhaps equivalently, an action-oriented view of perception. Consider, for example, the snapping behavior of frogs confronted with one or more fly-like stimuli. Ingle [62.20] found that it is only in a restricted region around the head of a frog that the presence of a fly-like stimulus elicits a snap, that is, the frog turns so that its midline is pointed at the stimulus and then lunges forward and captures the prey with its tongue. There is a larger zone in which the frog merely orients towards the target, and beyond that zone the stimulus elicits no response at all. When confronted with two *flies* within the snapping zone, either of which is vigorous enough that alone it could elicit a snapping response, the frog exhibits one of three reactions: it snaps at one of the flies, it does not snap at all, or it snaps in between at the *average fly*. Didday [62.21] offered a simple model of this choice behavior which may be considered as the prototype for a *winner-take-all* (WTA) model which receives a variety of inputs and (under ideal circumstances) suppresses the representation of all but one of them; the one that remains is the *winner* which will play the decisive role in further processing. This was the beginning of *Rana computatrix* (see Arbib [62.22, 23] for overviews).

Studies on frog brains and behavior inspired the successful use of potential fields for robot navigation strategies. Data on the strategies used by frogs to capture prey while avoiding static obstacles (Colletti [62.24]) grounded the model by Arbib and House [62.25] which linked systems for depth perception to the creation of spatial maps of both prey and barriers. In one version of their model, they represented the map of prey by a potential field with long-range attraction and the map of barriers by a potential field with short-range repulsion, and showed that summation of these fields yielded a field that could guide the frog's detour around the barrier to catch its prey. Corbacho and Arbib [62.26] later explored a possible role for learning in this behavior. Their model incorporated learning in the weights between the various potential fields to enable adaptation over trials as observed in the real animals. The success of the models indicated that frogs use reactive strategies to avoid obstacles while moving to a goal, rather than employing a planning or cognitive system. Other work

(e.g., *Cobas and Arbib* [62.27]) studied how the frog's ability to catch prey and avoid obstacles was integrated with its ability to escape from predators. These models stressed the interaction of the tectum with a variety of other brain regions such as the pretectum (for detecting predators) and the tegmentum (for implementing motor commands for approach or avoidance).

Arkin [62.28] showed how to combine a computer vision system with a frog-inspired potential field controller to create a control system for a mobile robot that could successfully navigate in a fairly structured environment using camera input. The resultant system thus enriched other roughly contemporaneous applications of potential fields in path planning with obstacle avoidance for both manipulators and mobile robots (*Khatib* [62.29]; *Krogh and Thorpe* [62.30]). The work on *Rana Computatrix* proceeded at two levels – both biologically realistic neural networks, and in terms of functional units called *schemas*, which compete and cooperate to determine behavior. Section 62.2.4 will show how more general behaviors can emerge from the competition and cooperation of perceptual and motor schemas as well as more abstract coordinating schemas too. Such ideas were, of course, developed independently by a number of authors, and so entered the robotics literature by various routes, of which the best known may be the subsumption architecture of *Brooks* [62.31] and the ideas of *Braitenberg* cited above, whereas *Arkin*'s work on behavior-based robotics [62.32] is indeed rooted in schema theory. *Arkin et al.* [62.33] present a recent example of the continuing interaction between robotics and ethology, offering a novel method for creating high-fidelity models of animal behavior for use in robotic systems based on a behavioral systems approach (i.e., based on a schema-level model of animal behavior, rather than analysis of biological circuits in animal brains), and describe how an ethological model of a domestic dog can be implemented with AIBO, the Sony entertainment robot.

62.2.3 Navigation in Rat and Robot

The tectum, the midbrain visual system which determines how the frog turns its whole body towards its prey or orients it for escape from predators (Sect. 62.2.2), is homologous with the superior colliculus of the mammalian midbrain. The rat superior colliculus has been shown to be *frog-like*, mediating approach and avoidance (*Dean et al.* [62.34]), whereas the best-studied role of the superior colliculus of cat, monkey, and human is in the control of saccades, rapid eye movements to ac-

quire a visual target. Moreover, the superior colliculus can integrate auditory and somatosensory information into its visual frame (*Stein and Meredith* [62.35]) and this inspired *Strosslin et al.* [62.36] to use a biologically inspired approach based on the properties of neurons in the superior colliculus to learn the relation between visual and tactile information in control of a mobile robot platform. More generally, then, the comparative study of mammalian brains has yielded a rich variety of computational models of importance in neurorobotics. In this section, we further introduce the study of *mammalian neurorobotics* by looking at studies of mechanisms of the rat brain for spatial navigation.

The frog's detour behavior is an example of what *O'Keefe and Nadel* [62.37] called the *taxon (behavioral orientation) system* [as in *Braitenberg*, [62.38] a *taxis* (plural *taxes*) is an organism's response to a stimulus by movement in a particular direction]. They distinguished this from a system for *map-based navigation*, and proposed that the latter resides in the hippocampus, though *Guazzelli et al.* [62.39] qualified this assertion, showing how the hippocampus may function as *part of* a cognitive map. The taxon versus map distinction is akin to the distinction between reactive and deliberative control in robotics (*Arkin et al.* [62.33]). It will be useful to relate *taxis* to the notion of an *affordance* (*Gibson* [62.40]), a feature of an object or environment relevant to action, for example, in picking up an apple or a ball, the identity of the object may be irrelevant, but the size of the object is crucial. Similarly, if we wish to push a toy car, recognizing the make of car copied in the toy is irrelevant, whereas it is crucial to recognize the placement of the wheels to extract the direction in which the car can be readily pushed. Just as a rat may have basic *taxis* for approaching food or avoiding a bright light, say, so does it have a wider repertoire of affordances for possible actions associated with the immediate sensing of its environment. Such affordances include *go straight ahead* for visual sighting of a corridor, *hide* for a dark hole, *eat* for food as sensed generically, *drink* similarly, and the various turns afforded by, e.g., the sight of the end of the corridor. It also makes rich use of olfactory cues. In the same way, a robot's behavior will rely on a host of reactions to local conditions in fulfilling a plan, e.g., knowing that it must go to the end of a corridor it will nonetheless use local visual cues to avoid hitting obstacles, or to determine through which angle to turn when reaching a bend in the corridor.

Both normal and hippocampal-lesioned rats can learn to solve a simple T-maze (e.g., learning whether to turn left or right to find food) in the absence of any

consistent environmental cues other than the T-shape of the maze. If anything, the lesioned animals learn this problem faster than normals. After the criterion was reached, probe trials with an eight-arm radial maze were interspersed with the usual T-trials. Animals from both groups consistently chose the side to which they were trained on the T-maze. However, many did not choose the 90° arm but preferred either the 45° or 135° arm, suggesting that the rats eventually solved the T-maze by learning to rotate within an egocentric orientation system at the choice point through *approximately* 90°. This leads to the hypothesis of an *orientation vector* being stored in the animal's brain but does not tell us where or how the orientation vector is stored. One possible model would employ coarse coding in a linear array of cells, coding for turns from -180° to +180°. From the behavior, one might expect that only the cells close to the preferred *behavioral* direction are excited, and that learning *marches* this peak from the old to the new pre-

ferred direction. To *unlearn* -90°, say, the array must reduce the peak there, while at the same time *building* a new peak at the new direction of +90°. If the old peak has *mass* $p(t)$ and the new peak has *mass* $q(t)$, then as $p(t)$ declines toward 0 while $q(t)$ increases steadily from 0, the center of mass will progress from -90° to +90°, fitting the behavioral data.

The determination of movement direction was modeled by *ratification* of the *Arbib and House* [62.25] model of frog detour behavior. There, prey was represented by excitation coarsely coded across a population, while barriers were encoded by inhibition whose extent closely matched the retinotopic extent of each barrier. The sum of excitation was passed through a winner-takes-all circuit to yield the choice of movement direction. As a result, the direction of the gap closest to the prey, rather than the direction of the prey itself, was often chosen for the frog's initial movement. The same model serves for behavioral orientation once

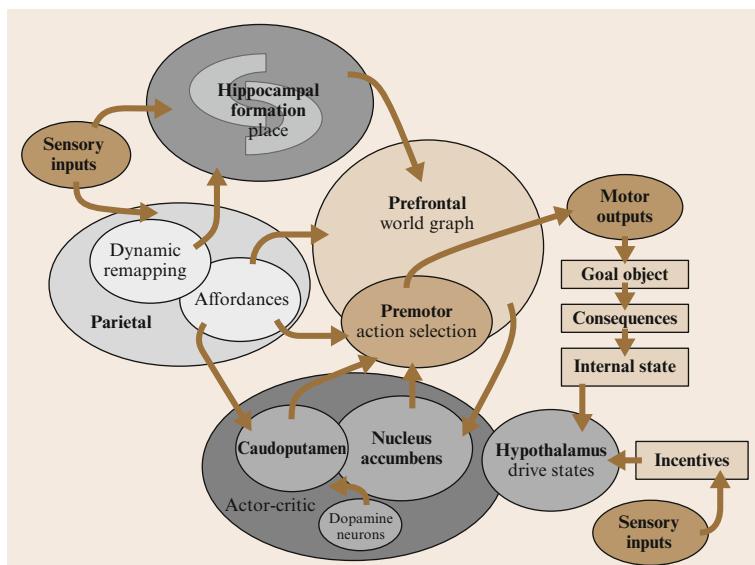

Fig. 62.2 The TAM-WG model has at its basis a system, TAM (the taxon affordance model), for exploiting affordances. This is elaborated by a system, WG (the world graph), which can use a cognitive map to plan paths to targets which are not currently visible. Note that the model processes two different kinds of sensory inputs. At the *bottom right* are those associated with, e.g., hypothalamic systems for feeding and drinking, and that may provide both incentives and rewards for the animal's behavior, contributing both to behavioral choices, and to the reinforcement of certain patterns of behavior. The nucleus accumbens and caudo-putamen mediate an actor-critic style of reinforcement learning based on the hypothalamic drive of the dopamine system. The sensory inputs at the *top left* are those that allow the animal to sense its relation with the external world, determining both where it is (the hippocampal place system) as well as the affordances for action (the parietal recognition of affordances can shape the premotor selection of an action). The TAM model focuses on the parietal–premotor reaction to immediate affordances; the WG (world graph) model places action selection within the wider context of a cognitive map. (after Guazzelli et al. [62.41])

we replace the direction of the prey (frog) by the direction of the orientation vector (rat), while the barriers correspond to the presence of walls rather than alley ways.

To approach the issue of how a cognitive map can extend the capability of the affordance system, *Guazzelli et al.* [62.43] extended the *Lieblich* and *Arbib* [62.44] approach to building a cognitive map as a *world graph*, a set of nodes connected by a set of edges, where the nodes represent recognized places or situations, and the links represent ways of moving from one situation to another. A crucial notion is that a place encountered in different circumstances may be represented by multiple nodes, but that these nodes may be merged when the similarity between these circumstances is recognized. They model the process whereby the animal decides where to move next, on the basis of its current drive state (hunger, thirst, fear, etc.). The emphasis is on spatial maps for guiding locomotion into regions not necessarily current visible, rather than retinotopic representations of immediately visible space, and yields exploration and latent learning without the introduction of an explicit exploratory drive. The model shows: (1) how a route, possibly of many steps, may be chosen that leads to the desired goal; (2) how short cuts may be chosen; and (3) through its account of node merging why, in open fields, place cell firing does not seem to depend on direction.

The overall structure and general mode of operation of the complete model is shown in Fig. 62.2, which gives a vivid sense of the lessons to be learned by studying not only specific systems of the mammalian brain but also their patterns of large-scale interaction. This model is but one of many inspired by the data on the role of the hippocampus and other regions in rat navigation. Here, we just mention as pointers to the wider literature the papers by *Girard et al.* [62.45] and *Meyer et al.* [62.46], which are part of the *Psikharpx* project, which is doing for rats what *Rana computatrix* did for frogs and toads.

62.2.4 Schemas and Coordinated Control Programs

Schema theory complements neuroscience's well-established terminology for levels of *structural* analysis (brain region, neuron, synapse) with a *functional* vocabulary, a framework for analysis of behavior with no necessary commitment to hypotheses on the localization of each *schema* (unit of functional analysis), but which can be linked to a structural analysis whenever appropriate. Schemas provide a high-level vocabulary which can

be shared by brain theorists, cognitive scientists, connectionists, ethologists, kinesiologists – and roboticists. In particular, schema theory can provide a distributed programming environment for robotics [see, e.g., the robots schemas (RS) language of *Lyons* and *Arbib* [62.47], and supporting architectures for distributed control as in *Metta et al.* [62.48]]. Schema theory becomes specifically relevant to *neurorobotics* when the schemas are inspired by a model constrained by data provided by, e.g., human brain mapping, studies of the effects of brain lesions, or neurophysiology.

A *perceptual schema* not only determines whether an object or other *domain of interaction* is present in the environment but can also provide important parameters to motor schemas (see below) for the guidance of action. The activity level of a perceptual schema signals the credibility of the hypothesis that what the schema represents is indeed present, whereas other schema parameters represent relevant properties such as size, location, and motion of the perceived object. Given a perceptual schema we may need several schema instances, each suitably tuned, to subserve perception of several instances of its domain, e.g., several chairs in a room.

Motor schemas provide the control systems which can be coordinated to affect a wide variety of actions.

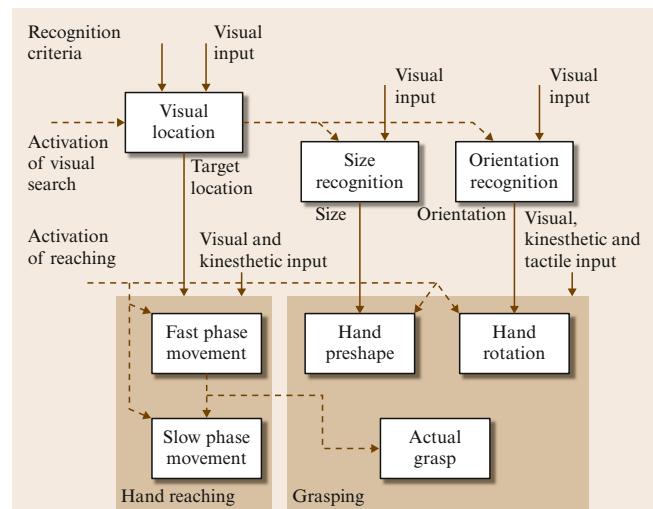

Fig. 62.3 Hypothetical coordinated control program for reaching and grasping. The perceptual schemas (*top*) provide parameters for the motor schemas (*bottom*) for the control of *reaching* (arm transport ≈ and reaching) and *grasping* (controlling the hand to conform to the object). *Dashed lines* indicate activation signals which establish timing relations between schemas; *solid lines* indicate transfer of data. (After *Arbib* [62.42])

The activity level of a motor schema instance may signal its *degree of readiness* to control some course of action. What distinguishes schema theory from usual control theory is the transition from emphasizing a few basic controllers (e.g., for locomotion or arm movement) to a large variety of motor schemas for diverse skills (peeling an apple, climbing a tree, changing a light bulb), with each motor schema depending on perceptual schemas to supply information about objects which are targets for interaction. Note the relevance of this for robotics – the robot needs to know not only *what* the object is but also *how* to interact with it. Modern neuroscience (see the works by *Ungerleider* and *Mishkin* [62.49] and *Goodale* and *Milner* [62.50]) has indeed established that the monkey and human brain each use a dorsal pathway (via the parietal lobe) for the *how* and a ventral pathway (via the inferotemporal cortex) for the *what*. Moreover, coupling between these two *streams* mediates their integration in normal ongoing behavior.

A *coordinated control program* interweaves the activation of various perceptual, motor, and coordinating schemas in accordance with the current task and sensory environment to mediate complex behaviors. Figure 62.3 shows the original coordinated control program (*Arbib* [62.42], inspired by the data of *Jeannerod* and *Biguer* [62.51]). As the hand moves to grasp a ball, it is *preshaped* so that, when it has almost reached the ball, it is of the right shape and orientation to enclose some part of the ball prior to gripping it firmly. The outputs of three perceptual schemas are available for the concurrent activation of two motor schemas, one controlling the arm to transport the hand towards the object and the other pre-shaping the hand. Once the hand is preshaped, it is only the completion of the fast initial phase of hand transport that *wakes up* the final stage of the grasping schema to shape the fingers under control of tactile feedback. [This model anticipates the much later discovery of perceptual

schemas for grasping in a localized area (**AIP**) of parietal cortex and motor schemas for grasping in a localized area (F5) of premotor cortex; see Fig. 62.4.] The notion of schema is thus *recursive* – a schema may be analyzed as a coordinated control program of finer schemas, and so on until such time as a secure foundation of neural specificity is attained.

Subsequent work has refined the scheme of Fig. 62.3, for example, *Hoff* and *Arbib's* [62.52] model uses the *time needed for completion* of each of the movements – transporting the hand and preshaping the hand – to explain data on how the reach to grasp responds to perturbation of target location or size. Moreover, *Hoff* and *Arbib* [62.53] show how to embed an optimality principle for arm trajectories into a controller which can use feedback to resist noise and compensate for target perturbations, and a predictor element to compensate for delays from the periphery. The result is a feedback system which can *act like* a feedforward system described by the optimality principle in *familiar* situations, where the conditions of the desired behavior are not perturbed and accuracy requirements are such that *normal* errors in execution may be ignored. However, when perturbations must be corrected for or when great precision is required, feedback plays a crucial role in keeping the behavior close to that desired, taking account of delays in putting feedback into effect. This integrated view of feedback and feedforward within a single motor schema seems to us of value for neurorobotics as well as the neuroscience of motor control.

It is standard to distinguish a *forward* or *direct* model which represents the path from motor command to motor output, from the *inverse* model which models the reverse pathway, i. e., going from a desired motor outcome to a set of motor commands likely to achieve it. As we have just suggested, the action plan unfolds *as if* it were feedforward or open-loop when the actual parameters of

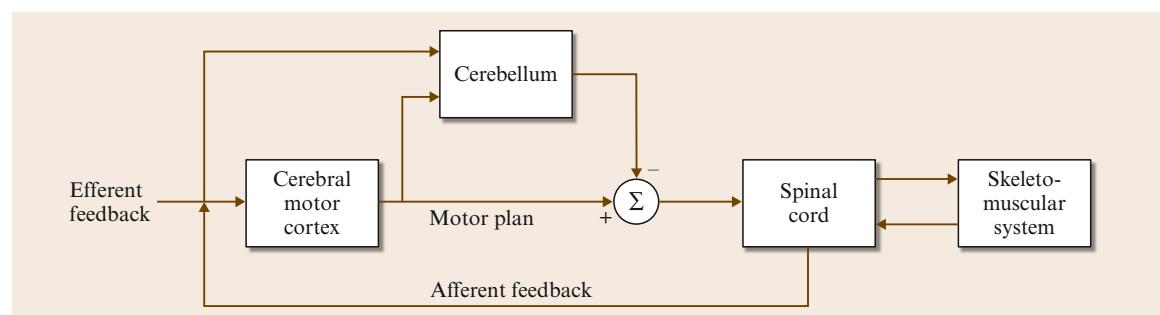

Fig. 62.4 Simplified control loop relating cerebellum and cerebral motor cortex in supervising the spinal cord's control of the skeletomuscular system

the situation match the stored parameters, while a feedback component is employed to counteract disturbances (current feedback) and to learn from mistakes (learning from feedback). This is obtained by relying on a forward model that predicts the outcome of the action as it unfolds in real time. The accuracy of the forward model can be evaluated by comparing the output generated by the system with the signals derived from sensory feedback (Miall et al. [62.54]). Also, delays must be accounted for to address the different propagation times of the neural pathways carrying the predicted and actual outcome of the action. Note that the forward model in this case is relatively simple, predicting only the motor output in advance: since motor commands are generated internally it is easy to imagine a predictor for these signals (known as an efference copy). The inverse model, on the other hand, is much more complicated since it maps sensory feedback (e.g., vision) back into motor terms. These concepts will prove important both in our study of the cerebellum (Sect. 62.3) and mirror systems (Sect. 62.4).

62.2.5 Salience and Visual Attention

Discussions of how an animal (or robot) grasps an object assume that the animal or robot is attending to the relevant object. Thus, whatever the subtlety of processing in the canonical and mirror systems for grasping, its success rests on the availability of a visual system coupled to an oculomotor control system that bring foveal vision to bear on objects to set parameters needed for successful interaction. Indeed, the general point is that attention greatly reduces the processing load for animal and robot. The catch, of course, is that reducing computing load is a Pyrrhic victory unless the moving focus of attention captures those aspects of behavior relevant for the current task – or supports necessary *priority interrupts*. Indeed, directing attention appropriately is a topic for which there is a great richness of both neurophysiological data and robotic application (see Deco and Rolls [62.55] and Choi, et al. [62.41]).

In their neuromorphic model of the bottom-up guidance of attention in primates, Itti and Koch [62.56] decompose the input video stream into eight feature channels at six spatial scales. After surround suppression, only a sparse number of locations remain active in each map, and all maps are combined into a unique *saliency map*. This map is scanned by the focus of attention in order of decreasing saliency through the interaction between a winner-takes-all mechanism (which selects the most salient location) and an *inhibition-of-return* mechanism (which transiently sup-

presses recently attended locations from the saliency map). Because it includes a detailed low-level vision front-end, the model has been applied not only to laboratory stimuli, but also to a wide variety of natural scenes, predicting a wealth of data from psychophysical experiments.

When specific objects are searched for, low-level visual processing can be biased both by the gist (e.g., *outdoor suburban scene*) and also for the features of that object. This top-down modulation of bottom-up processing results in an ability to guide search towards targets of interest (Wolfe [62.57]). Task affects eye movements (Yarbus [62.58]), as do training and general expertise. Navalpakkam and Itti [62.59] propose a computational model which emphasizes four aspects that are important in biological vision: determining the task relevance of an entity, biasing attention for the low-level visual features of desired targets, recognizing these targets using the same low-level features, and incrementally building a visual map of task relevance at every scene location. It attends to the most salient location in the scene, and attempts to recognize the attended object through hierarchical matching against object representations stored in long-term memory. It updates its working memory with the task relevance of the recognized entity and updates a topographic task-relevance map with the location and relevance of the recognized entity, for example, in one task the model forms a map of likely locations of cars from a video clip filmed while driving on a highway. Such work illustrates the continuing interaction between models based on visual neurophysiology and human psychophysics with the tackling of practical robotic applications.

Orabona et al. [62.60] implemented an extension of the Itti–Koch model on a humanoid robot with moving eyes, using log-polar vision as in Sandini and Tagliasco [62.61], and changing the feature construction pyramid by considering proto-object elements (blob-like structures rather than edges). The inhibition-of-return mechanism has to take into account a moving frame of reference, the resolution of the fovea is very different from that at the periphery of the visual field, and head and body movements need to be stabilized. The control of movement might thus have a relationship with the structure and development of the attention system. Rizzolatti et al. [62.62] proposed a role for the feedback projections from premotor cortex to the parietal lobe, assuming that they form a tuning signal that dynamically changes visual perception. In practice this can be seen as an implicit attention system which *selects* sensory information while the action is being prepared and subsequently ex-

ecuted (see *Flanagan and Johansson* [62.63], *Flanagan et al.* [62.64], and *Mataric and Pomplun* [62.65]). The early responses, before action onset, of many premo-

tor and parietal neurons suggest a premotor mechanism of attention that deserves exploration in further work in neurorobotics.

62.3 The Role of the Cerebellum

Although cerebellar involvement in muscle control was advocated long ago by the Greek gladiator surgeon Galen of Pergamum (129–216/17 CE), it was the publication by Eccle et al. [62.66] of the first comprehensive account of the detailed neurophysiology and anatomy of the cerebellum (*Ito* [62.67]) that provided the inspiration for the Marr–Albus model of cerebellar plasticity (*Marr* [62.68]; *Albus* [62.69]) that is at the heart of most current modeling of the role of the cerebellum in control of motion and sensing. From a robotics point of view, the most convincing results are based on *Albus'* [62.70] cerebellar model articulation controller (CMAC) model and subsequent implementations by *Miller* [62.71]. These models, however, are only remotely based on the structure of the biological cerebellum. More detailed models are usually only applied to two-degree-of-freedom robotic structures, and have not been generalized to real-world applications (see *Peters and van der Smagt* [62.72]). The problem may lie with viewing the cerebellum as a stand-alone dynamics controller. An important observation about the brain is that schemas are widely distributed, and different aspects of the schemas are computed in different parts of the brain. Thus, one view is that (1) the cerebral cortex has the necessary models for choosing appropriate actions and getting the general shape of the trajectory assembled to fit the present context, whereas (2) the cerebellum provides a side-path which (on the basis of extensive learning of a forward motor model) provides the appropriate corrections to compensate for control delays, muscle nonlinearities, Coriolis and centrifugal forces occasioned by joint interactions, and subtle adjustments of motor neuron firing in simultaneously active motor pattern generators to ensure their smooth coordination. Thus, for example, a patient with cerebellar lesions may be able to move his arm to successfully reach a target, and to successfully adjust his hand to the size of an object. However, he lacks the machinery to perform either action both swiftly and accurately, and further lacks the ability to coordinate the timing of the two subactions. His behavior will thus exhibit *decomposition of movement* – he may first move the hand till the thumb touches the object, and only then shape the hand appropriately to

grasp the object. Thus analysis of how various components of cerebral cortex interact to support forward and inverse models which determine the *overall shape of the behavior* must be complemented by analysis of how the cerebellum handles control delays and nonlinearities to transform a well-articulated plan into graceful coordinated action. Within this perspective, cerebellar structure and function will be very helpful in the control of a new class of highly antagonistic robotic systems as well as in adaptive control.

62.3.1 The Human Control Loop

Lesions and deficits of the cerebellum impair the co-ordination and timing of movements while introducing excessive, undesired motion: effects which cannot be compensated by the cerebral cortex. According to mainstream models, the cerebellum filters descending motor cortex commands to cope with timing issues and communication delays which go up to 50 ms one way for arm control. Clearly, closed-loop control with such delays is not viable in any reasonable setting, unless augmented with an open-loop component, predicting the behavior of the actuator system. This is where the cerebellum comes into its own. The complexity of the vertebrate musculoskeletal system, clearly demonstrated by the human arm using a total of 19 muscle groups for planar motion of the elbow and shoulder alone (see *Nijhof and Kouwenhoven* [62.73]) requires a control mechanism coping with this complexity, especially in a setting with long control delays. One cause for this complexity is that animal muscles come in antagonistic pairs (e.g., flexing versus extending a joint). Antagonistic control of muscle groups leads to energy-optimal (*Damsgaard et al.* [62.74]) and intrinsically flexible systems. Contact with stiff or fast-moving objects requires such flexibility to prevent breakage. In contrast, classical (industrial) robots are stiff, with limb segments controlled by linear or rotary motors with gear boxes. Even so, most laboratory robotic systems have passively stiff joints, with active joint flexibility obtainable only by using fast control loops and joint torque measurement. Although it may be debatable whether such robotic systems re-

quire cerebellar-based controllers, the steady move of robotics towards complete anthropomorphism by mimicking human (hand and arm) kinematics as well as dynamics as closely as possible, requires the search for alternative, neuromorphic control solutions.

Vertebrate motor control involves the cerebral motor cortex, basal ganglia, thalamus, cerebellum, brain stem, and spinal cord. Motor programs, originating in the cortex, are fed into the cerebellum. Combined with sensory information through the spinal cord, it sends motor commands out to the muscles via the brain stem and spinal cord, which controls muscle length and joint stiffness (see Bullock and Contreras-Vidal [62.75]). The full control loop is depicted in Fig. 62.4 (see Schaal and Schweighofer [62.76], for an overview of robotic versus brain control loops). The model in Fig. 62.4 clearly resembles the well-known computed torque model and, when the cerebellum is interpreted as a Smith model, it serves to cope with long delays in the control loop (see Miall et al. [62.54] and van der Smagt and Hirzinger [62.77]). It is thus understood to incorporate a forward model of the skeleto-muscular system.

Alternative approaches use the cerebellum as an inverse model (see Ebadzadeh et al. [62.78]), which however leads to increased complexity and control loop stability problems.

62.3.2 Models of Cerebellar Control

The cerebellum can be divided into two parts: the cortex and the deep nuclei. There are two systems of fibers bringing input to both the cortex and nuclei: the mossy fibers and the climbing fibers. The only output from the cerebellar nucleus comes from cells called Purkinje cells, and they project only to the cerebellar nuclei, where their effect is inhibitory. This inhibition sculpts the output of the nuclei which (the effect varies from nucleus to nucleus) may act by modulating activity in the spinal cord, the mid-brain or the cerebral cortex. We now turn to models which make explicit use of the cellular structure of the cerebellar cortex (see Eccles et al. [62.66] and Ito [62.79], and also Fig. 62.5a). The human cerebellum has 7–14 million Purkinje cells (PCs), each receiving about 200 000 synapses. Mossy

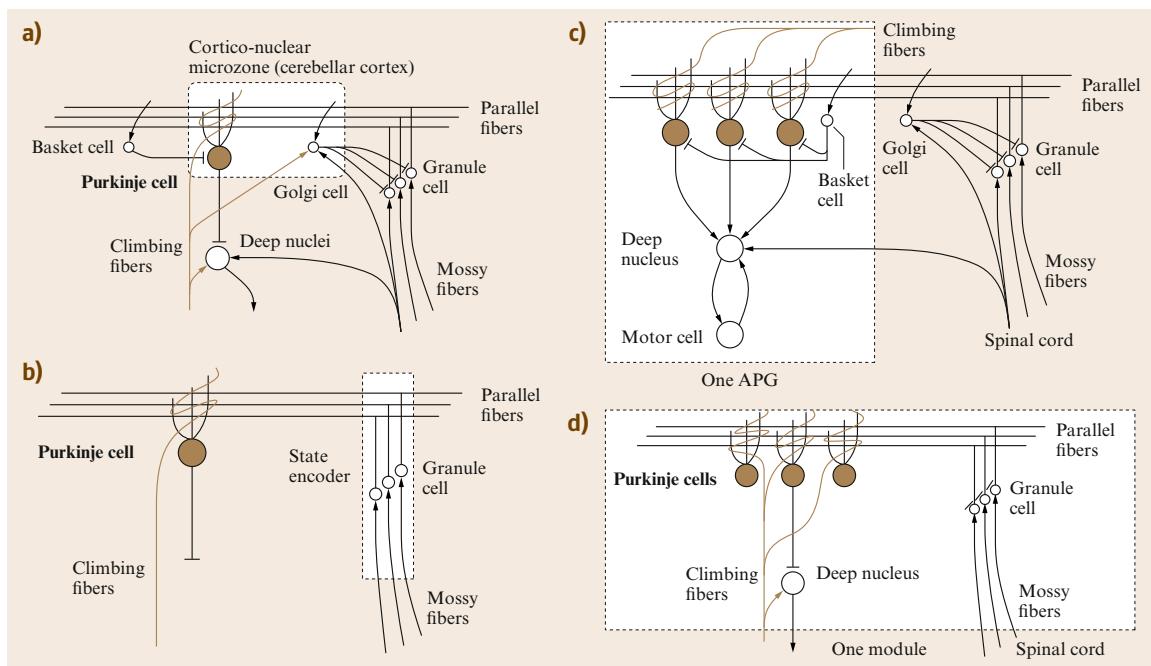

Fig. 62.5 (a) Major cells in the cerebellum. (b) Cells in the Marr-Albus model. The granule cells are state encoders, feeding system state, and sensor data into the PC. PC/PF synapses are adjusted using the Widrow-Hoff rule. The output of the PC are steering signals for the robotic system. (c) The APG model, using the same state encoder as in (b). (d) The MPFIM model. A single module corresponds to a group of Purkinje cells: predictor, controller, and responsibility estimator. The granule cells generate the necessary basis functions of the original information

fibers (**MFs**) arise from the spinal cord and brainstem. They synapse onto granule cells and deep cerebellar nuclei. Granule cells have axons which each project up to form a T, with the bars of the T forming the parallel fibers (**PFs**). Each **PF** synapses on about 200 **PCs**. The **PCs**, which are grouped into microzones, inhibit the deep nuclei. **PCs** with their target cells in cerebellar nuclei are grouped together in microcomplexes (see *Ito* [62.79]). Microcomplexes are defined by a variety of criteria to serve as the units of analysis of cerebellar influence on specific types of motor activity. The climbing fibers (**CF**) arise from the inferior olive. Each **PC** receives synapses from only one **CF**, but a **CF** makes about 300 excitatory synapses on each **PC** which it contacts. This powerful input alone is enough to fire the **PC**, though most **PC** firing depends on subtle patterns of **PF** activity. The cerebellar cortex also contains a variety of inhibitory interneurons. The basket cell is activated by **PF** afferents and makes inhibitory synapses onto **PCs**. Golgi cells receive input from **PFs**, **MFs**, and **CFs** and inhibit granule cells.

The Marr–Albus Model

In the Marr–Albus model (see *Marr* [62.68] and *Albus* [62.69]) the cerebellum functions as a classifier of sensory and motor patterns received through the **MFs**. Only a small fraction of the parallel fibers (**PF**) are active when a Purkinje cell (**PC**) fires and thus influence the motor neurons. Both Marr and Albus hypothesized that the error signals for improving **PC** firing in response to **PF**, and thus **MF** input, were provided by the climbing fibers (**CF**), since only one **CF** affects a given **PC**. However, Marr hypothesized that **CF** activity would strengthen the active **PF/PC** synapses using a Widrow–Hoff learning rule, whereas Albus hypothesized they would weaken them. This is an important example of a case where computational modeling inspired important experimentation. Eventually, Masao Ito was able to demonstrate that Albus was correct – the weakening of active synapses is now known to involve a process called long-term depression (*Ito* [62.79]). However, the rule with weakening of synapses still known as the Marr–Albus model, and remains the reference model for studies of synaptic plasticity of cerebellar cortex. However, both Marr and Albus viewed each **PC** as functioning as a perceptron whose job it was to control an elemental movement, contrasting with more plausible models in which **PCs** serve to modulate the involvement of microcomplexes (which include cells of the deep nuclei) in motor pattern generators (e.g., the **APG** model described below).

Since the development of the Marr–Albus model several cerebellar models have been introduced in which cerebellar plasticity plays a key role. Limiting our overview to computational models, we will describe (1) the cerebellar model articulation controller (**CMAC**), (2) the adjustable pattern generator (**APG**), (3) the Schweighofer–Arbib model, and (4) the multiple paired forward-inverse models (see *van der Smagt* [62.80, 81]).

The Cerebellar Model Articulation Controller (**CMAC**)

One of the first well-known computational models of the cerebellum is the **CMAC** (*Albus* [62.70]; see Fig. 62.5b). The algorithm was based on Albus' understanding of the cerebellum, but it was not proposed as a biologically plausible model. The idea has its origins in the **BOXES** approach, in which for n variables an n -dimensional hypercube stores function values in a lookup table. **BOXES** suffers from the curse of dimensionality: if each variable can be discretized into D different steps, the hypercube has to store D^n function values in memory. Albus assumed that the mossy fibers provided discretized function values. If the signal on a mossy fiber is in the receptive field of a particular granule cell, it fires onto a parallel fiber. This mapping of inputs onto binary output variables is often considered to be the generalization mechanism in **CMAC**. The learning signals are provided by the climbing fibers.

Albus' **CMAC** can be described in terms of a large set of overlapping, multidimensional receptive fields with finite boundaries. Every input vector falls within the range of some local receptive fields. The response of **CMAC** to a given input is determined by the average of the responses of the receptive fields excited by that input. Similarly, the training for a given input vector affects only the parameters of the excited receptive fields.

The organization of the receptive fields of a typical Albus **CMAC** with a two-dimensional input space can be described as follows. The set of overlapping receptive fields is divided into C subsets, commonly referred to as *layers*. Any input vector excites one receptive field from each layer, for a total of C excited receptive fields for any input. The overlap of the receptive fields produces input generalization, while the offset of the adjacent layers of receptive fields produces input quantization. The ratio of the width of each receptive field (input generalization) to the offset between adjacent layers of receptive fields (input quantization) must be equal to C for all dimensions of the input space. This organization of the receptive fields guarantees that only a fixed number, C , of receptive fields is excited by any input.

If a receptive field is excited, its response equals the magnitude of a single adjustable weight specific to that receptive field. The **CMAC** output is the average of the weights of the excited receptive fields. If nearby points in the input space excite the same receptive fields, they produce the same output value. The output only changes when the input crosses one of the receptive field boundaries. The Albus **CMAC** thus produces piecewise-constant outputs. Learning takes place as described above.

CMAC neural networks have been applied in various control situations *Miller* [62.71], starting from adaptation of **PID** control parameters for an industrial robot arm and hand–eye systems up to biped walking (see *Sabourin* and *Bruneau* [62.82]).

The Adjustable Pattern Generator APG

The **APG** model (*Houk* et al. [62.83]) got its name because the model can generate a burst command with adjustable intensity and duration. The **APG** is based on the same understanding of the mossy fiber–granule cell–parallel fiber structure as **CMAC**, using the same state encoder, but has the crucial difference (Fig. 62.2c) that the role of the nuclei is crucial. In the **APG** model, each nucleus cell is connected to a motor cell in a feedback circuit. Activity in the loop is then modulated by Purkinje cell inhibition, a modeling idea introduced by *Arbib* et al. [62.84].

The learning algorithm determines which of the **PF–PC** synapses will be updated in order to improve movement generation performance. This is the traditional credit assignment problem: *which* synapse (the structural credit assignment) must be updated based on a response issued *when* (temporal credit assignment). While the former is solved by the **CFs**, which are considered binary signals, for the latter eligibility traces on the synapses are introduced, serving as memory for recent activity to determine which synapses are eligible for updates. The motivation for the eligibility signal is this: each firing of a **PC** cell will take some time to affect the animal’s movement, and a further delay will occur before the **CF** can signal an error in the movement in which the **PC** is involved. Thus the error signal should not affect those **PF–PC** synapses which are currently active, but should instead act upon those synapses which affected the activity whose error is now being registered.

The **APG** has been applied in a few control situations, e.g., a single muscle–mass system and a simulated two-link robot arm. Unfortunately these applications do not allow us judge the performance of the **APG** scheme

itself due to the fact that the control task itself was hidden within spinal cord and muscle models.

The Schweighofer–Arbib Model

The Schweighofer–Arbib model was introduced in *Schweighofer* [62.85]. It does not use the **CMAC** state encoder but tries to copy the anatomy of the cerebellum. All the cells, fibers, and axons in Fig. 62.2a are included. Several assumptions are made: (1) there are two types of mossy fibers, one type reflecting the desired state of the controlled plant and another which carries information on the current state. A mossy fiber diverges into approximately 16 branches; (2) granule cells have an average of four dendrites, each of which receive input from different mossy fibers through a synaptic structure called the glomerulus; (3) three Golgi cells synapse on a granule cell through the glomerulus and the strength of their influence depends on the simulated geometric distance between the glomerulus and the Golgi cell; (4) the climbing fiber connection on nuclear cells as well as deep nuclei is neglected.

Learning in this model depends on directed error information given by the climbing fibers from the inferior olive (IO). Here, long-term depression is performed when the IO firing rate provides an error signal for an eligible synapse, while compensatory but slower increases in synaptic strength can occur when no error signal is present. Schweighofer applied the model to explain several acknowledged cerebellar system functions: (1) saccadic eye movements, (2) two-link limb movement control (see *Schweighofer* et al. [62.86, 87]), and (3) prism adaptation (*Arbib* et al. [62.88]). Furthermore, control of a simulated human arm was demonstrated.

Multiple Paired Forward–Inverse Models (MPFIM)

Building on a long history of cerebellar modeling, *Wolpert* and *Kawato* [62.89] proposed a novel functional model of the cerebellum which uses multiple coupled predictors and controllers which are trained for control, each being responsible for a small state-space region. The **MPFIM** model is based on the indirect/direct model approach by Kawato, and is also based on the microcomplex theory. We noted earlier that a microzone is a group of **PCs**, while a microcomplex combines the **PCs** of a microzone with their target cells in cerebellar nuclei. In **MPFIM**, a microzone consists of a set of modules controlling the same degree of freedom and is learned by only one particular climbing fiber. The modules in this microzone compete to control this particular synergy. Inside such a module there are three types of **PC** which

perform the computations of a forward model, an inverse model or a responsibility predictor, but all receiving the same input. A single internal model i is considered to be a controller which generates a motor command τ_i and a predictor which predicts the current acceleration. Each predictor is a forward model of the controlled system, while each controller contains an inverse model of the system in a region of specialization. The responsibility signal weights the contribution that this model will make to the overall output of the microzone. Indeed, **MPFIM** further assumes that each microzone contains n internal models of situations occurring in the control task. Model i generates motor command τ_i , and estimates its own responsibility r_i . The feedforward motor command τ_{ff} consists only of the output of the single models adjusted by the sum of responsibility signals: $\tau_{\text{ff}} = \sum r_i \tau_i / \sum r_i$.

The **PCs** are considered to be roughly linear. The **MF** inputs carry all necessary information including state information, efference copies of the last motor commands as well as desired states. Granule cells, and eventually the inhibitory interneurons as well, nonlinearly transform the state information to provide a rich set of basis functions through the **PFs**. A climbing fiber carries a scalar error signal while each Purkinje cell encodes a scalar output – responsibilities, predictions, and controller outputs are all one-dimensional values. **MPFIM** has been introduced with different learning methods: its first implementations were done using gradient descent methods; subsequently, expectation maximization (**EM**) batch-learning and hidden Markov chain **EM** learning have been applied.

Comparison of the Models

Summing up, we can categorize the cerebellar models **CMAC**, **APG**, Schweighofer–Arbib, and **MPFIM** as follows.

- State-encoder-driven models: This kind of model assumes that the granule cells are on–off types of entities which split up the state space. This kind of model is best suited for, e.g., simple function approximation, and suffers strongly from the curse of dimensionality.
- Cellular-level models: Obviously, the most realistic simulations would be at the cellular level. Unfortunately, modeling only a few Purkinje cells at realistic conditions is an immense computational challenge, and other relevant neurons are even less well understood. Still, from the biological point of view this kind of model is the most important since it allows

obtaining insight into cerebellar function on cellular level. The first steps in this direction were taken by the Schweighofer–Arbib model.

- Functional models: From the computer-science point of view, the most interesting models are based on functional understanding of the cells. In this case, we obtain only a basic insight of the functions of the parts and apply it as a crude approximation. This kind of approach is very promising and **MPFIM**, with its emphasis on the use of responsibility signals to combine models appropriately, provides an interesting example of this approach.

62.3.3 Cerebellar Models and Robotics

From the previous discussions, it is clear that a popular view is that the function of the cerebellum within the motor control loop is to represent a forward model of the skeletomuscular system. As such it predicts the movements of the body, or rather the perceptually coded (e.g., through muscle spindles, skin-based positional information, and visual feedback) representation of the movements of the body. With this prediction a fast control loop between motor cortex and cerebellum can be realized, and motor programs are played before being sent to the spinal cord (Fig. 62.4). Proprioceptive feedback is used for adaptation of the motor programs as well as for updating the forward model stored in the cerebellum. However, the Schweighofer–Arbib model is based on the view that the cerebellum offers not so much a total forward model of the skeletomuscular system as a forward model of the *difference* between the crude model of the skeletomuscular system available to the motor planning circuits of the cerebral cortex, and the more intricately parameterized forward model of the skeletomuscular system needed to support fast, graceful movements with minimal use of feedback. This hypothesis is reinforced by the fact that cerebellar lesions do not prohibit motion but substantially reduce its quality, since the forward model of the skeletomuscular system is of lesser quality.

As robotic systems move towards their biological counterparts, the control approaches can or must do the same. There are many lines of research investigating the former part; cf. Chap. 13 *Robots with Flexible Arms* and Chap. 60 *Biologically Inspired Robots*. It should be noted that the drive principle that is used to move the joints does not necessarily have a major impact on the outer control loop. Whether McKibben muscles, which are intrinsically flexible but bulky (see *van der Smagt et al. [62.90]*), low-dynamics polymer linear actuators,

or direct-current (DC) motors with spindles and added elastic components are used does not affect the control approach at the cerebellar level, but rather at the motor control level (cf. the spinal cord level). Of key importance, however, are the resulting dynamical properties of the system, which are of course influenced by its actuators.

Passive flexibility at the joints, which is a key feature of muscle systems, is essential for reasons of safety, stability during contact with the environment, and storage of kinetic energy. As mentioned before, however, biological systems are immensely complex, requiring large groups of muscles for comparatively simple movements. A reason for this complexity is the resulting nearly linear behavior, which has been noted for, e.g., muscle activation with respect to joint stiffness (see *Osu* and

Gomi [62.91]). By this regularization of the complexity of the skeleto muscular system, the complexity of the forward model stored in the cerebellum is correspondingly reduced. The whole picture therefore seems to be that the cerebellum, controlling a piecewise-linear skeleto muscular system, incorporates a forward model thereof to cope with delays in the peripheral nervous system. Consequently, although the applicability of cerebellar systems to highly nonlinear dynamics control of traditional robots is questionable, the use of cerebellar systems as forward models appears to be useful in the control of more complex and flexible robotic systems. The control challenge posed by the currently emerging generation of robots employing antagonistic motor control therefore opens a new wealth of applications of cerebellar systems.

62.4 The Role of Mirror Systems

Mirror neurons were first discovered in the brain of the macaque monkey – neurons that fire both when the monkey exhibits a particular grasping action, and when the monkey observes another (monkey or human) perform a similar grasp (see *Rizzolatti* et al. [62.92] and *Gallese* et al. [62.93]). Since then, human studies have revealed a *mirror system* for grasping in the human brain – a mirror system for a class X of actions being a set of regions that are active both when the human performs some action from X and when the human observes someone else performing an action from X (see, e.g., *Grafton* et al. [62.94], *Rizzolatti* et al. [62.95], and *Fadiga* et al. [62.96]). Until recently we had no single-neuron studies of humans proving the reasonable hypothesis that the human mirror system for grasping contains mirror *neurons* for specific actions. However, data from neurosurgery are now becoming available (M. Iacoboni, personal communication). In any case, most models of the human mirror system for grasping assume that it contains circuitry analogous to the mirror neuron circuitry of the macaque brain. However, the current consensus is that monkeys have little or no ability for imitation (but see *Voelkl* and *Huber* [62.97] for a very simple form of imitation-like behavior in marmoset monkeys); great apes have the ability to master certain skills after extended bouts of observation (*Byrne* [62.98]), whereas the human mirror system plays a key role in our capability for much richer forms of imitation (see *Iacoboni* et al. [62.99]), pantomime, and even language (see *Arbib* and *Rizzo-*

latti [62.100] and *Arbib* [62.101]). Indeed, it has been suggested that mirror neurons underlie the motor theory of speech perception of *Liberman* et al. [62.102], which holds that speech perception rests on the ability to recognize the motor acts that produce speech sounds.

Section 62.4.1 reviews basic neurophysiological data on mirror neurons in the macaque, and presents both the Fagg–Arbib–Rizzolatti–Sakata (FARS) model of canonical neurons (unlike mirror neurons, these are active when the monkey executes an action but not when he observes it) and the mirror neuron system (MNS) model of mirror neurons and their supporting brain regions. Section 62.4.2 then uses Bayes’s rule to offer a new, probabilistic view of the mirror system’s role in action recognition, and demonstrates the operation of the new model in the context of studies with two robots. Finally, Sect. 62.4.3 briefly shifts the emphasis of our study of mirror neurons to imitation, which in fact is the area that has most captured the imagination of roboticists.

62.4.1 Mirror Neurons and the Recognition of Hand Movements

Area F5 in the premotor cortex of the macaque contains, among others, neurons which fire when the monkey executes a specific manual action, e.g., one neuron might fire when the monkey performs a precision pinch, another when it executes a power grasp. (In discussing neurorobotics, it seems unnecessary to explain in any detail the areas like F5, AIP, and STS described here

– they will function as labels for components of functional systems. To fill in the missing details see, e.g., Rizzolatti et al. [62.103, 104]) A subset of these neurons, the so-called *mirror neurons*, also discharge when the monkey observes meaningful hand movements made by the experimenter which are similar to those whose execution is associated with the firing of the neuron. In contrast, the *canonical neurons* are those belonging to the complementary, anatomically segregated subset of grasp-related F5 neurons which fire when the monkey performs a specific action and also when it sees an object as a possible target of such an action – but do not fire when the monkey sees another monkey or human perform the action. Finally, F5 contains a large population of motor neurons which are active when the monkey grasps an object (either with the hand or mouth) but do not possess any visual response. F5 is clearly a motor area although the details of the muscular activation are abstracted out – F5 neurons can be effector-independent. In contrast, the primary motor cortex (F1) formulates the neural instructions for lower motor areas and motor neurons.

Moreover, macaque mirror neurons encode transitive actions and do not fire when the monkey sees the hand movement unless it can also see the object or, more subtly, if the object is not visible but is appropriately *located* in working memory because it has recently been placed on a surface and has then been obscured by a screen be-

hind which the experimenter is seen to be reaching (see Umiltà et al. [62.105]). All mirror neurons show visual generalization. They fire when the instrument of the observed action (usually a hand) is large or small, far from or close to the monkey. They may also fire even when the action instrument has shapes as different as those of a human or monkey hand. Some neurons respond even when the object is grasped by the mouth. When naive monkeys first see small objects grasped with a pair of pliers, mirror neurons do not respond, but after extensive training some precision pinch mirror neurons do show activity also to this new grasp type (see Ferrari et al. [62.106]).

Mirror neurons for grasping have also been found in parietal areas of the macaque brain and, recently, it has been shown that parietal mirror neurons are sensitive to the context of the observed action being predictive of the outcome as a function of contextual cues – e.g., some grasp-related parietal mirror neurons may fire for a grasp that precedes eating the grasped object while others fire for a grasp that precedes placing the object in a container (see Fogassi et al. [62.107]). In practice the parieto-frontal circuitry seems to encode action execution and simultaneously action recognition by taking into account a large set of potential candidate actions which are selected on the basis of a range of cues such as vision of the relation of the effector to the object and certain sounds (when relevant for the task). Further, feedback connections (frontal to parietal) are thought to be part of a stimulus selection process which refines the sensory processing by attending to stimuli relevant for the ongoing action (see Rizzolatti et al. [62.62] and recall the discussion in Sect. 62.2.5). Recognition is then supported by the activation of the same circuitry in the absence of overt movement.

We clarify these ideas by briefly presenting the **FARS** model of the canonical F5 neurons and the **MNS** model of the F5 mirror neurons. In each case, the F5 neurons function effectively only because of the interaction of F5 with a wide range of other regions. We have stressed (Sect. 62.2.3) the distinction between recognition of the category of an object and recognition of its *affordances*. The parietal area **AIP** processes visual information to extract *affordances*, in this case properties of the object relevant to grasping it (Taira et al. [62.108]). **AIP** and F5 are reciprocally connected, with **AIP** being more visual and F5 more motoric.

The Fagg–Arbib–Rizzolatti–Sakata (**FARS**) model (see Fagg and Arbib [62.109] and Fig. 62.6) embeds F5 canonical neurons in a larger system. The dorsal stream (which passes through **AIP**) can only analyze the

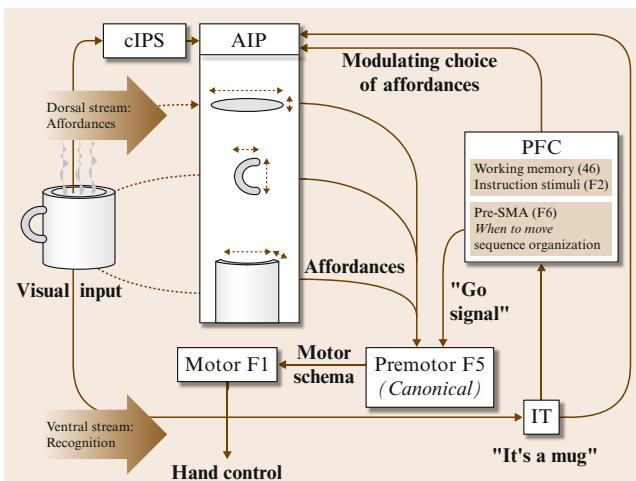

Fig. 62.6 The original **FARS** diagram (see Fagg and Arbib [62.45]) is here modified to show **PFC** acting on **AIP** rather than F5. The idea is that the prefrontal cortex uses the **IT** identification of the object, in concert with task analysis and working memory, to help the **AIP** select the appropriate affordance from its *menu*

object as a set of possible affordances, whereas the ventral stream (via the inferotemporal cortex, **IT**) is able to recognize what the object is. The latter information is passed to the prefrontal cortex (**PFC**) which can then, on the basis of the current goals of the organism, bias the choice of affordances appropriate to the task at hand. Neuroanatomical data (as analyzed by *Rizzolatti* and *Luppino* [62.110]) suggest that **PFC** and **IT** may modulate action selection at the level of the parietal cortex. Figure 62.6 gives a partial view of the **FARS** model updated to show this modified pathway. The affordance selected by **AIP** activates **F5** neurons to command the appropriate grip once they receive a *go* signal from another region, **F6**, of the prefrontal cortex. **F5** also accepts signals from other **PFC** areas to respond to working memory and instruction stimuli in choosing among the available affordances. Note that this same pathway could be implicated in tool use, bringing in semantic knowledge as well as perceptual attributes to guide the dorsal system (see *Johnson-Frey* [62.111]).

With this, we turn to the *mirror* system. Since grasping a complex object requires careful attention to motion of, e.g., fingertips relative to the object we hold that the primary evolutionary impetus for the mirror system was to facilitate feedback control of dexterous movement. We now show how *parameters relevant to such feedback* could be crucial in enabling the monkey to associate the visual appearance of what it is doing with the task at hand. The key side-effect will be that this feedback-serving self-recognition is so structured as to

also support recognition of the action when performed by others – and it is this *recognition of the actions of others* that has created the greatest interest in mirror neurons and systems.

The **MNS** model of *Oztop* and *Arbib* [62.112] provides some insight into the anatomy while focusing on the learning capacities of mirror neurons. Here, the task is to determine whether the shape of the hand and its trajectory are *on track* to grasp an observed affordance of an object using a known action. The model is organized around the idea that the **AIP** → **F5_{canonical}** pathway emphasized in the **FARS** model (Fig. 62.6) is complemented by another pathway **7b** → **F5_{mirror}**. As shown in Fig. 62.7 (middle diagonal), object features are processed by **AIP** to extract grasp affordances, these are sent on to the canonical neurons of **F5** that choose a particular grasp. Recognizing the location of the object (top diagonal) provides parameters to the motor programming area **F4** which computes the reach. The information about the reach and the grasp is taken by the motor cortex **M1** (=F1) to control the hand and the arm. The rest of the figure provides components that can learn and apply key criteria for activating a mirror neuron, recognizing that the preshape of the observed hand corresponds to the grasp that the mirror neuron encodes and is appropriate to the object, and that the hand is moving on an appropriate trajectory. Making crucial use of input from the superior temporal sulcus (**STSa**; see *Perrett* et al. [62.113] and *Carey* et al. [62.114]), schemas at the bottom left recognize the shape of the observed hand,

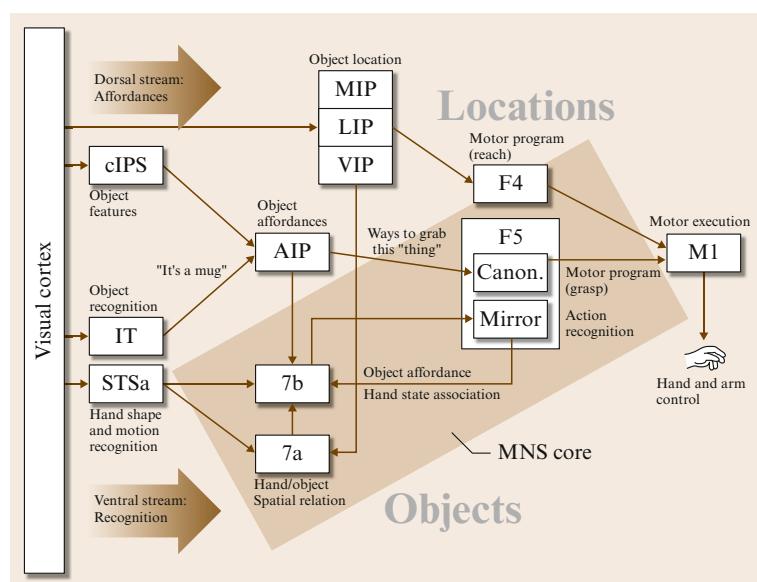

Fig. 62.7 The mirror neuron system (**MNS**) model (see *Oztop* and *Arbib* [62.92]). Note that this basic mirror system for grasping crucially links the visual process of the superior temporal sulcus (**STS**) to the parietal regions (b) and premotor regions (F5) which have been shown to contain mirror neurons for manual actions

and how that hand is moving. Other schemas implement hand–object spatial relation analysis and check how object affordances relate to hand state. Together with F5 canonical neurons, this last schema (in parietal area 7b) provides the input to the F5 mirror neurons.

In the [MNS](#) model, the *hand state* was defined as a vector whose components represented the movement of the wrist relative to the location of the object and of the hand shape relative to the affordances of the object. Oztürk and Arbib showed that an artificial neural network corresponding to [PF](#) and $F5_{\text{mirror}}$ could be trained to recognize the grasp type from the *hand state trajectory*, with correct classification often being achieved well before the hand reached the object, using activity in the F5 canonical neurons that commands a grasp as training signal for recognizing it visually. Crucially, this training prepares the F5 mirror neurons to respond to hand–object relational trajectories even when the hand is of the *other* rather than the *self* because the hand state is based on the view of movement of a hand relative to the object, and thus only *indirectly* on the retinal input of seeing hand and object, which can differ greatly between observation of self and other. Bonaiuto et al. [62.115] have developed MNS2, a new version of the [MNS](#) model to address data on audiovisual mirror neurons that respond to the sight and sound of actions with characteristic sounds such as paper tearing and nut cracking (see Kohler et al. [62.105]), and on the response of mirror neurons when the target object was recently visible but is currently hidden (see Umiltá et al. [62.105]). Such learning models, and the data they address, make clear that *mirror neurons are not restricted to recognition of an innate set of actions but can be recruited to recognize and encode an expanding repertoire of novel actions*.

The discussion of this section avoided any reference to imitation (Sect. 62.4.3). On the other hand, even without considering imitation, mirror neurons provide a new perspective for tackling the problem of robotic perception by incorporating action (and motor information) into a plausible recognition process. The role of the fronto-parietal system in relating affordances, plans, and actions shows the crucial role of motor information and embodiment. We argue that this holds lessons for neurorobotics: the richness of the *motor* system should strongly influence what the robot can learn, proceeding autonomously via a process of exploration of the environment rather than overly relying on the intermediary of logic-like formalisms. When recognition exploits the ability to act, then the breadth of the action space becomes crucially related to the precision, quality, and robustness of the robot’s perception.

62.4.2 A Bayesian View of the Mirror System

We now show how to cast much that is known about the mirror system into a controller–predictor model (see [Miall](#) et al. [62.54] and [Wolpert](#) et al. [62.116]) and analyze the system in Bayesian terms. As shown by the [FARS](#) model, the decision to initiate a particular grasping action is attained by the convergence in area F5 of several factors including contextual and object-related information; similarly many factors affect the recognition of an action. All this depends on learning both *direct* (from decision to executed action) and *inverse* models (from observation of an action to activation of a motor command that could yield it). Similar procedures are well known in the computational motor control literature (see [Jordan](#) and [Rumelhart](#) [62.117] and [Kawato](#) et al. [62.118]). Learning of the affordances of objects with respect to grasping can also be achieved autonomously by learning from the consequences of applying many different actions to different parts of different objects.

But how is the decision made to classify an observed behavior as an instance of one action or another? Many comparisons could be performed in parallel with the model for one action becoming predominantly activated. There are plausible implementations of this mechanism using a gating network (see [Demiris](#) and [Johnson](#) [62.119] and [Haruno](#) et al. [62.120]). A gating network learns to partition an input space into regions; for each region a different model can be applied or a set of models can be combined through an appropriate weight function. The design of the gating network can encourage collaboration between models (e.g., linear combination of models) or competition (choosing only one model rather than a combination). [Oztürk](#) et al. [62.121] offer a similar approach to the estimation of the mental states of the observed actor, using some additional circuitry involving the frontal cortex.

We now offer a Bayesian view of using the predictor–controller formulation approach to the mirror system. This Bayesian approach views affordances as priors in the action recognition process where the evidence is conveyed by the visual information of the hand, providing the data for finding the posterior probabilities as mirror neurons-like responses which automatically activate for the most probable observed action. Recalling that the presence of a goal (at least in working memory) is needed to elicit mirror neuron responses in the macaque. We believe it is also particularly important during the ontogenesis of the human mirror system, for example,

Woodward [62.122] has shown that even at nine months of age, infants recognized an action as being novel if it was directed toward a novel object rather than just having different kinematics, showing that the goal is more fundamental than the enacted trajectory. Similarly, if one sees someone drinking from a coffee mug then one can hypothesize that a particular action (that one already knows in motor terms) is used to obtain that particular effect. The association between the canonical response (object–action) and the mirror one (including vision) is made when the observed consequences (or goal) are recognized as similar in the two cases. Similarity can be evaluated following criteria ranging from kinematic to social consequences.

Many formulations of recognition tasks are available in the literature (see *Duda, Hart, and Stork* [62.123]) besides those keyed to the study of mirror neurons. Here, however, we focus on the *Metta et al.* [62.124] Bayesian interpretation of the recognition of actions. We equate the prior probabilities for actions with the object affordances, that is:

$$p(A_i|O_k), \quad (62.1)$$

where A_i is the i -th action from a motor repertoire of I actions and O_k is the target object of the grasping action out of a set of K possible objects. The affordances of an object identify the set of actions that are most likely to be executed upon it, and consequently the mirror activation of F5 can be thought as:

$$p(A_i|F, O_k), \quad (62.2)$$

where F are the features obtained by observation of the trajectory of the temporal evolution of the observed action. This probability can be computed from Bayes rule as

$$p(A_i|F, O_k) = p(F|A_i, O_k)p(A_i|O_k). \quad (62.3)$$

(An irrelevant normalization factor has been neglected so that, strictly speaking, the posterior in (62.3) is no longer a probability.) With this, a classifier is constructed by taking the maximum over the possible actions

$$\hat{A} = \max_i p(A_i|F, O_k). \quad (62.4)$$

Following *Lopes* and *Santos-Victor* [62.125], *Metta et al.* [62.124] assumed that the features F along the trajectories are independent. This is clearly not true for a smooth trajectory linking the movement of the hand and fingers to the observed action. However, this approximation simplified the estimation of the likelihoods

Table 62.1 Brain quantities and circuits

| | |
|-----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $p(A_i F, O_k)$ | Mirror neuron responses, obtained by a combination of the information as in (62.3) |
| $p(F A_i, O_k)$ | The activity of the F5 motor neurons generating certain motor patterns given the selected action and the target object |
| $p(A_i O_k)$ | Object affordances: the response of the circuit linking AIP and the F5 canonical neurons AIP → F5 |
| Visuomotor map | Transformation of the hand-related visual information into motor data: identified with the response of STS → PF/PFG → F5, which is represented in F5 by $p(F A_i, O_k)$ |

in (62.2), though later implementations should take into account the dependence across time.

The object recognition stage (i.e., finding O_k) requires as much vision as is needed to determine the probability of the various grasp types being effective, the hand features F correspond to the STS response, and the response of the mirror neurons determines the most probable observed action A_i . We can identify certain circuits in the brain with the quantities described before.

However Table 62.1 does not exhaust the various computations required in the model. In the *learning*

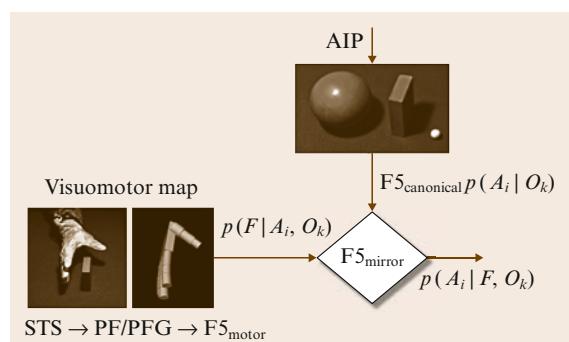

Fig. 62.8 Block diagram of the recognition process. Recognition (mirror neuron activation) is due to the convergence in F5 of two main contributions: signals from the AIP-F5 canonical connections and signals from the STS-PF/PFG-F5 circuit. In this model, activations are thought of as probabilities and are combined using Bayes's rule

phase, the visuomotor map is learned by a sigmoidal feedforward neural network trained with the backpropagation algorithm (both visual and motor signals are available); affordances are learned simply by counting the number of occurrences of actions given the object (visual processing of object features was assumed); and the likelihood was approximated by a mixture of Gaussians and the parameters learned by the expectation maximization (EM) algorithm. During the *recognition phase*, motor information is not available, but is recovered from the visuomotor map. Figure 62.8 shows a block diagram of the operation of the classifier.

A comparison (see Lopes and Santos-Victor [62.125]) was made of system performance: (a) when using the output of the inverse model and thus employing motor features to aid classification during the training phase, and (b) when only visual data were available for classification. Overall, their interpretation of the results is that by mapping in motor space they allow the classifier to choose features that are much better suited for performing optimally, which in turn facilitates general-

ization. The same is not true in visual space, since a given action may be viewed from different viewpoints. One may compare this to the viewpoint invariance of hand state adopted in the MNS model, which has the weakness there of being built in rather than emerging from training.

Another set of experiments was performed on a humanoid robot upper torso called Cog (see Brooks et al. [62.31]). Cog has a head, arms, and a moving waist for a total of 22 degrees of freedom but does not have hands. It has instead simple flippers that could be used to push and prod objects. Fitzpatrick and Metta [62.126] and Metta et al. [62.124] were interested in starting from minimal initial hypotheses yet yielding units with responses similar to mirror neurons. The robot was programmed to identify suitable cues to start the interaction with the environment and direct its attention towards potential objects, using an attention system similar to that (see Itti and Koch [62.56]) described in Sect. 62.2.5. Although the robot could not grasp objects, it could generate useful cues from touch, push, and prod actions.

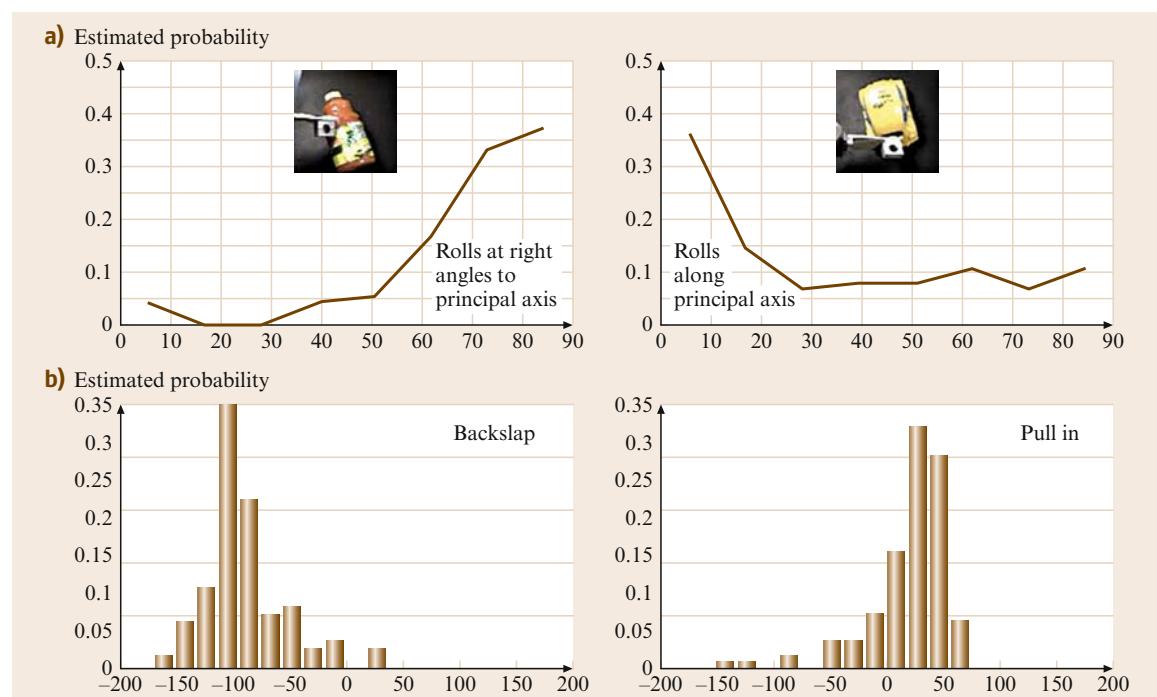

Fig. 62.9 (a) The affordances of two objects: a toy car and a bottle represented as the probability of moving along a given direction measured with respect to the object principal axis (visual). It is evident that the toy car tends to move mostly along the direction identified with the principal axis and the orange juice bottle at a right angle with respect to its principal axis. (b) The probability of a given action generating a certain object movement. The reference frame is anchored to the image plane in this case

The problem of defining objects reflects the problem of segmenting the visual scene. Criteria such as contrast, binocular disparity, and motion can be applied, but any of them can fail in a given situation. In the present system, optic flow was used to detect and segment an object after impact with the arm end point, and from segmentation based on shape, color, and behavior data. Depending on the available motor repertoire, the robot could explore a range of possible object behaviors (affordances) and form an object model which combines both sensorial and motor properties of the object that robot had the chance to interact with.

In a typical experiment, the human operator waves an object in front of the robot, which reacts by looking at it. If the object is dropped on the table in front of the robot, a reaching action is initiated, and the robot possibly makes contact with the object. Vision is used during the reaching and touching movement to guide the robot's flipper toward the object, to segment the hand from the object upon contact, and to collect information about the behavior of the object caused by the application of a certain action (see *Fitzpatrick* [62.127]). Unfortunately, interaction of the robot's flipper with objects does not result in a wide class of different affordances and so this study focused on the rolling affordances of a toy car, an orange juice bottle, a ball, and a colored toy cube. Besides reaching, the robot's motor repertoire consists of four different stereotyped approach movements covering a range of directions of about 180° around the object. For each successful trial, the robot stored the result of the segmentation, the object's principal axis which was selected as representative shape parameter, the action – initially selected randomly from the set of four approach directions – and the movement of the center of mass of the object for some hundreds of milliseconds after impact with the flipper was detected. This gives information about the rolling properties (affordances) of the different objects, e.g., the car tends to roll along its principal axis, the bottle at a right angle with respect to the axis. Figure 62.9 shows the result of collecting about 700 samples of generic poking actions and estimating the average direction of displacement of the object. Note, for example, that the action labeled as *backslap* (moving the object with the flipper outward from the robot) consistently gives a visual object motion upward in the image plane (corresponding to the peak at -100° , 0° being the direction parallel to the image x -axis; the y -axis pointing downward). A similar consideration applies to the other actions. Although crude, this implementation shows that with little pre-existing structure the robot could acquire the crucial elements for building knowledge of objects in

terms of their affordances. Given a sufficient level of abstraction, this implementation is close to the response of canonical neurons in F5 and their interaction with neurons observed in AIP that respond to object orientation (see *Sakata et al.* [62.128]).

62.4.3 Mirror Neurons and Imitation

Fitzpatrick and Metta [62.126] also addressed the question of what is further required for interpreting observed actions. Where in the previous section, the robot identified the motion of the object because of a specific action applied to it, here it could backtrack and derive the type of action from the observed motion of the object. It can further explore what is causing motion and learn about the concept of manipulator in a more general setting. In fact, the same segmentation procedure mentioned earlier could visually interpret poking actions generated by a human as well as those generated by the robot. One might argue that observation could be exploited for learning about object affordances. This is possibly true to the extent passive vision is reliable and action is not required. The advantage of the active approach, at least for the robot, is that it allows controlling the amount of information impinging on the visual sensors by, for instance, controlling the speed and type of action. This strategy might be especially useful given the limitations of artificial perceptual systems. Thus, observations can be converted into interpreted actions. The action whose effects are closest to the observed consequences on the object (which we might translate into the goal of the action) is selected as the most plausible interpretation given the observation. Most importantly, the interpretation reduces to the interpretation of the simple kinematics of the goal and consequences of the action rather than to understanding the complex kinematics of the human manipulator. The robot understands only to the extent it has learned to act. One might note that a more refined model should probably include visual cues from the appearance of the manipulator into the interpretation process. Indeed, the *hand state* that was central to the Oztop–Arbib model was based on an object-centered view of the hand's trajectory in a coordinate frame based on the object's affordances. The last question to address is whether the robot can imitate the *goal* of a poking action. The step is indeed small since most of the work is actually in interpreting observations. Imitation was generated in the following by replicating the latest observed human movement with respect to the object and irrespective of its orientation, for example, in case the experimenter poked the toy car sideways,

the robot imitated him/her by pushing the car sideways. Starting from this simple experiment, we need to formalize what is required for a system that has to acquire and deliver imitation.

Roboticians have been fascinated by the discovery of mirror neurons and the purported link to imitation that exists in the human nervous system. The literature on the topic extends from models of the monkey's (nonimitative) action recognition system (see *Oztop* and *Arbib* [62.112]) to models of the putative role of the mirror system in imitation (see *Demiris* and *Johnson* [62.119] and *Arbib* et al. [62.129]), and in real and virtual robots (see *Schaal* et al. [62.130]). *Oztop* et al. [62.131] propose a taxonomy of the models of the mirror system for recognition and imitation, and it is interesting to note how different the computational approaches that have been now framed as mirror system models are, including recurrent neural networks with parametric bias (see *Tani* et al. [62.132]), behavior-based modular networks (see *Demiris* and *Johnson* [62.119]), associative memory-based methods (see *Kuniyoshi* et al. [62.133]), and the use of multiple direct-inverse models as in the MOSAIC architecture (*Wolpert* et al. [62.134]; cf. the multiple paired forward-inverse models of Sect. 62.3.2).

Following the work of *Schaal* et al. [62.130] and *Oztop* et al. [62.131] we can propose a set of schemas required to produce imitation:

- determine what to imitate, inferring the goal of the demonstrator,
- establish a metric for imitation (correspondence; see *Nehaniv* [62.135]),
- map between dissimilar bodies (mapping),
- imitate behavior formation,

which are also discussed in greater detail by *Nehaniv* and *Dautenhahn* [62.136]. In practice, computational and robotic implementations have tackled these problems with different approaches and emphasizing different parts or specific subproblems of the whole, for example, in the work of *Demiris* and *Hayes* [62.137], the

rehearsal of the various actions (akin to the aforementioned theory of motor perception) was used to generate hypotheses to be compared with the actual sensory input. It is then remarkable how more recently a modified approach of this paradigm has been used in comparison with real human transcranial magnetic stimulation (TMS) data.

Ito et al. [62.138] (not the Masao Ito of cerebellar fame) took a dynamical systems approach using a recurrent neural network with parametric bias (RNNPB) to teach a humanoid robot to manipulate certain objects. In this approach the parametric bias (PB) encodes (tags) certain sensorimotor trajectories. Once learning is complete the neural network can be used either to recall a given trajectory by setting the PB externally or provide input for the sensory data only and observe the PB vector that would represent in that case the recognition of the situation on the basis of the sensory input only (no motor information available). It is relatively easy to interpret these two situations as the motor generation and the observation in a mirror neurons model.

The problem of building useful mappings between dissimilar bodies (consider a human imitating a bird's flapping wings) was tackled by *Nehaniv* and *Dautenhahn* [62.136] where an algebraic framework for imitation is described and the correspondence problem formally addressed. Any system implementing imitation should clearly provide a mapping between either dissimilar bodies or even in the case of similar bodies when either the kinematics or dynamics is different depending on the context of the imitative action.

Sausser and *Billard* [62.139] modeled the *ideomotor principle*, according to which observing the behavior of others influences our own performances. The ideomotor principle points directly to one of the core issues of the mirror system, that is, the fact that watching somebody else's actions changes something in the activation of the observer, thus facilitating certain neural pathways. The work in question also gives a model implemented in terms of neural fields (see *Sausser* and *Billard* [62.139] for details) and tries to explain the imitative cortical pathways and the behavior formation.

62.5 Extroduction

As the foregoing makes clear, robotics has much to learn from neuroscience and much to teach neuroscience. Neurorobotics can learn from the ways in which the brains and bodies of different creatures adapt to diverse ecological niches – as computa-

tional neuroethology helps us understand how the brain of a creature has evolved to serve *action-oriented perception*, and the attendant processes of learning, memory, planning, and social interaction.

We have sampled the *design* of just a few subsystems (both functional and structural) in just a few animals – optic flow in the bee, approach, escape, and barrier avoidance in frogs and toads, and navigation in the rat, as well as the control of eye movements in visual attention, the role of mammalian cerebellum in handling the nonlinearities and time delays of flexible motor systems, and the mirror systems of primates in action recognition and of humans in imitation. There are many more creatures with lessons to offer the roboticist than we can sample here.

Moreover, if we just confine attention to the brains of humans, this Chapter has mentioned at least 7a, 7b, AIP, area 46, caudo-putamen, cerebellum, cIPS, F2, F4, F5, hippocampus, hypothalamus, inferotemporal cortex,

LIP, MIP, motor cortex, nucleus accumbens, parietal cortex, prefrontal cortex, premotor cortex, pre-SMA (F6), spinal cord, STS, and VIP – and it is clear that there are many more details to be understood for each region, and many more regions whose interactions hold lessons for roboticists. We say this not to depress the reader, but rather to encourage further exploration of the literature of computational neuroscience and to note that the exchange with neurorobotics proceeds both ways: neuroscience can inspire novel robotic designs; conversely, robots can be used to test whether brain models still work when they make the transition from disembodied computer simulation to meeting the challenge of guiding the interactions of a physically embodied system with the complexities of its environment.

62.6 Further Reading

M.A. Arbib, (Ed.): *From Action to Language via the Mirror System* (Cambridge Univ. Press, Cambridge 2006).

This volume provides 16 articles on the mirror system, written by diverse experts. Of particular relevance to this Chapter are articles on dynamical systems: brain, body and imitation; attention and the minimal subscene; the development of grasping and the mirror system; and development of goal-directed imitation, object manipulation and language in humans and robots.

C. Bell, P. Cordo, S. Harnad: Controversies in neuroscience IV: motor learning and plasticity in the cerebellum. *Behavioral and brain sciences* **19**(3), (1996)

This somewhat older BBS special issue provides what was, back then, a rather definitive number of articles on the cerebellum, including an overview of models in a paper by Houk et al.

P. van der Smagt, D. Bullock: Applied intelligence, Scalable Applications of Neural Networks to Robotics **17**(1), (2002).

This special issue is focused on the application of cerebellar and other models to robotics tasks, and

lists some successful and – between the lines – more unsuccessful applications thereof.

V. Gallese, L. Fadiga, L. Fogassi, G. Rizzolatti: Action recognition in the premotor cortex. *Brain* **119**, 593–609 (1996)

This paper provides a detailed account of the neurophysiological evidence for mirror neurons. It is good reading to get the real data unbiased from further interpretation on the role of mirror neurons and it is complete and accurate. Although it is a technical paper it is easy to read also to a general audience.

L. Fadiga, L. Craighero, G. Buccino, G. Rizzolatti: Speech listening specifically modulates the excitability of tongue muscles: a TMS study. *Eur. J. Neurosci.* **15**(2), 399–402 (2002)

This work extends the mirror system concept with an interesting perspective on its role into into language. This paper is interesting reading by providing evidence in humans (the other references above are about monkey experiments). In this case, it has been shown that speech listening facilitates the activation of tongue muscles which match the specific phoneme being listened to.

Perceptual Robotics

Heinrich H. Bülow, Christian Wallraven, Martin A. Giese

Perceptual functions are central to many applications in robotics and for the construction of efficient human–robot interfaces. The study of perception in biological systems has revealed important information-processing principles that have been converted to powerful applications in robotics and computer vision. The chapter first discusses two central theories of object recognition: model- and exemplar-based theories. A review of experimental results from the study of object recognition in biological systems suggests that exemplar-based approaches capture important properties of object recognition in the brain. We then discuss how very similar principles have been realized in highly efficient technical systems for object recognition and detection, including realizations that are based on biologically inspired neural architectures. Principles for the efficient processing of complex shapes can be extended to the representation of complex movements and actions. We illustrate this by first reviewing some properties of the cortical mechanisms of the recognition of complex movements and actions, focusing on principles that are useful for robotics applications. Again, exemplar-based approaches seem to capture important properties of motion recognition in the brain, and at the same time provide a powerful approach for building technical movement recognition systems. Finally, it is shown that the example-based framework is not only useful for recognition, but also provides the basis for powerful synthesis methods. As one example we discuss the synthesis of photorealistic three-dimensional (3-D) models of faces, exploiting correspondence

between training examples. Related approaches have been developed for spatiotemporal patterns. We review a class of algorithms that permit the accurate modeling of movements and movement styles by interpolation between example trajectories with high relevance for the synthesis of movements, e.g., in humanoid robotics.

63.1 Overview

The technical realization of perceptual functions is a central problem for many applications in robotics. Robots

require perception to navigate in space and to localize and recognize goal objects, e.g., for manipulation (see,

e.g., Chap. 15 and Part D). Social interactive robots must be able to interpret gestures, actions, and even emotions (Chap. 58) in order to interact naturally with their users. One important approach for the programming of complex perceptual and behavioral functions such as those needed by humanoid robots is imitation learning (Chaps. 59 and 62). Imitation learning requires the robot to *perceive* complex actions that are executed by the user and to subsequently map them into an efficient representation that is suitable for the synthesis of the corresponding motor behavior on the available platform. This chapter focuses on important principles of the representation of complex shapes and movements, which can be derived from biological perception systems, and more specifically the basic functionality of the primate visual cortex. Such principles have interesting implications for the design of technical systems in robotics and computer vision for the *recognition of objects, shapes, and faces*, and for the recognition and synthesis of *complex movements and actions*. The limited space of the chapter forces us to focus mainly on visual perception and related technical applications. In the context of robotics many other aspects of perception are important, for example haptic perception (Chap. 30), auditory perception, sensory cue fusion (Chap. 25), or the interaction between the visual recognition of objects and actions and motor programs, e.g., during grasping (specifically treated in Chap. 62).

In the following, we will first formulate several biological principles that are relevant for form and motion representations, specifically in the visual system. We will then, on the one hand, describe technical systems that implement these principles using neural mechanisms that are inspired by the basic architecture of the brain. On the other hand, we will also discuss implementations that are inspired by biological principles on a more abstract level, and which exploit instead of neural networks more efficient technical algorithms for the realization of biologically relevant functions. Many of these systems were derived in the field of computer vision and are based on the advantages and limitations of modern digital computers in order to realize biological principles of information processing more efficiently.

Our approach to establish relationships between biological perception and robotics systems at different levels reflects *David Marr's* classical distinction of multiple levels of description, originally developed for the analysis of vision systems [63.1]: robotics systems can be inspired by biological systems at the level of *implementation*, i.e., one can try to build robots containing

neural mechanisms that imitate the function of neurons in the central nervous systems of biological organisms. This type of analogy between technical and biological systems coincides with the definition of ‘neurorobotics’ given in Chap. 62. A transfer of principles from biological perception systems to robots might also be accomplished at the more abstract levels of *computational problems* and *algorithms*. The computational level is defined by the abstract theoretical formulation of computational problems that have to be solved by perception systems. Examples are the identification or classification of goal object, or the recognition of human gestures. Marr's level of algorithms specifies the computational methods for the solution of such problems, independent of the underlying specific hardware or architecture. For example, an object might be represented by modeling its full 3-D structure, e.g., using a parametric 3-D shape model, or it might be represented in terms of two-dimensional (2-D) example views. Example views, however, might be represented using neural networks, establishing an analogy with the human brain at the level of implementation, or using more efficient computational methods, e.g., as support vectors of a classifier that has been trained with appropriate images of the object and distractor patterns. In both cases, the robot system realizes mechanisms that are derived from perception in biological systems.

Marr's distinction of levels is only one way to introduce description levels for complex systems. Other approaches, particularly relevant for robotics, are for example the subsumption architecture [63.2] and behavior-based approaches (Chap. 38) that decompose robotics system into a system of simpler behavioral modules. Another example are dynamical systems approaches to robotics [63.3–5] that are based on the biologically motivated idea that behaviors can be mapped onto stable states of (nonlinear) dynamical systems or recurrent neural networks. Individual behaviors result from self-organization over the whole system as collectively stable modes, which can be described and analyzed by the introduction of appropriate collective variables. Interestingly, such robotics-inspired approaches have been quite successful in modeling human navigation behavior [63.6].

In the following we will apply the term *perceptual robotics* to signify the design of robots based on principles that are derived from human perception on all three levels in the sense of Marr. This includes a realization in terms of specific neural circuits as well as the transfer

of more abstract biologically inspired strategies for the solution of relevant computational problems. A direct interaction between robotics and perception research can be very fruitful for both disciplines. On the one hand, our current knowledge about human perception and the underlying computational principles might help to build more efficient robotics architectures that inherit properties from biological perception, e.g., very efficient and robust processing or complex dynamic flexibility. Such architectures will be a necessary prerequisite for the creation of truly intelligent, cognitive robots (Chaps. 9, 38, and 58). On the other hand, perception science

often uses robots as a test bed for gaining a deeper understanding of computational processes, and in particular for testing the computational power of specific computational solutions under *real-world conditions*. How can a child, for example, learn how to handle new objects, and what allows us to learn the visual categorization of thousands of objects from just a few examples? *Perceptual robot platforms*, equipped with a variety of sensory inputs and operating in different types of artificially structured or real-world environments, provide very helpful tools for the study of such questions.

63.2 Example-Based Object Representations

Object recognition is a fundamental visual function that is critical for many applications in robotics. Manipulation and grasping (Chaps. 26 and 28) require exact knowledge about the shape of the goal object that is often derived from visual sensors. Also the imitation of goal directed movements (Chap. 59) requires knowledge about target objects. Finally, social and collective robots require robust recognition of other agents and objects which are taking part in the present action (Chaps. 41 and 58). The importance of object and shape recognition for many other applied robot systems, like construction and assembly robots or smart cars (Chap. 51) is immediately evident.

63.2.1 Perceptual and Computational Basis of Object Representations

The question of how humans learn, represent, and recognize objects under a wide variety of viewing conditions presents a great challenge to both neurophysiology and cognitive research. Frameworks for explaining the amazing robustness of human recognition processes and how humans represent objects can be broadly classified into two approaches: in the *model-based representation*, an image on the retina is analyzed to yield three-dimensional parts of an object based on geometric primitives (Chap. 23). These primitives are then matched to an internal, three-dimensional model of the object (Fig. 63.1). *Exemplar-based representation* approaches assume that the internal storage consists of, typically two-dimensional, snapshot-like representations of objects, which are directly compared to the visual input via simple image transformations. In the following, we

will briefly describe the basic properties of these two approaches as well as perceptual evidence for their plausibility in explaining human recognition performance.

Structural Description Models

The basic idea of structural description models is that object recognition or categorization is based on a structural representation, which is defined as a configuration of elementary object parts that are regarded as *shape primitives* [63.7]. Structural description models aim to supply abstract and propositional descriptions of objects, while at the same time disregarding irrelevant spatial information. Therefore, structural description models typically predict that recognition performance is invariant regarding spatial transformations. Biederman's recognition-by-components (RBC) or geon structural description (GSD) model can be regarded as the best developed example of the structural description model type [63.8]. According to this model objects are represented as configurations of elementary three-dimensional primitive parts, called geons. These geons are derived from nonaccidental properties (NAPs) in the image, i.e., from properties which unlikely arise by chance, and are more or less invariant over a wide range of views. For example, the properties straight versus curved, symmetrical versus asymmetrical, parallel versus nonparallel are regarded as nonaccidental properties (nonaccidental properties were originally proposed within an image-based approach by Lowe [63.9]). According to the model, geons and their spatial configuration are combined into a structural representation, called geon structural description. The spatial relations between parts are described in a categorical way, using relations such as *above*, *below*, etc. Like other struc-

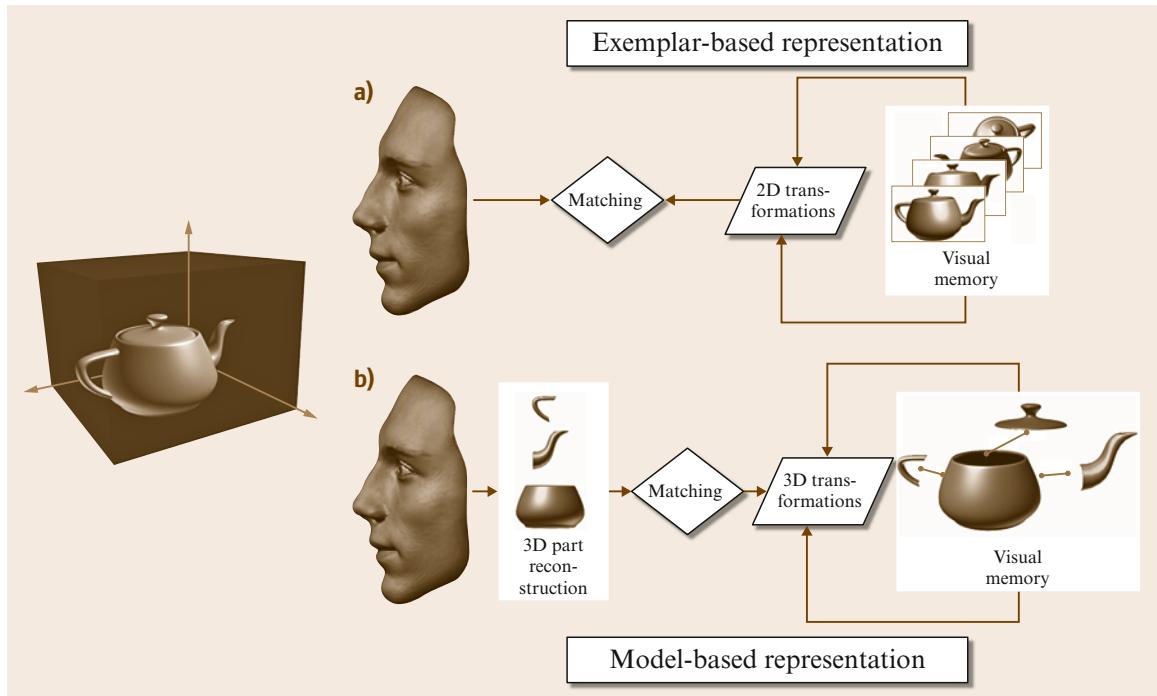

Fig. 63.1a,b Schematic drawing comparing exemplar-based (a) and model-based (b) representations. Object perception based on model-based representations assumes that the brain extracts 3-D parts from the visual image, which are then matched to an internally stored 3-D model of the teapot. Contrasting with this approach, object perception based on exemplar-based representations is accomplished by directly comparing stored templates or example images with the current picture of the teapot

tural description models, Biederman's model predicts invariance in relation to position and size and also in relation to orientation in depth, as long as no parts are occluded.

The question has to be raised whether objects can be decomposed into geons at all. It was argued that Biederman's RBC cannot be applied to a whole range of biological stimuli [63.10], or that biological shapes in general cannot be adequately described by structural description models [63.11]. This problem extends also to artefact categories such as *shoe*, *hat*, or *backpack*, which seem to exceed the scope of the geon model. Therefore it has to be doubted that object parts are necessarily represented as geons, or as similar geometrical primitives (for further problems of RBC see [63.12, 13]). However, this does not mean that category representations do not have a part structure: in fact it is not the notion of part structure in object representations by itself which is problematic, but the use of parts and relations as a basis to derive invariant recognition performance [63.14].

Exemplar-Based Models

Over the last two decades, an increasing number of studies has demonstrated that recognition is not view-independent. Orientation-dependent recognition effects were found for novel objects [63.15, 16], and also for common, familiar objects [63.17, 18]. Orientation-dependent recognition performance has been shown not to be limited to individual objects, such as faces [63.19, 20], or to objects on the subordinate level of categorization [63.15, 21], but was also demonstrated for basic-level recognition [63.18, 22].

Moreover, recognition performance is not only influenced by orientation, but also by the *size* of the stimulus. Results are quite similar: reaction times (RTs) and error rates depend on the extent of transformation that is necessary to align memory and stimulus representation. RTs increase in a monotonic way with increasing change of (perceived) size (for a review see [63.23]). Several studies even show a systematic relationship between the amount of *translation* and recognition performance:

Increasing displacement between two sequentially presented stimuli led to a deterioration of performance, both for novel objects [63.24] and familiar objects [63.25]. Overall, view-independent models are difficult to reconcile with these findings which indicate that recognition performance depends systematically on different spatial transformations.

In the following, we will briefly review three types of exemplar-based models, which – by virtue of different computational mechanisms and processes (including alignment, interpolation, and pooling/thresholding) – explain the transformation-dependent performance that was found in the psychophysical experiments.

In the class of *alignment models*, *Ullman*'s [63.10, 26] 3-D alignment model and *Lowe*'s [63.9] SCERPO model are probably the best known examples. Both models work by storing 3-D models of objects, which are aligned to images by perspective projection of corresponding features (edges or feature points on the object). As an alternative to *Ullman*'s [63.26] model, which relies on 3-D object representations, *Ullman* and *Basri* [63.27] suggested an alignment model on the basis of 2-D views. In this model, an internal object model is constructed by a linear combination of a small number of stored 2-D exemplar images. Thus, the alignment is not achieved by a spatial compensation process, but by a linear combination of images. The intuition behind the linear combination approach can be explained in simple terms: suppose that two views of the same three-dimensional object are stored, taken from somewhat different viewing directions. An intermediate view can then be described as a weighted sum of the views that are already stored. In this case, the representation is based on the two-dimensional positions of corresponding features in each view. Making the set of views closer results in an object representation that is equivalent to storing a 3-D model.

In the *interpolation model*, recognition is achieved by localization in a multidimensional representational space, which is spanned by stored views [63.28]. The interpolation model is based on the theory of approximation of multivariate functions and can be implemented with radial basis functions (RBFs). In this scheme, the whole viewing space of an object is approximated by the learned exemplar views through a limited number of series of so-called radial basis functions (such as Gaussian functions) each of which becomes activated within a limited region of the high-dimensional feature space. Object recognition then means to examine whether a new point corresponding to the actual stimulus can be approximated by the existing tuned set of basis functions. Thus,

recognition does not occur by transformation or reconstruction of an internal image, but rather by interpolation or approximation of exemplars in a high-dimensional representational space.

At the end of the 1990s – and as an extension to the interpolation models – recognition models based on *pooling and thresholding* were developed [63.29–32]. Recognition is explained on the basis of the behavior of cells that are selectively tuned to specific image features (fragments or whole shapes) in a view-dependent (and size-dependent) way. A hierarchical pooling of the outputs of view-specific cells provides generalization over viewing conditions [63.29]. A similar proposal was made by *Riesenhuber* and *Poggio* [63.30]. The threshold model [63.33] also accounts for the systematic relation between recognition latencies and the amount of rotation (and size scaling): the speed of object recognition depends on the rate of accumulation of activity from neurons selective for the object, evoked by a particular viewing circumstance. For a familiar object, more tuned cells will be activated in the views most frequently presented, so that a given level of evidence (threshold) can be achieved fast. When the object is seen in an unusual view, fewer cells will respond, and activity among the population of cells selective for the object's appearance will accumulate more slowly. Consequently, these threshold models explain orientation dependency without the need to postulate transformation or interpolation processes.

Several computational models have been proposed that aim to model and explain the dependence of human recognition performance on spatial transformations. All of these models rely on storing exemplars – in the simplest form just 2-D views of objects – and matching the retinal image to these stored examples by different computational methods. The later models of recognition take their inspiration from recent findings from physiological studies concerning the functional building blocks of human vision in the brain. In the following, we will therefore briefly review the neural processing of visual information in the brain that underlies our ability to recognize objects.

63.2.2 Neural Representations in Object Recognition

Functionally, it has been shown that the flow of visual information in the brain can be divided into two major pathways: the *dorsal pathway* is believed to process motion and motor- or action-related visual information, whereas the *ventral pathway* is usually associated with

the task of object recognition. The structure of the ventral pathway is hierarchically organized and consists of a series of interconnected stages that start from the retina, passing through the lateral geniculate nucleus (**LGN**) to the primary visual cortex (V1) and extrastriate visual areas V2, V4, and **IT**. The *inferotemporal cortex* (**IT**) provides input to the *prefrontal cortex* (**PFC**), which is believed to play an important role in identification and categorization of visual stimuli. Recordings in the *parietal cortex* [63.34] suggest, in addition, that specifically for grasping and object manipulation dorsal regions might also be centrally involved in the recognition of manipulable objects and their affordances (see Chap. 62 for a more detailed discussion).

The seminal work of *Hubel* and *Wiesel* [63.35] in the cat (and later also in the macaque) visual cortex first established the idea of a hierarchical organization of visual processing. They found so-called simple cells in the early visual cortex (area V1) that responded best to bar-like stimuli at a particular orientation and position in the visual field. The response pattern of these cells could be modeled as a receptive field using Gabor-type functions. Later in the processing stream they found so-called complex cells which responded best to bar-like stimuli at a particular orientation nearly everywhere in the visual field: cells, which had become partially position invariant. This general idea of increasing invariance to stimulus properties with later stages of the processing stream has been verified in further physiological studies. In general, it has been found that the receptive field of the neurons increases and that the complexity of the stimulus it responds to increases. One of the key studies about the functional role of **IT** regions has investigated the responses of neurons to real-world objects in anesthetized monkeys ([63.36]; see also [63.37] for a review). Although some neurons that responded maximally to simple bar-like stimuli were found, the majority of neurons in the *posterior inferotemporal cortex* (**PIT**) preferred complex objects such as star shapes or circles with protruding elements. Interestingly, neurons were highly sensitive to minuscule changes to these objects such as the relative orientation or thickness of the elements. On the other hand, neurons were quite insensitive to stimulus variations such as size, contrast or retinal location. These findings were taken as evidence that one of the strategies for representing objects might be to use a number of moderately complex visual elements, whose pattern of coactivation encodes the visual appearance of the stimulus. In addition, *Wang* et al. [63.36] found neurons in the *anterior inferotemporal cortex* (**AIT**), that responded

maximally to images of whole objects such as faces or cars, indicating that already in the **IT** object-specific encodings might be present. Several other studies have also found neurons in this area which are tuned to faces, parts of faces, as well as body parts (see [63.38] for a review).

In another set of experiments, *Logothetis* et al. [63.39] found **AIT** neurons that showed a strong view-based behavior for the same stimuli that were used in the study of *Bülthoff* and *Edelman* [63.15], whereas they were invariant to the size and location of the stimulus. Their findings provide strong evidence that a neural implementation of view-based object encoding is possible and indeed seems to be used for recognition. In addition to view selectivity and size invariance, the investigated cells were also found to be maximally selective for the holistic stimulus rather than its constituent parts. This finding indicates that these cells might be encoding the pooled coactivation pattern of earlier **PIT** cells and thus form view-tuned units of recognition. It is important to stress in this context that an abstraction such as *grandmother* neurons, which specifically encode only one stimulus, does not seem plausible. Rather, the majority of neural responses in this and other experiments showed selectivity for a number of stimuli. A plausible explanation for this finding is that objects are encoded not by a single neuron but by a population code encompassing a number of neurons, which greatly increases the robustness of the representation (see also [63.32]).

The findings from this area of research can be summarized in a simple functional architecture: going from early stages to later stages of visual processing in a feedforward fashion, feature complexity increases from simple edge detectors towards view-tuned complex object cells and invariance to changes in the stimulus increases. This functional architecture is reflected not only in the object recognition framework discussed previously, but it also provides the motivation for computational vision systems that have been developed over the last few decades, which will be discussed in the following.

63.2.3 Object Recognition: Lessons from Computer Vision

Computer vision started out as a subfield of artificial intelligence in the 1960s. Early work on scene understanding by *Roberts* [63.40] showed how computers could parse worlds consisting of simple, geometric objects such as cubes, pyramids, etc. The main thrust of computer vision systems in the following decades

consisted of building algorithms for reconstructing a three-dimensional world from images – this development was further stimulated by Marr's highly influential theory of vision as 3-D reconstruction [63.1]. This theory was built on extracting geometric primitives from images that could be mathematically described as generalized cylinders. Although the mathematical rigor of such approaches was very appealing, computational implementations turned out to have strong limitations. Extracting robust features is a necessary prerequisite for building a 3-D reconstruction of the image, and finding these features proved to be hard under real-world conditions due to the enormous amount of variation in the image caused by changes in lighting, depth rotations, noise, occlusion, etc.

Parallel to the paradigm shift in human psychophysics and physiology, exemplar-based computational systems began to emerge, which for the first time showed good recognition performance under a larger range of viewing conditions. These recognition systems were based on – sometimes surprisingly simple – histograms of pixel values [63.41], local feature detectors [63.42, 43] or on a straightforward pixel representation of images using principle components analysis [63.44]. All of these recognition systems relied on a database of labeled example images, an algorithm for extracting features from these images, and a suit-

able classification method for comparing sets of image features.

Returning to the discussion of modeling human vision, in the following we provide an exemplary review of three relatively recent recognition systems that are based on a functionally plausible, exemplar-based architecture: these are SpikeNET [63.45], LeNet [63.46], and a framework by Serre et al. [63.47]. The first system is motivated by the finding that humans are amazingly fast at categorizing images as containing an animal or a face [63.48]. Typical response times for this task are so small (on the order of 100 ms) that the visual signal only has time for one feedforward pass through the visual areas of the brain (Fig. 63.2) – any recurrent feedback processing would necessarily delay the decision and therefore result in longer response times. Based on this finding, a neural network architecture was designed [63.45] that exploits the timing of neuronal responses (spikes) to encode visual signals using a *who fires first* strategy. This is different from traditional neural networks in that the timing is used rather than the firing strength. An object in this system will therefore be represented by an ensemble of neurons that represents a pattern of spike responses from earlier low-level feature extraction neurons. In their implementation these low-level neurons consist of standard Gabor-type receptive fields that are similar to the receptive fields found in

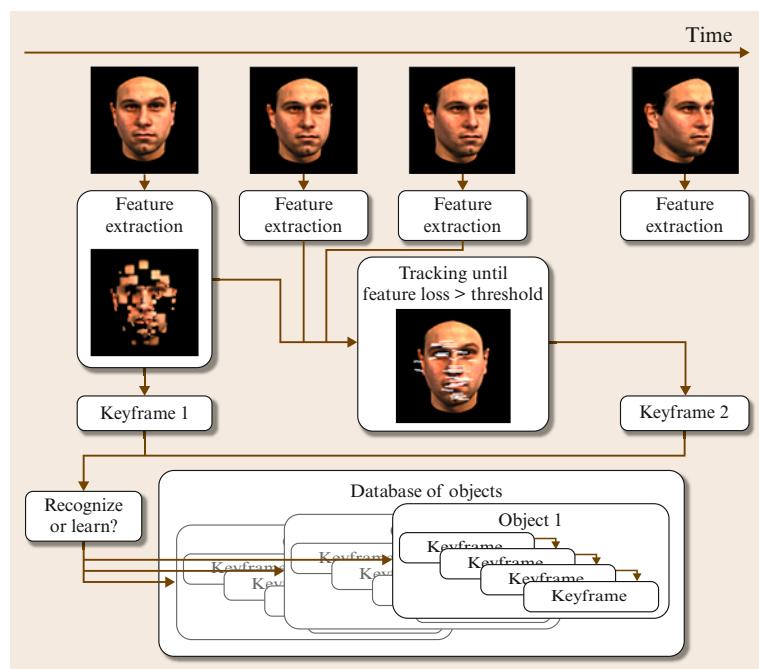

Fig. 63.2 The keyframe representation. This computational framework is a simple architecture that incorporates temporal input, incremental learning, structured object representations as well as efficient indexing. Note that this framework was also used for active exploration coupled with proprioceptive information (see text)

the cat's visual cortex [63.35]. This spike time encoding allows for very fast processing of visual stimuli and has been shown to provide robust recognition results. The network architecture LeNet [63.46] consists of a neural network that uses a hierarchy of layers of trainable convolutions and spatial subsampling, as well as nonlinear filtering to extract features of increasingly large receptive fields, increasing complexity, and increasing robustness. Using extensive, supervised training of the full hierarchy, such a network provides a very efficient, sparse set of features for many visual recognition tasks. Finally, the network architecture by Serre et al. [63.47] uses a very similar hierarchical structure of layers in which feature complexity and invariance are successively increased by linear and nonlinear pooling; its lower-level feature detectors, however, are trained in an unsupervised fashion on a large database of natural images, yielding a large set of detectors that are optimally tuned to natural image statistics. Again, the performance of this model in recognition tasks has been shown to be very good; in addition, comparisons with physiological and psychophysical experiments have shown that this framework is also capable of modeling human results from these experiments. All of these systems have been demonstrated to work on real-world vision problems (such as recognition of objects in cluttered environments) and in the case of the system by Serre et al. [63.47] have been shown even to outperform other state-of-the-art computer vision algorithms. This would make them good candidates for building the visual learning and recognition system for a perceptual robot.

63.2.4 Object Learning and Recognition for Perceptual Robotics

In general, it can be said that the success of perceptually inspired recognition systems can be seen as a strong indicator for the feasibility of a data-driven exemplar-based approach to recognition. There are three issues, however, which so far have not been addressed in any of these vision systems and which will be important both for achieving human performance in generic recognition tasks in a perceptual robotics application – as well as for a full understanding of the processes in human object recognition.

First of all, all of the aforementioned systems are feedforward; virtually no feedback, recurrent processing is implemented in their architecture, which makes them in a sense very similar to the simpler frog- or bee-like neural systems discussed in Chap. 62. Although there

is evidence that humans solve some recognition tasks using very little feedback (see, for example, [63.48]), it is nevertheless a crucial component of visual processing driving, for example, attentional focus, context awareness, as well as memory and reasoning processes – basically everything that makes up visual *intelligence*. Some visual attention models that are relevant for robotics systems are reviewed in Chap. 62.

Secondly, a severe limitation of most of today's artificial recognition systems is that they solely focus on the static domain of object recognition. Visual input on the retina, however, consists of dynamic changes due to object- and self-motion, nonrigid deformations of objects, articulated object motion as well as scene changes such as variations in lighting, occluding and re- and disappearing objects, where at any given point in time several of these changes can be interacting. Several psychophysical experiments indeed suggest an important role for dynamic information, both in learning and recognition of objects [63.49–52]. These results ask for an extension of current object recognition frameworks with a temporal component in order to arrive at truly spatiotemporal object representations. Combining methods from computer vision, psychophysics, and machine learning, Wallraven et al. [63.53] developed a framework that fulfills this requirement and learns spatiotemporal exemplar-based object representations from image sequences (the so-called keyframe framework, Fig. 63.3). More specifically, spatiotemporal characteristics of the visual input are integrated into a connected view-graph representation based on tracked local features. In order to provide robust classification performance, machine learning techniques are used to design efficient methods for combining support vector classification schemes with these local feature representations [63.54]. In several studies it was shown that the framework achieved excellent recognition results on both highly controlled databases as well as on real-world data. The integration of spatiotemporal information provides characteristic information about dynamic visual input via the connection of views and the two-dimensional image motion of discriminative features. In addition to delivering good recognition performance, the framework was also able to model results from psychophysical experiments on face and object recognition.

A third issue that – in our view – will be essential for designing and implementing efficient perceptual robots consists of the multisensory nature of our perceptual system (see also the discussion of embodied robots in Chap. 56). As an example, there is a close coupling between the human visual and haptic system – touch can

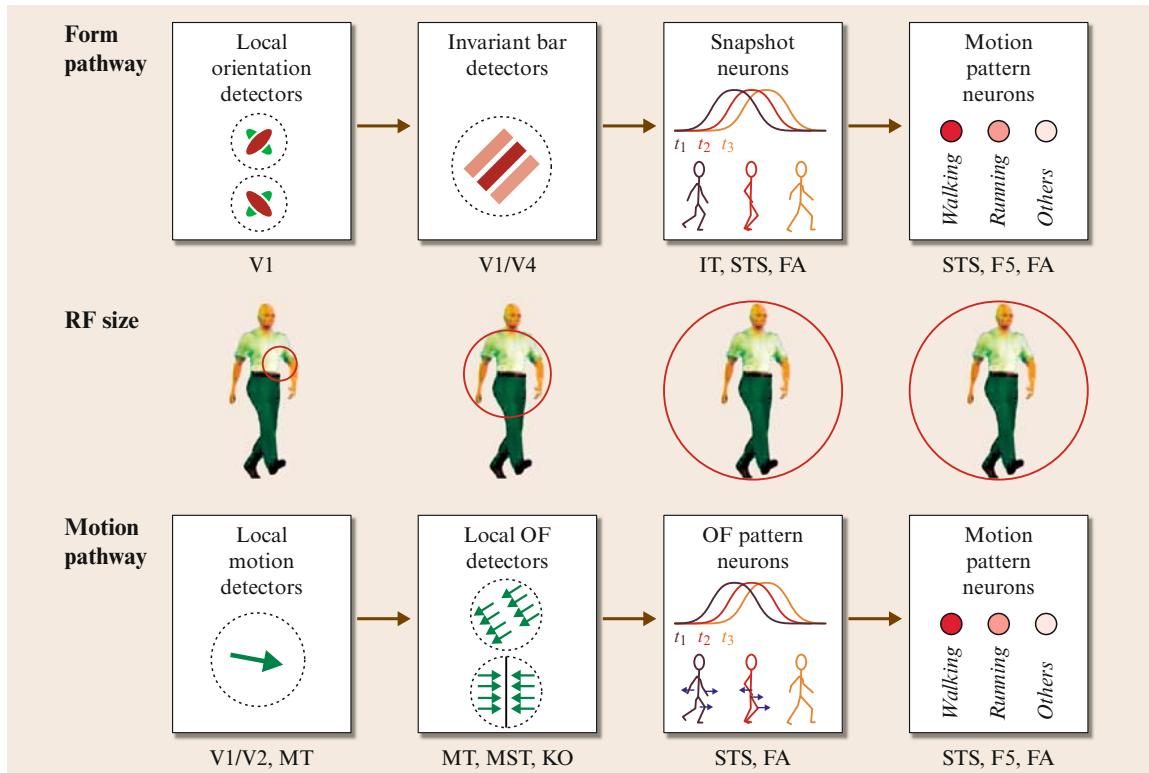

Fig. 63.3 Example-based neural model for the visual recognition of body movements that integrates the processing of form and motion features (after Giese and Poggio [63.56])

provide a wealth of complementary information about an object when it is manipulated, such as its texture, its shape, its position in space relative to our body, etc. In a series of psychophysical experiments (see [63.55]), participants had to learn views of four simple 3-D objects made of stacked toy bricks either in the haptic modality (when they were blindfolded) or in the visual modality (without being able to touch them). Subsequently they were tested both within the same modality as well as across modalities. Recognition results showed that cross-modal recognition is possible well above chance. Not surprisingly, recognition of rotated objects in the within-modality condition was severely affected by rotation in both modalities. This shows that not only is visual recognition highly view dependent but that haptic recognition performance is also directly affected by different viewing parameters. The results from this experiment thus support the view that haptic recognition is also mediated by exemplar-based processes.

Taken together with the keyframe framework outlined above, this cross-modal transfer might be an

important reason for the excellent visual performance of human object recognition – after all, it is known that infants learn extensively by grasping and touching objects, which could thus provide a *database* of object representations for visual recognition. Using this basic perceptual principle as a motivation, Wallraven and Bühlhoff [63.57] applied an extension of the keyframe framework in an online robotics scenario for efficient learning and recognition of multisensory object representations. More specifically, a framework was developed to integrate both *proprioceptive* information originating from haptic sensors in the robot's hands and *visual* information coming from the robot's cameras. For this, the robot would perform an exploratory movement with an object in its hand (such as turning it and looking at it from all angles) and from the resulting image sequence learn spatiotemporal view-based representations using the framework depicted in Fig. 63.2. Each view of this representation, however, is also linked to the current proprioceptive state (i.e., the joint angles of the hand at that point in time) and therefore provides an anchor into

a hand-centered three-dimensional space. In this way a representation is generated that *links perception and action*. The proprioceptive information can then be used

as an additional constraint for both learning of objects and recognition of objects and was shown to provide increased robustness compared to visual matching alone.

63.3 Example-Based Movement Representations

The recognition and modeling of complex movements and actions is fundamental to many applications in robotics, for example, interactive robots need to analyze users' movements in order to respond in a natural way to their behavior. This problem is specifically relevant for the realization of social and emotional behavior in robots (Chap. 58). Another important domain is the recognition and modeling of complex movements for humanoid robots (Chaps. 56 and 59) in order to learn new movements by imitation and to mimic human-like motor behavior.

63.3.1 Recognition of Complex Movements in Visual Cortex

The recognition of complex movements is also a fundamental problem for biological systems. While simple movement patterns are sufficient for eliciting stereotypical prey-catching behavior in simple vertebrates ([63.58]; see also Chap. 62), higher animals exploit more complex movement patterns, e.g., for the recognition of conspecifics or predators, or for communication by facial movements, gestures, or body expressions. Human perception of complex motion patterns is very efficient, even for extremely impoverished stimuli. This has been demonstrated in classical experiments by Johansson [63.59], who showed that complex dynamic actions can be recognized even from displays that consist of only a small number of dots moving like the joints of a human actor. Subsequent research has demonstrated that humans can extract highly specific information from such *point-light displays*, e.g., the gender or the identity of people. To our knowledge, no technical system for motion recognition has been proposed so far that accomplishes a comparable level of robustness. While much more research in neuroscience has been dedicated to object recognition (Sect. 63.2.2), some studies have tried to uncover neural [63.60–62] and computational principles [63.56, 63, 64] of visual movement recognition. Some of these principles seem interesting for the construction of robotics systems.

Neurophysiological and brain-imaging studies indicate that the recognition of facial and body movements

involves the ventral and the dorsal visual pathways. This implies that form and optic flow information are likely integrated during the processing of action stimuli in visual cortex. The ventral pathway, which is specifically responsible for the processing of form information, has already been discussed in Sect. 63.2.2. Like the ventral stream, the dorsal pathway is also hierarchically structured, and the size of the receptive fields of the neurons increases along the hierarchy. Some cortical areas that are part of the dorsal pathway are listed in Fig. 63.3. The *medial temporal area (MT)* contains neurons that are selective for simple local motion and coherent motion. On higher levels of the dorsal stream, e.g., in the *superior temporal sulcus (STS)*, neurons that are selective for hand and body movements and for facial expressions have been found in monkeys and humans [63.62]. It seems likely that areas selective for human body shapes, e.g., the *extrastriate body part area (EBA)*, contribute to the recognition of actions, even though some of them are not specifically selective for motion [63.65]. Finally, neurons that are active during action recognition have also been found in the *mirror neuron system*, which includes regions in the premotor and parietal cortex [63.66]. Parietal areas might also be specifically relevant for the recognition of action-related objects and their relationship to moving effectors [63.34]. The mirror neuron system has been very influential in recent research on the construction of biologically inspired robots (Chaps. 60 and 62).

A first biological principle of movement recognition that is supported by experimental data, and which seems useful for technical systems, is action recognition by detection of specific relevant motion and form features. Such detection does not necessarily require a reconstruction of facial or body shape, nor an exact simulation of the dynamics of the underlying movements. Instead it can be accomplished by much simpler feature detectors. Like object recognition, the recognition of complex motion patterns is strongly orientation and view dependent. This property has also been observed at the level of individual neurons in the STS, and for the activation of biological motion-selective areas in the human cortex [63.62]. View and orientation

dependence seem to be compatible with an encoding of visually perceived movements in terms of potentially learned example views or *keyframes* [63.56, 60]. While there might be some innate preferences for specific features, psychophysical and functional magnetic resonance imaging (**fMRI**) experiments suggest an important role of learning in visual movement recognition [63.67, 68]. For example, subjects can learn easily to recognize individually-specific body and facial movements [63.69, 70]. Also the fact that learning-based theoretical models, exploiting similar principles as neural object recognition models, can account for a variety of the experimental data [63.56, 71] supports a central role of learning.

As an example, Fig. 63.3 illustrates a hierarchical model for the recognition of complex movements that has been described in [63.56]. Its neural architecture consists of two hierarchical streams modeling the ventral and the dorsal visual pathways, which contain detectors for action-specific motion and form features. The form pathway of this model is similar to the object recognition models described in Sect. 63.2.2. The motion pathway of the model contains detectors for action-specific optic flow features with different complexity. Like for the described object recognition models, position and scale invariance is accomplished by appropriate nonlinear pooling of the responses of detectors with different spatial and scale selectivity along the hierarchy. In addition, the model contains recurrent neural circuits that make the responses of the recognition neurons selective for temporal order. In this way the model responds only to actions that are executed with the correct temporal order, and also with approximately the correct speed. The underlying network dynamics can be interpreted as a neural implementation of a Markov model, where the present recognized pattern predicts possible future patterns. A strong activity in the network emerges only when the stimulus sequence matches these predictions. A similar neural implementation exploiting the SPIKENET architecture by [63.45] (Sect. 63.2.3) has recently been applied in the context of a technical system for tracking of walkers in video sequences [63.72]. Hierarchical neural architectures inspired by the visual cortex have also been used in the context of mirror neuron robots [63.73].

A second principle of movement recognition that is important for the recognition of *imitable* actions, i. e., actions that can be executed by the observer, is an internal simulation of the observed motor behavior. While the exact nature of the underlying representations has not yet been clarified, a large body of experimental evidence suggests that observation of imitable movements acti-

vates the *mirror neuron system* in premotor and parietal cortex [63.66]. Computational models for action recognition by internal simulation have been proposed, e.g., exploiting feedforward controllers [63.74]. Theoretical models for the mirror neuron system with relevance for robotics are discussed in more detail in Chaps. 59 and 62.

63.3.2 Example-Based Motion Recognition in Robots and Computer Vision

Many systems for motion recognition and tracking in computer vision demonstrate the computational feasibility and applicability of the first principle: recognition by extraction of action-specific form and motion features without explicit modeling of the geometric shape of bodies or faces [63.75, 76]. In fact, most existing recent systems for face and body tracking are based on this approach. As opposed to the discussed neural models, many of these technical systems exploit nonbiological feature detectors and mechanisms for accomplishing temporal order selectivity and propagation of information over time (hidden Markov models (**HMMs**), and Kalman or particle filters [63.77–79]). Even though most of these solutions are not based on neural mechanisms, they are highly relevant in robotics for gesture recognition or the tracking of user behavior.

The second principle of action recognition by internal simulation, or by online fitting of geometrical or dynamical models, matches the traditional approach in computational vision, which had already been proposed by Marr [63.80]. A variety of implementations for model-based tracking and recognition of body movements [63.81] and facial movements [63.76] have been proposed in computer vision. Typically, such methods combine 2- or 3-D models, and sometimes even dynamic muscle models with predictive models such as Kalman or particle filters (for reviews see [63.77–79, 82]).

While in the biological system the exact nature of the representation of actions in the mirror neuron system is still quite unclear, it seems likely that the brain combines recognition of specific motion and form features and some form of internal simulation of motor programs for the recognition of imitable movements. Likewise, recent approaches in computer vision, computer graphics, and robotics have tried to combine feature-based recognition (e.g., of body silhouettes) and model-based tracking for the reconstruction of 2- or 3-D shape models from video streams [63.83, 84]. In fact, the combination of view-based recognition and model-based tracking improves the accuracy and robustness of body tracking [63.85].

63.4 Example-Based Synthesis Models: From Faces to Movements

In Sects. 63.2 and 63.3 biologically inspired approaches to the example-based recognition of shapes and movement patterns were discussed. For biological systems it seems likely that the visual recognition of complex patterns and the synthesis of complex patterns in motor control share fundamental principles, like example-based representations that are capable of efficient generalization [63.86]. Referring back to the most abstract level of analogies between biological and technical systems, example-based models have also been applied for the synthesis of complex patterns in technical applications, such as highly realistic face pictures and movements. These applications are highly relevant for robotics since they form the basis of the simulation of human-like behavior with high believability. The increasing importance of humanoid robots (Chaps. 56, 58, and 59) and of robotics systems that can interface with normal human social behavior (Chap. 58) makes believable simulation of human behavior a central topic in modern robotics. In several cases, example-based learning techniques have been superior to classical methods based on geometrical or physical models for such applications. A further application domain for example-based synthesis is the automatic generation of virtual training examples for learning-based robotics (Chap. 59) or computer vision systems [63.87].

63.4.1 Face Synthesis: Realistic Faces for Avatars and Robots

One of the crucial ingredients of careful studies of face processing – both for facial expressions and identity recognition – is a highly controllable, yet at the same time realistic stimulus set. While it is certainly possible to do research with impoverished or highly abstracted stimulus sets (such as line drawings) or only in the static domain (the majority of research has been done using static photographs), the results are certainly limited in terms of their generalizability to the real world. One of the recent thrusts in cognitive research has therefore been to use highly realistic face renderings – both static and dynamic – using advanced computer graphics techniques. As this technology also offers novel insights in the context of robotics, we will briefly describe a high-end facial animation system that was used in several studies. One important application domain of synthetic faces is for communication and interaction in any scenario in which communication between a robot and a human is required. Being able to synthe-

size realistic faces allows the robot to communicate its internal state and intentions in a manner that is very natural and easy to understand for humans. In addition, this research can be used not only for synthesis purposes but also for analysis purposes, that is, to design vision systems for robots that understand and react to the complexity of human faces appropriately. Again, we envision such a recognition and analysis system to be an essential component of any robotic application that relies on interactions with humans, especially in the field of anthropomorphic robotics.

The idea of a face space – in which faces are represented in a high-dimensional vector space – was pioneered by Valentine in 1991 and has been influential especially in perceptual research on face processing [63.88]. A number of techniques in computer vision and computer graphics have implemented the concept of a face space, first by interpolation or morphing between example pictures [63.89, 90]. As a further step towards the simulation of highly realistic pictures of faces, Blanz and Vetter [63.91] created a three-dimensional face space from 3-D laser scans of faces. The critical step for defining a vector space of faces was to bring the example patterns into correspondence. For 3-D laser scans this means that, for example, the tip of the nose can be uniquely identified in all scans. By using a modified optic flow algorithm, which establishes a dense correspondence between two 3-D scans, Blanz and Vetter were able to create such a face space. Such vector space models generated by interpolation between example pictures (or scans) that are in spatial correspondence are also called *morphable models* (Fig. 63.4). Based on such models the properties of face images, e.g., their male- or femaleness, can be continuously varied. This allows the synthesis of artificial new facial expressions, or of face pictures with novel identities. Also existing pictures of faces can be modified, resulting in novel pictures with photorealistic quality [63.91].

By analysis of the statistical properties of face spaces, perception researchers have been able to conduct highly controlled experiments, e.g., addressing gender perception [63.92] or identity coding [63.93]. In addition, an encoding of face stimuli in terms of a vector space seems to be compatible with recent psychophysical results in humans [63.94], and electrophysiological results in monkeys [63.95]. This makes this concept interesting as a basis for the design of perceptual robots that have to synthesize and analyze faces (Chap. 58).

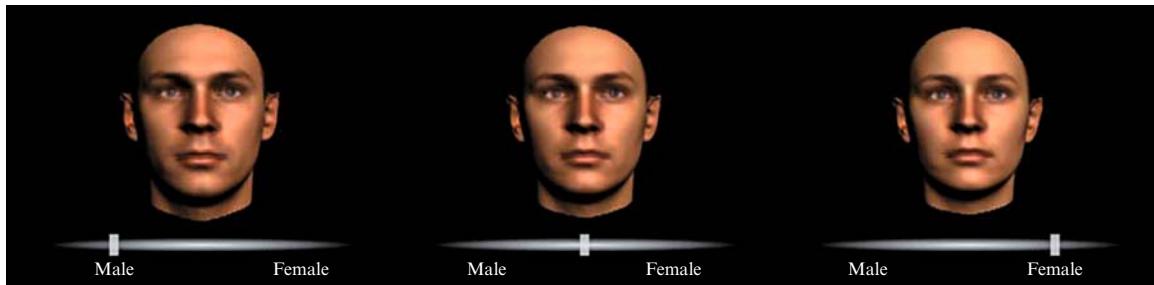

Fig. 63.4 Morphable model: the three images show a morph from an average male face to an average androgynous face to an average female face

Recently, static morphable models were extended as the basis of a dynamic animation system [63.96]. The basic idea is to combine the high spatial resolution of 3-D laser scans with the high temporal resolution of motion capture. Facial geometry is first captured using a structured light scanner, which produces a detailed 3-D scan of each peak expression. The individual scans are put into correspondence with each other based on a control mesh whose 3-D fiducial points are aligned to each scan, which results in a morphable model in much the same way as the one described earlier. The second step in creating the animation system is to capture motion data with an optical motion capture system. On this motion capture data, simple linear detectors for facial action elements are specified by using distances between markers to drive the expression activation. This yields a realistic animation based on the amplitude and timing of marker motion in the motion capture data. The morph animations of the final animation system thus allow full control over important information channels used in facial expressions (such as internal motion of the face, rigid head motion, or fidelity of shape and texture), making it ideally suited for experiments on perception of facial expressions [63.97]. The results from such experiments could, for example, be used in perceptual robotics to design robots that are able to understand (being able to analyze what is said and meant by a human) and react (being able to synthesize a realistic facial expression) to the variety of human facial expressions in a realistic fashion thus enabling lifelike interaction with users.

63.4.2 Example-Based Trajectory Synthesis

Example-based techniques have been successful for the synthesis of photorealistic pictures (Sect. 63.4.1) and the recognition of complex movements (Sect. 63.3.1). It turns out that related methods are also suitable for the

modeling of complex movement trajectories by interpolation between learned examples. This approach has been very successful in computer graphics, specifically for the modeling of highly realistic human movements. The simulation of realistic human movements for platforms with many degrees of freedom, like avatars and humanoid robots, based on physical or dynamical models is extremely difficult. Learning-based techniques exploiting motion capture data have thus become the most successful approach for the high-quality synthesis of complex human movements. A variety of methods for the synthesis of movement trajectories by interpolation and editing of motion-captured trajectory segments have been developed in computer graphics. Many of these approaches are also interesting for movement synthesis in robotics.

Simple approaches for example-based trajectory modeling by interpolation define novel movement styles by *motion morphing* between presegmented trajectories [63.98, 99]. An example is the interpolation between different gait styles. A variety of methods have been proposed for motion morphing (for a review see [63.100]), i.e., the blending between different movements styles. Some of these methods define linear Euclidean-style spaces by linear combination of example trajectories [63.83, 101, 102]. Such style spaces can be seen in analogy to face spaces. Linear combination methods for trajectories thus represent a spatiotemporal equivalent of morphable models (see Sect. 63.4.1). Another class of methods interpolate between example trajectories by learning of generative statistical models for the space-time texture of the training patterns. Such methods often yield real-time capable stochastic models for the generation of novel trajectories, e.g., exploiting hidden Markov models [63.103]. Real-time capability is essential for robotics applications, since usually it is not possible to presynthesize complete movements offline. Instead, robotic systems need to be reactive and

capable of online correction of synthesized movements depending on changes in the environment.

While simple motion interpolation techniques require presegmented and aligned example trajectories, more-advanced techniques have been proposed that accomplish an automatic segmentation of complex action streams into simpler components, or *movement primitives*. The concept of movement primitives has been quite influential in the theory of motor control of biological systems. A variety of different definitions of primitives has been given in the literature of motor control, ranging from coordinated activation patterns (synergies) at the muscle level to more abstract cognitive units of movement planning (for a review see [63.104]). In the context of robotics different approaches have been taken to identify and implement movement primitives. Sometimes, primitives have been predefined heuristically, e.g., as single goal-directed or periodic movements. Recent studies have tried to learn primitives directly from trajectory data sets applying supervised or unsupervised learning techniques, for example principle components analysis (**PCA**) or ISOMAP [63.105, 106]. Temporal correspondence between learned primitives and movements novel sequences can be established by appropriate dynamic alignment algorithms [63.107]. Optimized transitions between prestored or synthesized trajectory segments can be generated automatically, e.g., exploiting graph optimization algorithms [63.108, 109]. In this way, trajectories for complex action sequences can be synthesized automatically from learned example trajectories, ensuring that they fulfill specific style properties and are consistent with additional kinematic or dynamic constraints.

Some studies have embedded such learned trajectory models into real-time capable systems, e.g., for online tracking and synthesis of movement trajectories inter-

active applications like computer games [63.101, 110]. Such methods seem highly suitable for online imitation of movements in humanoid robots. Finally, movement primitives can also be modeled as dynamical control policies. It has been shown that such policies can be encoded by nonlinear dynamical systems whose stable solutions reproduce complex training movements [63.111] (see Chap. 59 for details).

Movements generated by interpolation between example trajectories can violate constraints of robot systems, e.g., the kinematic or dynamic limits of the platform and the environment. One possibility is to use the synthesized movement as a *virtual trajectory* that specifies a temporal sequence of goal states for the robot controller [63.107]. A variety of *filtering techniques* have been proposed that deform the synthesized trajectories in a way that makes them compatible with additional spatial or temporal constraints [63.112]. By exploiting physical models compatibility with dynamic constraints, like the minimization of torques, can also be accomplished [63.106]. For walking avatars and robots additional dynamic stability constraints have to be taken into account, e.g., concerning the dynamic stability of walking. Methods for deforming synthesized trajectories to make them compatible, for example with the zero moment point (**ZMP**) criterion (Chap. 16), have been proposed [63.113]. Such approaches try to combine the advantages of example-based trajectory generation (high degrees of accuracy and realism) with the ones of classical physics-based trajectory planning (real-time capability, simplicity of expressing physical and task constraints). However, the optimal integration of efficient learning models of complex movements and classical concepts in robot control is an active field of research in learning-based and humanoid robotics (Chap. 59).

63.5 Conclusions and Further Reading

In this chapter we have presented several principles derived from high-level cognitive processing in vision in the human brain that have been fruitful for the development of systems in robotics and computer vision. The recognition of shapes and complex movements and actions is an important problem for many applications in robotics. We have discussed a variety of results from neuroscience that indicate that in the brain these functions are likely realized by example-based representations. We have discussed the neural implementations

of such representations, which have been tested in the context of technical applications and which are strongly inspired by the real cortical neural architecture. In addition, we have discussed a class of methods for the highly accurate modeling of complex shapes and movement trajectories that are also based on learned examples, but which exploit more efficient technical algorithms for interpolation between the example patterns. We finally discussed approaches that try to link such example-based representations to more traditional model-based

recognition and tracking approaches. In addition, we have mentioned some methods for adapting patterns that are synthesized by such example-based techniques to boundary conditions and constraints of real robot platforms, and to accomplish real-time capability. We think that the discussed spectrum of results and applications shows that a transfer between biological and robotics systems on multiple levels can help to develop more efficient technical systems.

Example-based mechanisms for object and motion recognition account for the invariant recognition of complex patterns. However, they do not automatically extract the metric information about the object geometry and position and the spatial parameters of complex trajectories in world coordinates. For some tasks in robotics, such as grasping, manipulation or obstacle avoidance, such information is required (see, e.g., Chaps. 28 and 52). For such tasks, example-based recognition must be fused with methods for the extraction of the relevant metric information. In robotics such information can be extracted by stereo vision or using special sensors such as laser range finders. In the brain the fusion between such spatial information and information about objects likely occurs in the parietal areas, such as the *anterior interparietal area* (AIP) [63.114]. However, it is unclear whether the information about objects is only represented in terms of 2-D example views. Instead, it seems likely that some form of 3-D information is also encoded, potentially in an example-based manner. Also haptic and visual information about object shape might be merged in higher brain areas, e.g., in the parietal

and fusiform areas [63.115]. A more detailed discussion of biologically inspired models for the extraction of action-relevant geometrical information of objects and its combination with spatial information for grasping is presented in the context of the mirror neuron system.

In Sect. 63.2.1 we contrasted example- and model-based theories of the representation of objects in the brain. In fact, in a recent paper an attempt was made to reconcile these two approaches to object processing [63.116]: a careful study of the view dependency of novel objects was designed by combining structural properties (number of parts) with metric properties (thickness, size of parts) and found that both view-dependent and view-independent processing seem to be combined in object recognition. Thus, instead of taking the extreme standpoints of view-based versus view-invariant processing, one might envisage a visual processing framework in which features are selected according to the current task, where the optimality, efficiency, and thus the dependency on viewing parameters of the features depend on the amount of visual experience with this particular task. This suggests that a similar flexible approach might be suitable for the solution of problems in robotics. The combination of metric model-based representations for the planning of goal-directed movements and of example-based representations for the recognition of objects, people, and actions might result in powerful robotics systems with performance levels more similar to biological systems than the presently available solutions in robotics.

64. Roboethics: Social and Ethical Implications of Robotics

Gianmarco Veruggio, Fiorella Operto

The present chapter outlines the main social and ethical issues raised by the ever-faster application of robots to our daily life, and especially to sensitive human areas.

Applied to society in numbers and volumes larger than today, robotics is going to trigger widespread social and economic changes, opening new social and ethical problems for which the designers, the end user, the public, and private policy must now be prepared.

Starting from a philosophical and sociological review of the depth and extent of the two lemmas of robotics and robot, this section summarizes the recent facts and issues about the relationship between technoscience and ethics.

The new applied ethics, called roboethics, is presented. It was put forward in 2001/2002, and publicly discussed in 2004 during the First International Symposium on Roboethics.

Some of the issues presented in the chapter are well known to engineers, and less or not known to scholars of humanities, and vice versa. However, because the subject is complex, articulated, and often misrepresented, some of the fundamental concepts relating ethics in science and technology are recalled and clarified.

At the conclusion of the chapter is presented a detailed taxonomy of the most significant ethical, legal, and societal issues in Robotics. This study is based on the Euron Roboethics Roadmap, and it is the result of three years of discussions and research by and among roboticists and scholars of Humanities. This taxonomy identifies the most evident/urgent/sensitive ethical problems in the main applicative fields of robotics, leaving deeper analysis to further studies.

Many roboticists, as well as authoritative scholars of the history of science and technology, have already labeled the 21st century as the *age of the robots*. Actually, in the course of the present century, intelligent autonomous machines will gradually substitute many automatic machines [64.1].

Humanity has built tools to increase its power by eliminating manual labor and needless drudgery. This factor has become one of the keys to successful economic progress, especially since the Industrial Revolution and the emergence of a mechanized economy, and even more so with the introduction of automatic machines in the 20th century [64.2].

Today, progress in the field of computer science and telecommunications allows us to endow machines with enough intelligence that they can act autonomously. Thus, we can forecast that in the 21st century humanity will coexist with the first *alien* intelligence we have ever come into contact with – robots.

A few years from now, many more fields of application will be robotized, because robotics will have occupied more territories. The figures of the annual *World Robotics Survey*, issued by the United Nations (UN) Economic Commission for Europe and the International Federation of Robotics (IFR), show a steady tendency for growth with the characteristic curve of a rapidly developing field, with short slowdowns and steep climbing.

Certainly, robotics is changing our way of living, working, and operating in the world.

While the application field of robots is widening, the robot is coming out of the factories and into our homes – it is becoming a consumer item. The robot – which was expected to be an extended, intelligent tool for the human – is becoming a partner and a companion [64.3].

Moreover, robotics is also changing our method of conducting scientific inquiry and perhaps even our concept of ourselves [64.4]. Synergies between robotics, neurosciences, medicine, education, and psychology, have broadened the scope of application of the latter, making robotics a platform of global scientific research on humankind, on our galaxy and on the interaction between humankind and nature [64.5].

When robotics is applied to society in numbers and volumes larger than today, it will trigger widespread social and economic changes, for which public and private policy must now be prepared [64.6].

It will be an event rich in ethical, social and economic problems.

In the next decades in the industrialized world – in Japan, South Korea, Europe, United States – humanoid

robots will be among us, companions to the elderly and children, assistants to nurses, physicians, firemen, and workers. They will have eyes, human voices, hands and legs, skin to cover their gears, and brains with multiple functions. Often, they will be smarter and quicker than people they ought to assist. Placing robots in human environments inevitably raises important issues of safety, ethics, and economics.

What is going to happen when these smart robots are our servants and house stewards, and when our lives will depend on them?

Could people who mean no good use these robots to harm others?

The theme of the relationship between humankind and *autonomous* machines appeared early in world literature, developed firstly through legends and myths, then in scientific and moral essays. In early mythology, the ancient peoples expressed their worries about the disrupting power of machines over the old societies: when these artificial creatures to which we have given birth have learned everything from us, or understood that we are weaker than them, will they try to dominate us [64.7]?

In our time, facing the development of ever more powerful computers and the variety of humanoid robots, some scholars and scientists have warned about the dangers of the unlimited use of technology, and especially about the hubristic endeavor to design and manufacture intelligent creatures [64.8, 9].

Their concern has been amplified by the harsh discussion around bioengineering and bioethics. The famous physicist and Nobel prize winner Joseph Rotblat said that robotics, genetic engineering, and computer science are threatening the life on our planet [64.8, 9].

Thinking computers, robots endowed with artificial intelligence and which can also replicate themselves (...) this uncontrolled self replication is one of the dangers in the new technologies.

Less dramatically, others have pointed out the need to introduce ethical rules in technological applications, especially regarding the behavior of intelligent machines. In this frame, the most matter-of-fact issue is: what will be the cultural and social implications of the robotics invasion? Could robots be dangerous to humankind in any way [64.10]?

Under the pressure of public opinion and the media, roboticists cannot avoid engaging in a critical analysis of the social implications of their researches, in order

to be able to give *scientific and technical*, as well as *philosophical*, answers to questions such as:

- How far can we go in embodying ethics in a robot?
- What kind of *ethics* is robotic ethics?

- How contradictory is, on one side, the need to implement in robots an ethics, and, on the other, the development of robot autonomy?
- Is it right to talk about the *consciousness, emotions, and personality* of robots [64.11, 12]?

64.1 A Methodological Note

This chapter is by its nature somewhat different from – although complementary to – the remainder of this Handbook, because it deals not only with the scientific and technological issues inherent in the matter, but also with cultural and moral topics related to the introduction of robots in sensitive human areas.

The authors worked on the assumption that:

- This handbook – and in particular the present chapter – is going to be read by roboticists, and also by nonroboticists, by students of robotics as well as by students and scholars of ethics, philosophy of science, sociology, laws, etc. Some of the issues presented here are well known to some, and less or not known to the others, and vice versa. Nonetheless, the authors deemed it useful and important to recall and clarify some of the fundamental concepts relating ethics in science and technology, because the subject is complex, articulated, and often misrepresented.
- Roboethics is an applied ethics that refers to studies and works done in the field of science and ethics (science studies, science and technology studies (S&TS), science technology and public policy, professional applied ethics), and whose main premises are derived from these studies. In fact, roboethics was not born without parents, but it derives its principles from the global guidelines of the universally adopted applied ethics [64.13]. This is the reason why the substantial part of this Chapter is devoted to this subject, before specifically discussing the sensitive areas of roboethics.
- Many of the issues of roboethics are already covered by applied ethics such as computer ethics or bioethics [64.14]. For instance, problems arising in roboethics of dependability, technological addiction, the digital divide, the preservation of human identity and integrity [64.15]; the applications of precautionary principles, economic and social discrimination, artificial system autonomy and accountability, related to responsibilities for (possibly unintended) warfare applications [64.16]; and the nature and impact of human–machine cognitive and affective

bonds on individuals and society have already been matters of investigation in the fields of computer ethics and bioethics [64.16].

The specificity of robotics is underlined from a general point of view. Subsequently, in the taxonomy herein, the specific ethical issues related solely to robotics are carefully evaluated. The present taxonomy is not developed on the basis of affinity to the techno-scientific or disciplinary areas – like the index of the present book. Rather, the roboethics taxonomy is based on the application areas of robots, and on the specificity inherent to the human–robot interaction of these applications [64.17].

In terms of scope, we have taken into consideration – from the point of view of the ethical issues connected to robotics – a temporal range of two decades, in whose frame we could reasonably locate and infer – on the basis of the current state-of-the-art in robotics – certain foreseeable developments in the field.

For this reason, we consider premature – and have only hinted at – problems related to the possible emergence of human qualities in robots: consciousness, free will, self-consciousness, sense of dignity, emotions, and so on. Consequently, this is why we have not examined problems – debated in some other papers and essays – like the proposal to not behave with robots like with slaves, or the need to guarantee them the same respect, rights, and dignity we owe to human workers.

Likewise, and for the same reasons, the target of roboethics is not the robot and its artificial ethics, but the human ethics of the robots' designers, manufacturers, and users.

Although informed about the issues presented in some papers on the need and possibility to attribute moral values to robots' decisions [64.18], and about the chance that in the future robots might be moral entities like – if not more so than – human beings [64.19], the authors have chosen to examine the ethical issues of the human beings involved in the design, manufacturing, and use of the robots.

The authors felt that problems such as those connected with the application of robotics within the

military and the possible use of military robots against some populations not provided with this sophisticated technology, as well as problems of terrorism in robotics and problems connected with biorobotics, implantations, and augmentation, were pressing and serious

enough to deserve a focused and tailor-made investigation. It is absolutely clear that, without a deep rooting of roboethics in society, the premises for the implementation of an artificial ethics in the robots' control systems will be missing.

64.2 Specificity of Robotics

Robotics is a discipline originating from:

- Mechanics
- Automation
- Electronics
- Computer science
- Cybernetics
- Artificial intelligence

but it draws on from several other disciplines:

- Physics/mathematics
- Logic/linguistics
- Neuroscience/psychology
- Biology/physiology
- Anthropology/philosophy
- Art/industrial design

Is robotics a new science? On one side, robotics could be regarded only as a branch of engineering dealing with intelligent, autonomous machines. In this case, it shares experiences with other disciplines, and it is somehow the linear sum of all the knowledge.

On the other side, it could be seen as a new science, in its early stage. Actually, it is the first time in history that humanity is approaching the challenge of replicating a biological organism in the form of an intelligent and autonomous entity. This extraordinary mission gives to robotics the special feature of being a platform where sciences and humanities are converging – an experiment in itself [64.20].

It is not without some grounds that we could forecast that robotics will emerge as a new science, with its own theory, principles, theorems, proofs, and mathematical language [64.21].

However, even before that, robotics displays a specificity, which compels the scientific community to examine closely many of the notions until now applied only to human beings.

Although the authors consider it premature to study scientifically the possible emergence in the robot of human functions, we do not exclude that in the future we will be confronted with problems that today we can only imagine through the work of the artists of the science fiction [64.22, 23].

64.3 What Is a Robot?

From the point of view of how today's society sees robots, we can say that robotics scientists, researchers, and the general public have different evaluations about robots, as described below.

social and ethical implications of robotics fall into the categories of applying ethics to engineering.

64.3.2 Robots (and Technology in General) Have an Ethical Dimension

64.3.1 Robots Are Nothing Else But Machines

Many consider robots as mere machines: very sophisticated and helpful ones, but always machines. According to this view, robots do not have any hierarchically higher characteristics, nor will the designer provide them with human/animal qualities. In this frame, the issues of the

This derives from a conception according to which technology *is not an addition to man but is, in fact, one of the ways in which mankind distinguishes itself from animals*. So that, as language, and computers, but even more so, humanoids robots are symbolic devices designed by humanity to improve its capacity of reproducing itself, and to act with charity and good. "The humanoid (...) is the most sophisticated thinking machine able to assist

human beings in manifesting themselves, and this is ethically very good, as it supposes a radical increment of human symbolic capacity; humanoids will develop a lot of activities in order to increase the human quality of life and human intersubjectivity" [64.24].

64.3.3 Robots as Artificial Moral Agents (AMA)

According to this concept, robots and artificial agents extend the class of entities that can be involved in moral situations, for they can be conceived as moral patients (as entities that can be acted upon for good or evil) and also as moral agents [64.25] (not necessarily exhibiting free will, mental states or responsibility, but as entities that can perform actions, again for good or evil) [64.13].

64.3.4 Robots: the Evolution of a New Species

In the United States, one of the main discussions in the field of ethics and robotics is how to consider robots, as only *objects* or *subjects* which deserve legal rights: robots, not slaves.

According to this point of view, not only will our robotics machines have autonomy and consciousness, emotions and free will, but also humanity will create machines that "*exceed us in the moral as well as the intellectual dimensions*. Robots, with their rational mind and unshaken morality, will be the new species: Our machines will be better than us, and we will be better for having created them" [64.26].

64.4 Cultural Differences in Robot's Acceptance

While we analyze the present and future role of robots in our societies, we shall be aware of the underlying principles and paradigms that influence social groups and individuals in their relationships with intelligent machines.

Different cultures and religions regard differently intervention in sensitive fields such as human reproduction, neural therapies, implantations, and privacy. These differences originate from the cultural specificities towards the fundamental values regarding human life and death.

In different cultures, ethnic groups, and religions the very concept of *life* and *human life* differ, first of all concerning the immanence or transcendence of human life. While in some cultures women and children have fewer rights than adult males (not even *habeas corpus*), in others the ethical debate ranges from the development to a post-human status, to the rights of robots. Thus, the

different approach in roboethics concerning the rights in diversity (gender, ethnicity, minorities), and the definition of human freedom and animal welfare. From these concepts derive all the other ethical specificities such as privacy, and the border between privacy and traceability of actions.

Cultural differences also emerge in the realm of *natural* versus *artificial*: think of the attitude of different peoples towards surgical or organ implantation. How could human enhancement be viewed [64.27]?

Bioethics has opened important discussions: How is the integrity of the person conceived? What is the perception of a human being?

Last but not least, the very concept of *intelligence*, human and artificial, is subject to different interpretation. In the field of AI and robotics alone, there is a terrain of dispute – let us imagine how harsh it could be outside of the circle of the inner experts [64.4].

64.5 From Literature to Today's Debate

Literature is the instrument by which society expresses itself, free from rigid constraints, and by which it can simulate future social developments. Sometimes, by way of literature, important and foresighted scientific issues have been anticipated.

The topic of the threat posed by artificial entities designed by human's ingenuity (legends like *the rebellions of automata*, Frankenstein' myth, the Golem) recurs in classical European literature, as well as the misuse or

the evil use of the product of engineering (the myth of Dedalus). This is not the case in all world cultures. For instance, the Japanese culture does not include such a paradigm; on the contrary machines (and, in general, human products) are always beneficial and friendly to humanity.

In 1942, the outstanding novelist Isaac Asimov, who coined the word *robotics*, formulated his famous three laws of robotics in his novel *Runaround*:

- Law 1: A robot may not injure a human being, or through inaction, allow a human being to come to harm.
- Law 2: A robot must obey the orders given it by human beings except where such orders would conflict with the first law.
- Law 3: A robot must protect its own existence as long as such protection does not conflict with the first or second law.

Later on, in 1983, Asimov added the fourth law (known as the zeroth Law).

- Law 0: No robot may harm humanity or, through inaction, allow humanity to come to harm [64.28, 29].

Although farsighted and forewarning, could these laws really become the *ethics of robots* or are they too *naïve* to be considered seriously in this debate?

Over the last few decades, scientific and technological developments have brought forward the frontiers of robotics, so that those problems that years ago seemed only theoretical, or a matter of literature and science fiction, are becoming very practical, and even urgent.

Some of these problems have alerted the robotics community on the need to open a discussion on the principles that should inspire the design, manufacturing, and use of robots.

In 2001, the collaboration between the roboticist Paolo Dario and the philosopher José María Galván expressed the concept of *technoethics* [64.30].

In the same year, on the occasion of Italy–Japan 2001 (Tokyo, Japan), Paolo Dario and Japanese roboticist Atsuo Takanishi organized the Workshop *Humanoids. A Techno-Ontological Approach*, which was held at Waseda University. The lecture given by Galván was published in the December 2003 issue of *IEEE Robotics & Automation Magazine, On Technoethics* [64.24].

64.6 Roboethics

In 2002 the roboticist Gianmarco Veruggio, in the framework of the cultural and educational activity of the Association School of Robotics, started to discuss the need for an ethics which could inspire the work of robotics scientists. He called this new applied ethics, roboethics.

Roboethics is an applied ethics whose objective is to develop scientific/cultural/technical tools that can be shared by different social groups and beliefs. These tools aim to promote and encourage the development of Robotics for the advancement of human society and individuals, and to help preventing its misuse against humankind [64.31].

According to the definition, roboethics is not the *ethics of robots*, nor any artificial ethics, but it is the human ethics of robots' designers, manufacturers, and users.

In January 2004, in Sanremo, Italy, the authors, in collaboration with roboticists and philosophers, organized the First International Symposium on Roboethics, where the word roboethics was officially used for the first time.

On this occasion Paolo Dario ([RAS](#) president 2002-03) and Kazuo Tanie ([RAS](#) president 2004-

05) established a technical committee (TC) on roboethics, with the aims of providing the *IEEE* Robotics and Automation Society with a framework for analyzing the ethical implications of robotics

Fig. 64.1 The Roboethics' logo, sketched by the renowned Italian artist Emanuele Luzzati (1920 – 2007), is represented by a young smiling girl receiving a flower from a chivalrous humanoid robot

research, by promoting the discussion among researchers, philosophers, ethicists, and manufacturers, but also by supporting the establishment of shared tools for managing ethical issues in this context.

In 2005, the European Robotics Research Network (EURON) funded the project called the EURON Roboethics Atelier, with the aim of drawing the first roboethics roadmap. In 2006, in Genoa, Italy, scholars from humanities met for three days with engineers and

roboticists to draw the lines of the EURON roboethics roadmap [64.17].

Roboethics is not a veto or a prohibitionist ethics. Its main lines of development are: the promotion of culture and information; the permanent education; a vigorous and straight public debate; and the involvement in all these activities of the young generations who are the actors of the future [64.32].

Now, it is worth analyzing briefly the general principle of ethics.

64.7 Ethics and Morality

Ethics is the branch of philosophy concerned with the evaluation of human conduct [64.33].

The difference between ethics and morality is subtle. According to Italian philosopher Remo Bodei: "The word Ethics is generally associated to our relationship with others, to our public dimension; while morality concerns more with our conscience's voice, our relationship with ourselves. The distinction, however, is purely conventional, because the word comes from the Greek word *ethos*, which means habit, and morality from Latin *mos/moris*, which again means habit."

Another definition is the following:

In simple terms morality is the right or wrong (or otherwise) of an action, a way of life or a decision, while ethics is the study of such standards as we use or propose to judge such things [64.34].

In short *morality* is the subject of a science called *ethics* (although *morality* may also refer to a code of conduct: see <http://plato.stanford.edu/entries/morality-definition/>) [64.35].

64.8 Moral Theories

Apart from *virtue ethics*, the classical Greek moral philosophy, the dominant moral theories are:

- *Utilitarianism* - or more generally *consequentialism*: guideline properties that depend only on the consequences, not on the circumstances or the nature of the act in itself;
- *Contractualism*: morality as the result of an imaginary contract between rational agents, who are agreeing upon rules to govern their subsequent behavior. The idea is not that moral rules have resulted from some explicit contract entered into by human beings in an earlier historical era, a claim that is almost certainly false. (John Locke seems to have held a view of this sort.) Nor is the idea that we are, now, implicitly committed to a contract of the *I will not hit you if you do not hit me* variety, which implausibly reduces moral motivation;

- *Deontologism*, or duty-based ethics. What is my moral duty? What are my moral obligations? How do I weigh one moral duty against another? Kant's theory is an example of a deontological or duty-based ethics: it judges morality by examining the nature of actions and the will of agents rather than the goals achieved.

In scientific circles, *secular humanism* – a nontheistically ethical philosophy based upon naturalism, rationalism, and free thought – has gained great importance and influence [64.36].

It is true that in the scientific and technological domain a professional conception of ethics, closer to professional deontology, is becoming dominant and a universal standard of practice.

Furthermore, ethics in the digital world needs new approaches, beyond the classical moral theories, opening new and unresolved moral problems.

64.9 Ethics in Science and Technology

In the last years, concerned scientists, stakeholders, nongovernmental organizations (NGOs), parents, and consumers associations have increased their influence on the development of the scientific and technological researches, proposing (often imposing) to scientists, manufacturers, distributors, and advertising agencies the adoption of ethical conducts. Sometimes their intervention was mild, other times it had the result of closing down wealthy lines of research.

That is one of the reasons why we cannot underestimate the impact of society's opinions on *science and society* issues, and on the trend of the advancement of science and technology.

How can ethical concerns and visions become practical rules of society [64.37]? How can the ethical principles discussed in transdisciplinary assemblies; expressed by warnings or the public's concern; suggested by religious personalities, theologians, and moral leaders; and/or forwarded by a community of concerned scientists modify research and development (R&D) [64.38]? How can ethical thrust be embodied in the R&D activity without imposing on it unjustified restrictions, so depriving the scientist of his/her own freedom of thought [64.39]?

Through the millennia of the history of science and technology, society has envisaged ways to express their ethical concern [64.40].

The professional *oath* is either a statement or a promise expressed by a new entry into professional careers to be faithful to the traditional values of the professional order he/she is entering in. The ancient *Hippocratic oath* is the recurrent example for other initiatives to develop and implement codes of conduct for scientists in general, and in specific areas in particular.

Otherwise, a *manifesto* is a public declaration of intentions, opinions, objectives or motives, often issued by a private organization or a government. For example, the Russell–Einstein Manifesto of 1955 is a public declaration against war and the further development of weapons of mass destruction.

A *statement* or a *declaration* can be employed to underline a given topic. As such, it can be either weakly or strongly prescriptive, morally or legally binding.

During the World Robot Conference which took place in Fukuoka, Japan, the participants released a three-part list of *expectations for next-generation robots*, called the *World Robot Declaration* issued on 25 February 2004. It states that:

- Next-generation robots will be partners that coexist with human beings;
- Next-generation robots will assist human beings both physically and psychologically;
- Next-generation robots will contribute to the realization of a safe and peaceful society.

A *recommendation* serves to induce acceptance or favor. It is a prescription only in the weak sense of offering advice: a normative suggestion that is neither legally nor morally binding. More conclusive is the *appeal*, an earnest request for support: a petition, entreaty, or plea.

A *resolution* is a formal expression of opinion or intention made (usually after voting) by a formal organization, legislature, or other group.

In the last 50 years, many professional associations have adopted their *code*: a written text that offers a collection of laws, regulations, guidelines, rules, directives or principles for moral conduct.

The *guiding principles* of the Code of Research Ethics are *non-maleficence* and *beneficence*, indicating a systematic regard for the rights and interests of others in the full range of academic relationships and activities. *Non-maleficence* is the principle of doing, or permitting, no official misconduct. It is the principle of doing no harm in the widest sense. *Beneficence* is the requirement to serve the interests and well being of others, including respect for their rights. It is the principle of doing well in the widest sense.

In the field of roboethics, the Government of Japan through the Ministry of Economy, Trade, and Industry has issued a *hugely complex set of proposals*, which is an articulated set of guidelines to ensure a safe deployment of robots in nonstructured environments. Under these guidelines, all robots would be required to report back to a central database any and all injuries they cause to the people they are meant to be helping or protecting. The draft is currently open to public comment with a final set of principles being made public in 2007. Among the indications:

Via a structure of general regulation and the adoption of that regulation, the planning, manufacturing, administration, repair, sales and use of robots shall observe the need for safety at every stage (...) The reasonably predictable misuse of robots shall be defined as the management, sale and use of next-generation robots for purposes not intended by manufacturers (...) There should, in principle, be no serious accidents such as fatal accidents involving

robots, and the frequency of such accidents should be lowered as far as possible. Affordable multiple security measures should be taken in case one protection method alone is insufficient.

The *charter* is an ancient form of agreement. An example is the charter of the United Nations. Charters have a legal character and are connected, in principle, to sanctions when not properly executed.

In 2007, the Government of the Republic of Korea announced the birth of a governmentally sponsored working group whose aim is the definition of a roboethics charter.

The process towards the Korean Roboethics Charter is the following. The first step concerns the establishing of a working group (**WG**) on roboethics composed by robot developers, chief executive officers (CEOs), psychologists, futurists, writers, government officials, users, lawyers, and doctors. The **WG** will release a draft

that will be circulated for feedbacks among online international communities, and through public hearings [64.41].

The revised draft will go for deliberation to the *Robot Industry Policy Forum*, which will be composed of 40 members, representing the main stakeholders. Subsequently, the draft will go to the *Industrial Development Council* (composed of 29 members). At this point – presumably at the end of 2007 – the draft becomes the Korean Roboethics Charter, and it will be officially announced. Then, application rules and detailed guideline will be released.

Other means of implementing ethical concerns in science and technology are the *convention*, a form of agreement, or a contract, and also a practice established by general consent.

Then, principles established by a government applicable to a people and enforced by judicial decision become *law*.

64.10 Conditions for Implementation

Once the chosen code of research ethics has been defined, a list of conditions for implementation should be drawn up. Actually, no regulation can be implemented without at least some of those conditions, which should favor the application of the rules.

From the *individual* scientist's point of view, he/she has to guarantee some conditions, without which he/she is not in the position to adhere to nor to implement the Code of Ethics. These are: decision-making capacity, that is the empowered position and freedom to identify and choose alternatives based on the values and preferences defined and accepted; individual scientists' honesty and integrity; and transparency of processes.

On the other side, the given scientific institution, and in the final analysis society, should guarantee the individual scientist the reasonable general framework in which he/she finds the best conditions to work. These are:

- Periodic review of the application procedures
- Review and assistance by ethics committees
- Promotion of public debate
- Definition of risk assessment, management and prevention
- Transnational practices: comparison of conducts across countries and comparisons of professional ethics around the world

64.11 Operativeness of the Principles

The implementation of regulations or of codes of conduct should provide guidelines for operationalizing and reconciling the principles to be implemented, in case such principles appear inherently contradictory.

For instance, ethical guidelines may – by virtue of their collective nature – pose a threat to the individual's moral autonomy. Or, the public's demand for accountability could threaten the professions' pursuit of autonomy.

64.12 Ethical Issues in an ICT Society

The importance of ethics in science and technology has been demonstrated by our recent history. Three of

the front-rank fields of science and technology: nuclear physics, bioengineering, and computer science, have al-

ready been forced to face the consequences of their research's applications because of pressure caused by dramatic events, or because of the concern of the general public.

The introduction of intelligent machines in our daily life brings up global social and ethical problems which are usually summarized as

- dual-use technology (every technology can be used and misused)
- anthropomorphization of technological products (it is well known and documented that people attribute intentions, goals, emotions, and personalities to even the simplest of machines with life-like movement or form)
- humanization of the human–machine relationship (cognitive and affective bonds toward machines)
- technology addiction;
- digital divide, socio-technological gap (per ages, social layer, per world areas)
- fair access to technological resources
- the effects of technology on the global distribution of wealth and power
- the environmental impact of technology

Due to the interdisciplinarity of robotics, roboethics shares problems and solutions with other applied ethics: computer ethics, information ethics, bioethics, technoeconomics and neuroethics.

Computer ethics (**CE**), a term coined by Walter Maner in the mid 1970s, denotes the field of research that studies ethical problems *aggravated, transformed or created by computer technology*.

Perhaps the first contact between ethics and computer science took place in the 1940s, when Norbert Wiener, professor at the MIT and one of the founding fathers of computer science, expressed his concern about the social effects of the technologies he himself contributed to develop [64.42]. In 1948, in his book *Cybernetics: or Control and Communication in the Animal and the Machine*, and in his following book, *The Human Use of Human Beings*, he pointed out the dangers of nuclear war and the role of scientists in weapons development in 1947, shortly after Hiroshima. Although he did not use the term *computer ethics* he laid down a comprehensive foundation for computer ethics research and analysis. Wiener's foundation of computer ethics was far ahead of its time [64.43, 44].

It was not until 1968 that Wiener's concern became actual practice, when Donn Parker, one of the most famous scientist of the Stanford Research Institute (SRI) at Menlo Park, began to examine unethical and ille-

gal uses of computers by computer professionals. He writes:

It seemed that when people entered the computer center, they left their ethics at the door.

In 1968 he published his *Rules of Ethics in Information Processing* and promoted the development of the first code of professional conduct of the Association for Computing Machinery (**ASM**), which was adopted by the **ACM** in 1973.

During the late 1960s, Joseph Weizenbaum, the designer of the computer program Eliza, shocked by the emotional involvement of psychiatric scholars towards his simple programs, expressed his concern that an *information processing model* of human beings was reinforcing an already growing tendency among scientists, and even among the general public, to see humans as mere machines. Weizenbaum wrote the book *Computer Power and Human Reason*, in which he expressed his thoughtful ethical philosophy [64.45].

In the late 1970s, Walter Maner of the Virginia Old Dominion University was the first to employ the label *computer ethics* to define the field of inquiry dealing with ethical problems aggravated, transformed, or created by computer technology [64.46].

In 1985, James Moor of Dartmouth College published his article *What is Computer Ethics?* [64.47], and Deborah Johnson of the Rensselaer Polytechnic Institute published her book, *Computer Ethics*, the first textbook – and for more than a decade, the defining textbook – in the field. In 1983 the Computer Professional for Social Responsibility (**CPSR**) was founded at Palo Alto: a global organization promoting the responsible use of computer technology. Incorporated in 1983 (following discussions and organizing that began in 1981), **CPSR** is the first international association whose mission is to educate policymakers and the public on a wide range of issues [64.48].

In 1991 computer ethics was officially added as a subject to the programs in the computer science departments of the United States.

In the 1990s, it was proposed that the core of the issues of **CE** did not lie in the specific technology, but in the raw material manipulated by it (data/information), as a result of which several researchers (especially the team at Oxford led by Luciano Floridi) developed *information ethics* (**IE**).

Bioethics is the study of the ethical, social, legal, philosophical, and other related issues arising in health care and in the biological sciences (International Association of Bioethics, IAB) [64.49, 50].

In 1970 Van Rensselaer Potter (1911–2001) coined the term *bioethics* [64.50]. He was an American biochemist, Professor of Oncology at the McArdle Laboratory for Cancer Research at the University of Wisconsin, Madison. The first appearance of the term was in his book *Bioethics, A Bridge to the Future*. He coined it after trying for many months to find the right words to express the need to balance the scientific orientation of medicine with human values.

Potter's original concept of bioethics was comprised of a global integration of biology and values designed to guide human survival, with a new bioethics as the bridge between science and humanities. Increasingly, he felt the need to link what he came to realize had become mainstream biomedical ethics with environmental ethics.

During his career he continued to modify the term bioethics to differentiate his conceptions from the dominant view of biomedical ethics. He eventually selected the term global bioethics and this became the title of his second book [64.51]. In it, there is a new definition of the term bioethics, as *biology combined with diverse humanistic knowledge forging a science that sets a system of medical and environmental priorities for acceptable survival*.

64.13 Harmonization of Principles

Internationally recognized institutions such as the United Nations, the World Health Organization (WHO), the Food and Agricultural Organization (FAO), the UN Educational, Scientific, and Cultural Organization (UNESCO)'s World Commission on the Ethics of Scientific Knowledge and Technology (COMEST), the International Labor Organization (ILO), the World Medical Association, the World Summit on the Information Society, and the European Union have identified general ethical principles that have been adopted by most nations, cultures, and people of the world.

Furthermore, the international scientific, juridical, economic, and regulatory community has on many occasions proposed a harmonization of world ethical principles applied to science and technology, especially in those cases when these principles involve sensitive issues such as life, human reproduction, human dignity, and freedom.

The Ethics of Science and Technology Programme, part of UNESCO's Division of Ethics of Science and Technology in the Social and Human Sciences Sector, and COMEST, an advisory body to UNESCO composed

The field of bioethics is at a critical stage of evolution, having now passed the 13th year of the development of bioethics programs. It is in a phase of professionalization attending to both the ethical framework for clinical and industrial bioethical consultation and the creation of the next level of academic organizational success, namely departments and PhD programs [64.52].

Technoethics is a recent definition, derived from Christian theology,

as a sum total of ideas that bring into evidence a system of ethical reference that justifies that profound dimension of technology as a central element in the attainment of a finalized perfection of man [64.53].

Neuroethics is concerned with the ethical, legal, and social policy implications of neuroscience, and with aspects of neuroscience research itself [64.54]. Neuroethics encompasses a wide array of ethical issues emerging from different branches of clinical neuroscience (neurology, psychiatry, psychopharmacology) and basic neuroscience (cognitive neuroscience, affective neuroscience).

of 18 independent experts, have proposed, in the field of bioethics, to start a process towards a *declaration on universal norms on bioethics*. In Rio de Janeiro in December 2003, COMEST organized an international conference on the issue of a *universal ethical oath for scientists*.

In Europe, the 6th Framework Program, funded under the Science and Society work Programme, the ETHICBOTS project (an abbreviation for merging technoethics of human interaction with communication, bionic, and robotic systems). The project aims to promote and coordinate a multidisciplinary group of researchers in artificial intelligence, robotics, anthropology, moral philosophy, philosophy of science, psychology, and cognitive science, with the common purpose of identifying and analyzing technoethical issues concerning the integration of human beings and artificial (software/hardware) entities. Three kinds of integration are analyzed:

1. Human–softbot integration, as achieved by AI research on information and communication technologies

2. Human–robot noninvasive integration, as achieved by robotic research on autonomous systems inhabiting human environments
3. Physical, invasive integration, as achieved by bionic research

64.14 Ethics and Professional Responsibility

Although ethics in science and technology is not limited to deontology or professional ethics, but concerns a broader range of questions involving the fundamental beliefs and moral principles, its results and conclusions become guidelines for conduct in professional daily life.

From the social and ethical standpoints, in deciding the design, development, and application of a new technology, designers, manufacturers, and end users should be following rules, which are common to all human beings:

- human dignity and human rights
- equality, justice, and equity
- benefit and harm
- respect for cultural diversity and pluralism
- nondiscrimination and nonstigmatization
- autonomy and individual responsibility
- informed consent
- privacy and confidentiality
- solidarity and cooperation
- social responsibility
- sharing of benefits
- responsibility towards the biosphere
- obligatory cost-benefit analysis (whether ethical issues are to be considered as part of a proper cost–benefit analysis)
- exploiting potential for public discussion

(the Charter of Fundamental Rights of the European Union, 2001 [64.55]).

Computer and information ethics has developed a codes of ethics called *PAPA* (an acronym of: privacy, accuracy, intellectual property, and access), which could be adopted by robotics. It is composed as follows.

- *Privacy*: What information about ones self or ones associations must a person reveal to others, under what conditions, and with what safeguards? What things can people keep to themselves and not be forced to reveal to others?
- *Accuracy*: Who is responsible for the authenticity, fidelity, and accuracy of information? Similarly, who

is to be held accountable for errors in information and how is the injured party to be made whole?

- *Property*: Who owns information? What are the just and fair prices for its exchange? Who owns the channels, especially the airways, through which information is transmitted? How should access to this scarce resource be allocated?
- *Accessibility*: What information does a person or an organization have a right or a privilege to obtain, under what conditions, and with what safeguards?

Problems of the *delegation* and *accountability* to and within technology are problems of daily life for every one of us. Today, we give responsibility for crucial aspects of our security, health, life-saving, and so on to machines.

Professionals are advised to apply, in performing sensitive technologies, the *precautionary principle*:

When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause-and-effect relationships are not fully established scientifically.

(Source: January 1998 Wingspread Statement on the Precautionary Principle; see also the Rio Declaration from the 1992 United Nations Conference on Environment and Development, Agenda 21; and the Commission of the European Communities, Brussels, 02.02.2000, com (2000) 1 communication from the Commission on the precautionary principle.)

From the precautionary principle other rules can be derived, such as:

- noninstrumentalization
- nondiscrimination
- Informed consent and equity
- Sense of reciprocity
- Data protection

All over the world, associations and orders of engineers have adopted codes of ethics guiding towards responsible conduct in research and practice. In this context,

security and *reliability* are the most important ethical codes of conduct.

Among the other important recommendations are the following:

- Hold paramount the safety, health, and welfare of the public in the performance of their professional duties.
- Perform services only in areas of their competence.

- Issue public statements only in an objective and truthful manner.
- Act in professional matters for each client as faithful agents or trustees.
- Avoid improper solicitation of professional assignments.

(From the *American Council of Engineering Companies Ethical Guidelines*).

64.15 Roboethics Taxonomy

In this section we outline a first classification of the most evident ethical issues of robotics, based on the EURON roboethics roadmap.

Certainly, classifying the different branches of robotics is not an easy task. Likewise, it is a complex undertaking to organize a matrix of field of robotics/ethical issues. We have tried to classify these topics according to homogeneous fields from an applicative point of view.

Furthermore, in the present taxonomy, we have chosen the *triage process* of identify the most evident/urgent/sensitive ethical problems in robotics, leaving to other times and further studies more complex problems.

64.15.1 Humanoids

One of the most ambitious aims of robotics is to design an autonomous robot that could reach – and even surpass – human intelligence and performance in partially unknown, changing, and unpredictable environments.

Artificial intelligence will be able to lead the robot to fulfill the missions required by the end users. To achieve this goal, over the past decades scientists have worked on [AI](#) techniques in many fields, including:

1. Artificial vision
2. Perception and analysis of the environment
3. Natural language processing
4. Human interaction
5. Cognitive systems
6. Machine learning and behaviors
7. Neural networks

In this context, one of the fundamental aspects of the robots is their capability to learn: to learn the characteristics of the surrounding environment, that is, (1) the physical environment, but also (2) the living beings that inhabit it. This means that robots working in a given en-

vironment have to distinguish human beings from other objects.

In addition to learning about their environment, robots have to learn about their own behavior, through a self-reflective process. They have to learn from the experience, replicating somehow the natural processes of the evolution of intelligence in living beings (synthesis procedures, trying-and-error, learning by doing, and so on).

It is almost inevitable that human designers are inclined to replicate their own conception of intelligence in the intelligence of robots. In turn, the former gets wired into the control algorithm of the robots. Robotic intelligence is a learned intelligence, fed by the world models uploaded by the designers. It is a self-developed intelligence, evolved through the experience which robots have gained through the learned effects of their actions. Robotic intelligence also includes the ability to evaluate and attribute a judgment to the actions carried out by robots.

All these processes embodied in the robots produce a kind of intelligent machine endowed with the capability to express a certain degree of autonomy. It follows that a robot can behave, in some situations, in a way that is unpredictable to their human designers. Basically, the increasing autonomy of the robots could give rise to unpredictable and nonpredictable behaviors.

So, without necessarily imagining some science-fiction scenarios where robots are provided with consciousness, free will, and emotions, in a few years we are going to be cohabiting with robots endowed with self-knowledge and autonomy – in the engineering meaning of these words.

64.15.2 Artificial Body

Humanoids are robots whose body structure resembles the human one. They answer an age-old dream of hu-

manity, and certainly do not spring only from rational, engineering, or utilitarian motivations, but also from psychoanthropological ones.

Humanoids are the expression of one of the demands of our European culture, that is, that humankind be the creator of some mechanical being in the shape of a human. In Japanese culture, it is the demand to carefully replicate nature in all its forms.

This is a very difficult and demanding enterprise, a project of the level of the mission to the moon. However, precisely because it is one of humanity's dreams, large investments are being made and progress is quick.

It has been forecast that in the not-so-distant future we will cohabit with humanoids whose shape will be so similar to that of human beings that it will render it possible to get mixed up in certain situations with the latter. Humanoids will assist human operators in human environments, will replace human beings, and will cooperate with human beings in many ways.

Given the high cost and the delicacy of the humanoids, they will probably be employed in tasks and in environments where the human shape would really be needed, that is, in all these situations where the human-robot interaction is primary, compared to any other mission – human-robot interactions in health care; children/disable people/elderly assistance; baby sitting; office clerks, museum guides; entertainers, sexual robots, and so on. Or, they will be employed as testimonials for commercial products.

The special tasks humanoid robots can fulfill are manifold. Humanoids are robots so adaptable and flexible that will be rapidly used in many situations and circumstances. They can assist humans to perform very difficult tasks, and behave like true and reliable companions in many ways. Their shape, and the sophisticated human–robot interaction, will be very useful for situations in which a human shape is needed.

The research carried out in humanoids laboratories throughout the world will have as a side-effect the development of a platform to study the human body, for training, haptic testing, and training, with extraordinary results for healthcare, education, edutainment, and so on [64.56].

Faced with an aging population, the Japanese society see humanoids robots as one way to enable people to continue to lead an active and productive life in their old age, without being a burden to other people.

From the point of view of *safety* in the use of humanoids, and taking into account that in the not distant future they will be used as companions to human beings, humanoids can rise serious problems related to the

reliability of their *internal evaluation systems* and to the *unpredictability* of robots' behavior. Thus, designers should guarantee the traceability of evaluation/actions procedures, and the identification of robots.

Concerning safety, it should be underlined that an incorrect action by humanoids can lead to a dangerous situation for living beings and the environment. Furthermore, there could be also the case where the incorrect action by the robot is caused by a criminal intent, if robot's autonomy was controlled by ill-intentioned people, who modified the robot's behavior in a dangerous and fraudulent course.

Because humanoids combine almost all of the characteristics of the whole spectrum of robots, their use implies the emergence of nearly all of the problems we will examine below. In particular, their introduction into human environments, workplaces, homes, schools, hospitals, public places, offices, and so on, will deeply and dramatically modify our society.

There is already an important and well-documented literature on the implication of coexistence between human beings and humanoids. The problems range from the replacement of human beings (economic problems; human unemployment; reliability; dependability; and so on) to psychological problems (deviations in human emotions, problems of attachment, disorganization in children, fears, panic, confusion between the real and the artificial, feeling of subordination towards robots) [64.57].

On the technological and scientific side, trust towards and ever-greater autonomy of humanoids (and of the robots in general) are the dominant trends. From the ethical standpoint, many have expressed fear that too much autonomy can harm human beings. For instance, Japan's Ministry of Economy, Trade, and Industry are working on a new set of safety guidelines for next-generation robots. This set of regulations would constitute a first attempt at a formal version of the first of Asimov's science-fiction *laws of robotics*, or at least the portion that states that humans shall not be harmed by robots.

Recently, Japan's ministry guidelines will require manufacturers to install a sufficient number of sensors to prevent robots from running into people. Lighter or softer materials will be preferred, to further prevent injury. Emergency shut-off buttons will also be required.

Another set of questions arises around the shape of the humanoids. Is it right that robots can exhibit a *personality*? Is it right that robot can express *emotion*? The concern expressed by psychologists is that, well before evolving to become conscious agents, hu-

manoids can be an extraordinary tool used to control human beings.

In one of their papers, Wagner, Cannon, Van der Loos [64.58] list the main questions posed by the introduction of a new technology:

- Under what conditions should we decide that deployment is acceptable?
- At what point in the development of the technology is an increase in deployment acceptable?
- How do we weigh the associated risks against the possible benefits?
- What is the rate of the ethics of functional compensation or repair versus enhancement? This issue is especially notable regarding the problem of *augmentation*: In some cases a particular type of technology is regarded as a way of compensating for some function that is lacking compared to the majority of humans; in other cases, the same technology might be considered an enhancement over and above that which the majority of humans have. Are there cases where such enhancement should be considered unethical?
- Are there cases where a particular type of technology itself should be considered unacceptable even though it has the potential for compensation as well as enhancement?
- The question of identifying cause, and assigning responsibility, should some harm result from the deployment of robotic technology [64.59].

64.15.3 Industrial Robotics

An industrial robot is officially defined by ISO as an automatically controlled, reprogrammable, multipurpose manipulator.

Typical applications of industrial robots include welding, painting, ironing, assembly, pick and place, palletizing, product inspection, and testing, all accomplished with high endurance, speed, and precision.

Complexity can vary from simple single robot to very complex multirobot systems:

- Robotic arms
- Robotic work cells
- Assembly lines

From the social and economic standpoint, the benefits of these robots are extraordinary. They can relieve human beings of heavy work, dangerous workplaces, and routine and tedious activities.

In the future, we can imagine robotic factories, completely managed by robots. In the industrialized countries, which are facing a looming labor shortage due to their aging populations, robots in factories will cut costs.

Industrial robots increase productivity (higher speed, better endurance); they increase quality (precision, cleanliness, endurance); they make highly miniaturized devices possible (building the European Robotics Platform, EUROP).

Social problems stemming from the introduction of robots in factories are, first of all, loss of jobs and unemployment. On the other hand, while a welfare policy is to be implemented at a national level to facilitate workers' redeployment, and educational programs to create new skills, it should also be said that robots have also created new jobs directly and can create wealth, leading to the development of new industries and workplaces.

64.15.4 Adaptive Robot Servants

Robots come in several shapes and sizes (wheeled, legged, humanoids), equipped with different kinds of sensing systems (artificial vision systems, ultrasonic, radio) and manipulations (grippers, hands, tools, probes). Service robots support and back up human operators.

According to the UN's annual World Robotics Survey issued by the UN Economic Commission for Europe (UNECE) and the International Federation of Robotics, 607,000 automated domestic helpers were in use at the end of 2003, two-thirds of them purchased during that year. The survey forecasts that the use of robots around the home – to mow lawns, vacuum floors and manage other chores – will increase year on year.

By the end of the decade, the study said, robots will *not only clean our floors, mow our lawns and guard our homes but also assist old and handicapped people with sophisticated interactive equipment, carry out surgery, inspect pipes and sites that are hazardous to people, fight fire and bombs*.

Servant robots can: clean and housekeep; they are fast and accurate, and never bored. They can babysit, because they are patient, talkative, and able to play many games, both intellectual and physical. They can assist patients, the elderly, and the handicapped in clinics or at home, being always available, reliable, and taught to provide physical support.

Certainly, servant robots can guarantee a better quality of life, providing that designers guarantee safety and security (unpredictability of machine behavior from ma-

chine learning; assignment of liability for misbehavior or crime).

From a social and psychological standpoint, overuse could lead to technology addiction or invasion of privacy. Humans in robotized environments could face psychological problems [64.60].

64.15.5 Distributed Robotic Systems

The fast growth of the many wireless systems makes it possible to link all robots to the Web. Network robotics will allow remote human–robot interaction for teleoperation and telepresence, and also robot–robot interaction for data sharing, and cooperative working and learning. When Web speed become comparable to that of the internal local-area network (**LAN**) of the robot, the machine will explode into a set of specialized systems distributed over the net.

Complex robotic systems will be developed, constituted by a team of cooperating robotic agents/components connected through information and communication technology (**ICT**) and GRID, on distributed computing, technologies:

- Networked knowledge system
- Networked intelligence systems
- Multirobot systems

Multirobot systems are self-organizing robot teams consisting of a large number of heterogeneous team members. The organization in robot teams or squads is needed to perform specific tasks that require automatic task distribution and coordination at a global and local level, and when central control becomes impossible due to large distances and the lack of local information, or when signal transmission delays.

A full-scale robot team would be of tremendous value in a number of applications such as security, surveillance, monitoring, gardening, and pharmaceutical manufacturing. In addition, the coordination of heterogeneous teams of robots will also be of significant value in terms of planning, coordination, and the use of advanced manufacturing systems.

The benefits of robot teams are manifold, including increases in efficiency in performing complex tasks, and the capability to manage large-scale applications. They also provide abundant and replaceable interchangeable agents, which improves the reliability because the group can perform even after losing most of its parts.

On the other side, scientists should be aware of some of the risks in applying robot teams, for instance, the increasing dependability of primary services from com-

plex systems, and the unpredictability of robot team behavior. From a criminal point of view the assignment of liability for misbehavior or crimes, vulnerability to hacking, and concerns about privacy are some of the important issues.

64.15.6 Outdoor Robotics

Outdoor robots are intelligent machines that explore, develop, secure, and feed our world. Robots could also be employed in dangerous operations such as laying explosives, going underground after blasting to stabilize a mine roof, and mining in areas where it is impossible for humans to work or even survive.

They can work in the following environments:

Land

- Mining (automated load–haul–dump trucks, robotic drilling and blasting devices)
- Cargo handling (cranes and other automation technology for cargo lift on/lift off)
- Agricultural (autonomous tractors, planters and harvesters, applicators for fertilizers and pest control)
- Road vehicles (autonomous vehicles for humans or cargo transportation)
- Rescue robotics (robots that support first-response units in disaster missions)
- Humanitarian demining (robots for detecting, localizing, and neutralizing landmines)
- Environmental protection (robots for pollution cleaning and decommissioning of dangerous facilities).

Sea

- Research (marine robots for oceanography, marine biology, geology)
- Offshore (underwater robots for inspection, maintenance, repair and monitoring of oil and gas facilities in deep and ultradeep waters)
- Search and rescue (underwater robots for first-response intervention in case of accidents at sea, such as a submarine that has run aground).

Air

- **UAV** (autonomous airplanes for weather forecasting, environmental monitoring, road traffic control, large-area survey, and patrolling).

Space

- Space exploration (deep-space vehicles, landing modules, rovers)

- Space stations (autonomous laboratories, control and communication facilities)
- Remote operation (autonomous or supervised dexterous arms and manipulators)

Mobile robots in particular can be highly valuable tools in urban rescue missions after catastrophes such as earthquakes, bomb or gas explosions, or everyday incidents such as fires and road accidents involving hazardous materials. Robots can be used to inspect collapsed structures, to assess the situation and to search and locate victims.

Among the benefits of employing such robots is the increased efficiency of the exploitation of natural resources, which could increase food production for the world's population.

Concerning space robotics, it is obvious that, on the basis of current knowledge and technology, the robot can be our pioneer in space travel and missions to explore the far planets of the solar system and beyond.

On the social front, the unrestrained use of outdoor robots could extend the excessive anthropization and exploitation of the planet, which can become in turn a threat to biodiversity and all other forms of life on the planet. As for AI, the other branch of robotics, this could lead to technology addiction. Furthermore, given the versatility of these robots, they can be converted from civilian use for warfare and misuse (terrorism, pollution).

64.15.7 Surgical Robotics

The field of surgery is entering a time of great change, spurred on by remarkable recent advances in surgical and computer technology. Computer-controlled diagnostic instruments have been used in the operating theater for years to help provide vital information through ultrasound, computer-aided tomography (CAT), and other imaging technologies. Recently robotic systems have made their way into the operating room as dexterity-enhancing surgical assistants and surgical planners, in answer to surgeons' demands for ways to overcome the surgical limitations of minimally invasive laparoscopic surgery, a technique developed in the 1980s. On 11 July 2000, the Food and Drug Administration (FDA) approved the first completely robotic surgical device.

Typical applications are:

- Robotic telesurgical workstations
- Robotic devices for endoluminal surgery
- Robotic systems for diagnosis (Cat Scan - Computerized Axial Tomography Scan; NMR, Nuclear

- magnetic resonance; PET - Positron emission tomography)
- Robots for therapy (laser eye treatment, targeted nuclear therapy, ultrasonic surgery, etc.)
- Virtual environments for surgical training and augmentation
- Haptic interfaces for surgery/physiotherapy training

64.15.8 Biorobotics

Biorobotics comprises many different but integrated field of researches. Among them, the design and fabrication of novel, high performance bio-inspired machines and systems, for many different potential applications. The development of nano/ micro/ macro devices that can better act on, substitute parts of, and assist human beings - in diagnosis, surgery, prosthetics, rehabilitation and personal assistance. The development of devices for biomedical applications (e.g. mini-invasive surgery and neuro-rehabilitation).

Biorobotics is a new scientific and technological area with a unique interdisciplinary character. It derives its methodology mainly from the sectors of robotics and biomedical engineering, but also includes knowledge from, and provides useful applications to, many sectors of engineering, basic and applied sciences (medicine, neuroscience, economics, law, bio/nanotechnologies in particular), and even the humanities (philosophy, psychology, ethics).

Biorobotics offers a new paradigm for engineers. The engineer no longer just cooperates with neuroscientists, but has also become a scientist in order to discover basic biological principles that make their job easier [64.61].

64.15.9 Biomechatronics

Human prostheses for locomotion, manipulation, vision, sensing, and other functions include:

- Artificial limbs (legs, arms)
- Artificial internal organs (heart, kidney)
- Artificial senses (eye, ears, etc.)
- Human augmentation (exoskeleton)

This field has an important connection with neuroscience, to develop neural interfaces and sensory-motor coordination systems for the integration of these bionics devices into the human body/brain.

64.15.10 Health Care and Quality of Life

Health care and quality-of-life robotics is certainly a very promising field, where progress will be directly measured by the well being of people. It is also the best way to promote robotics among the public, especially amongst aging populations.

Surgical robotics allows minimally invasive surgery, which can reduce patient recovery time, and may also improve accuracy and precision. Robotics systems increase the precision of microsurgery and enhance the performance of complex therapies. Surgical robots can restore a surgeon's dexterity. Robotic surgery is also applied to very delicate neurological procedures that are practically impossible to perform without robotic assistance.

Assistive technology will help many people to conduct a more independent life.

Biorobotics, while enhancing the quality of life after diseases or accidents, provides tools for studying biological behavior and brain functions, and is a test bed for the study and evaluation of biological algorithms and modeling.

From the social and ethical standpoint, this is one of the fields in robotics that suffers from the most difficult safety and ethical problems. From a technical point of view, scientists in robotic surgery are working on the problems of reduced dexterity, workspace, and sensory input and possible fatal trouble, which could originate from the breakdown of surgical robot systems. Issues of size, cost, and functionality should also be addressed in surgery, haptic, and assistive robotics.

In the context of assistive technology, some questions concerning the relationship between patients and the health structures in which they are treated can be posed. Are we going to mechanize hospitals and to dehumanize our patients? Shall we improve our health structures, where human nurses can care for patients? May we not develop new psychological and physical dependences?

As a general principle of awareness, we should underline that the high cost of robotic systems in the medical field could widen the digital divide between developed and developing countries, and between layers of the same population.

The field of implantations raises concerns related to the fact that direct brain interfaces may at the same time pose ethical questions related to the enhancement of human function.

The BioX program at the University of Stanford, and the Stanford Center for Biomedical Ethics, funded

a pilot study in this domain called cross-cultural considerations in establishing roboethics for neuro-robot applications [64.62, 63]. This study explores funding mechanisms to investigate the span of ethical issues currently confronting direct brain interface investigators, how different kinds of interfaces may indicate different approaches to bioethics, and how other stakeholders in the deployment and use of this technology (for example, from law, government, and healthcare provider professions) perceive the relative importance of the various bioethics issues for the variety of interfaces that currently exist and those on the horizon.

64.15.11 Military Robotics

Intelligent Weapons

This field includes all devices resulting from the development of traditional military systems using robotics technology (automation, artificial intelligence, etc.):

- Integrated defense systems: an [AI](#) system for intelligence and surveillance, controlling weapons and aircraft capabilities
- Autonomous tanks: armored vehicles carrying weapons and/or tactical payloads
- Intelligent bombs and missiles
- Unmanned aerial vehicles ([UAVs](#)): unmanned spy planes and remotely piloted bombers
- Autonomous underwater vehicles ([AUVs](#)): intelligent torpedoes and autonomous submarines

Robot Soldiers

Humanoids will be employed to substitute humans in performing *sensitive* tasks and missions in environments populated by humans. The main reasons for using humanoids are to permit a one-by-one substitution, without modifying the environment, the human–human interaction, or the rules of engagement. This could be required where safeguarding human life is considered a priority in many different scenarios:

- Urban terrain combat
- Indoor security operations
- Patrolling
- Surveillance

Outdoor security robots could be able to make their night watch rounds and even chase criminals, directed by a remote-control system via an Internet connection or moving autonomously via their own artificial intelligence systems.

Superhumans

There are several projects aimed at developing a superhuman soldier. Actually, the human body cannot perform a task with the same strength, speed, and fatigue resistance as machines. Robotic *augmentation* describes the possibility of extending existing human capabilities through wearable robot exoskeletons, to create superhuman strength, speed, and endurance, including applications such as:

- artificial sensor systems
- augmented reality
- exoskeletons

The benefits of military robots are:

1. tactical/operational strength superiority
2. unemotional behavior, potentially more ethical than humans
3. limiting the loss of human lives in the robotized army
4. better performance of superhuman over human soldiers

Problems could arise from:

1. the inadequacy to manage the unstructured complexity of a hostile scenario
2. the unpredictability of machine behavior
3. the assignment of liability for misbehavior or crimes
4. the increased risk of starting a videogame-like war, due to the decreased perception of its deadly effects

From the human point of view, humans in mixed teams could face psychological problems, such as the practical and psychological problems of having to distinguish between humans from robots and the stress and dehumanization of superhuman soldiers.

In 2007, the Georgia Tech Mobile Robot Lab – lead by Ronald Arkin – led an online *opinion survey on the use of robots capable of lethal force in warfare*. The opinion survey is part of an important research project under a grant from the Army Research Office. The goal of this survey was to determine how acceptable the robots capable of lethal force in warfare are to different people of varying backgrounds and positions.

Military robotics should be thoroughly examined by specialized international organizations, as happens for every type of military technology, to be regulated by international conventions or agreements [64.64].

64.15.12 Educational Robot Kits

The beneficial applications of robotics in education are known and documented.

Robotics is a very good tool for teaching technology (and many other subjects) whilst, at the same time, always remaining very tightly anchored to reality. Robots are real three-dimensional objects which move in space and time, and can emulate human/animal behavior; but, unlike video games, they are real machines, true objects, and students learn much more quickly and easily if they can interact with concrete objects as opposed to formulas and abstract ideas.

In the age of electronics, computers, and networks, it is necessary to modernize not only educational content and tools, but also the methods used in traditional schools.

It is also important to consider that the lifestyle of young people has changed as well as the communication tools they use in their free time. Today, young people communicate via the Internet and mobile telephones using e-mail, SMS, and chat rooms, which allow them to be continually connected to a global community that has no limits regarding location and time.

Young people spend more time playing videogames, playing with their mobile phones or downloading files from the Internet. These activities provide them with experiences that are by now at the same standard as the most sophisticated technological systems. All this has accelerated the pace of life; so much so that fruition and consumption of experiences are both real and virtual. In fact, we are entering the age of cyberspace, which will not replace normal life relationships, but will certainly alter their characteristics.

In this context, we need to consider that traditional teaching and classical tools of support (books, documentaries) are at risk of becoming unsuitable when compared with the everyday possibilities offered to these young people by the world of mass media. Therefore, it is necessary to begin to plan new ways to transmit knowledge which exploit the potential of this new technology.

Learning about robotics is important not only for those students who want to become robotics engineers and scientists, but for every student, because it provides a strong method of reasoning and a powerful tool for grappling with the world. Robotics collects all the competencies needed for designing and constructing machines (mechanics, electrotechnics, electronics), computers, software, communications systems, and networks. The special features of robotics boost student creativity, communication skills, cooperation, and teamwork.

Learning about robotics promotes students' interest in and commitment to traditional basic disciplines (mathematics, physics, technical drawing). Robotic

construction kits, which can combine the physical building of artifacts with their programming, can foster the development of new ways of thinking that encourage new reflections on the relationship between: (1) life and technology, (2) science and its experimental toolset, and (3) robot design, and values and identity.

64.15.13 Robot Toys

The Aibo robot is the Sony's robotic puppy dog with a software-controlled personality and abilities. The entertaining robot, which costs upwards of \$2000, can dance, whimper, guard, and play, developing personalities based on interaction with its owners. Sony has sold over 150 000 Aibos since launching the product in May 1999.

Company officials said that there was a real effort this time to make the Aibo's movements more doglike; designers even studied the way dogs move. Developers replaced a relatively un-dog-like sideways head motion of one motor (as with the previous model, there are 20 motors) with a sort of forward-and-down movement.

Robot toys can be intelligent toys: they can be specifically designed to stimulate children's creativity and the development of their intellectual faculties. They can become children's companions, and – for only children – could play the role of *friends, brothers*, or the traditional *imaginary friend*. They could also be used in the pedagogical assistance of autistic children.

On the negative side of technology, robot toys could cause psychological problems, such as:

- lost touch with the real world
- confusion between the natural and the artificial
- confusion between the real and the imaginary
- technology addiction [64.65]

64.15.14 Entertainment Robotics

Robots will enable the construction of real environments that could either be the perfect (or scaled) copies of some existing environments, or the reconstruction of settings existed centuries/millennia ago, and which we can populate with real or imaginary animals.

Robots and robotics settings will make it possible to build natural phenomena and biological processes, even cruel ones, without involving living beings.

In these settings, the users/audience could live interactive experiences, which are *real*, not only *virtual*.

As extraordinary theatrical machines, robots will develop ever more *real* special effects.

Entertaining robots are already used to display and advertise corporate logos, products, and events. These are marketing tools showed off by the manufacturers on special occasions.

In this framework, we should also consider sexual robots, which will be an important market. They could be used as sexual partners in many fields, from therapy to prostitution, and their use could decrease sexual exploitation of women and children [64.66]. This also raises issues related to intimacy/attachments, and about safety and reliability.

64.15.15 Robotic Art

The role of robotics in contemporary art, along with all the types of interactive artistic expressions (telecommunications, and interactive installations), is gaining importance and success.

Artists are employing advanced technologies to create environments and works of art, utilizing the actuators and sensor to allow their robots to react and change in relation to viewers.

Robotic art will spread because:

- It recalls (and it is inspired by) the mythological traditions of various cultures. These traditions have created fantastic synthetic creatures;
- Robots exert on the population at large a special fascination;
- Robots can be used as tools in artwork and enable the building of artistic expression in shorter times, thus expanding the borders of human creativity;
- Robots can also perform actor's rules and allow playing living art.

The social and individual problems that can be produced by robotic art are, on the one hand, the dissemination of misinformation (by spreading of false information using technology), while on the other hand, technology may prevail over creativity.

64.16 Conclusions and Further Reading

In this chapter we have analyzed the main social and ethical issues in robotics, five years after the birth of roboethics, and after three years of wide and intense international discussion. In the conclusions, we develop some assessments, foresee lines of progress, and give some indications for those who wish to study the subject of roboethics in more depth.

The so-called robotics invasion has not yet been unleashed. Surely, the recent figures of the World Robotics Report (Unece/Fir 2005) show a steady growing trend of the robotics production and sales. However, often the media demand more inventions and *gadgets* from the robotics laboratories than the laboratories can afford and, looking at the many automatas that are still struggling to walk, the latter's efforts have so far proved to be something of a disappointment. This is certainly a problem and a pressure for the robotics scientists. For the time being, robotics is a field of research and development that can be applied in, and depends, a high level of technology.

However, we are witnessing a true, growing interest in robots from the general public, who are often more excited than the insiders, whose feelings swing between a position of cultural indifference to a behavior dictated by external pressures, be they political or industrial. We are also noticing the modern change – which had already happened in the 1970s in the field of computer science – of the transformation of the robot from a research platform and a working tool to a consumer item, and an object of entertainment. This is a juvenile phenomenon, as shown by the increase of robotics contests among high-school students. Today's young people who are getting their hands on robotics kits will be the robotics professionals and consumers of tomorrow.

Growing interest in the social effects of robotics is easy to observe among international professional associations and orders, stretching over the sister fields of computer ethics and bioethics.

Certainly, roboethics is still far from being a well-established applied ethics, and by *well established* authors mean that it should demonstrate two qualities: to be universally accepted and standardized, or at least adopted by some communities, relevant in size and in political/economic/cultural influence, and to be embodied in the design, production, and use of robots.

In this chapter, we have mentioned two important steps in this general direction: the guidelines for the use of robots in the human environment, drawn up by the ad hoc group of the Japanese METI; and the Roboethics

Charter, which is still in progress, being edited by the appointed committee of the Republic of South Korea. We should recall a few other projects that are studying the effects of the application of robotics to the neurosciences [64.58] and to bioethics/biorobotics [64.67, 68]. However, there is no question that we are still at an initial stage of the subject's development.

In fact, considering the history of the two widely applied and structured ethics which are extensively studied and which reach a certain organic unity, bioethics and computer and information ethics [64.46], we acknowledge that their development, which has been happening for over 30 years, came about through leaps and contradictions, chasms and bends, and that they are far from being a suitable ethical standard shared by a plurality of subjects. Both these ethics were born in a policy and legislative vacuum, as technological changes outpaced ethical developments, bringing about unanticipated problems [64.47].

The standardization of roboethics requires the accomplishment of some fundamental steps, both culturally and institutionally. From the general standpoint, it demands that the application of robotics to the human environment, especially to sensitive areas of the human life, will be accepted by the quasi totality of cultures, as has happened with other techno-scientific innovations such as electricity and computer systems. (In the case of free access to the Internet, the issue is still questionable in many nations.) Should this be achieved, roboethics would have already passed the phase of being adjusted to fit different answers and situations, to being modified to the point of having acquired the capability of adapting to different points of views. Different cultures and religions regard the intervention in sensitive fields such as human reproduction, neural therapies, implantations, and privacy differently. These differences originate from cultural specificities regarding fundamental issues, for example, the limit between a human and a cyborg; the separation between the natural and the artificial; the difference between human and artificial intelligence; the border between privacy and the traceability of actions; the concept of integrity and the unity of the human being; the acceptance of diversity (in gender, ethnicity, minorities, etc.); the boundary between replacement and human enhancement; and so on [64.49]. These are all milestones in defining the underlying paradigms, which in turn influence the day-by-day behavior of everyone.

There are many different aspects to be looked at, for instance, in some cultures the reproduction of the

human figure is forbidden. In others, the difference between human and nonhuman is not so sharp. The application of humanoid robots should be set against this background [64.69]. The diversity of ideas on these issues, such as natural versus artificial or animate versus inanimate, has immediate effects on the field of organ transplants, and subsequently of robotic organ implants. As a matter of fact, the debate on human enhancement versus rehabilitation is very active in Europe and the United States, for the time being mainly in the field of bioethics.

From the experience provided by more than 30 years of discussions and disputes in the fields of bioethics and information ethics, we know that all the achievements in the field of science and ethics are neither easy nor negligible.

For those who wish to thoroughly investigate some elements of philosophy of science; of history of science and ethics; of science and engineering's ethics; of the law applied to science and technology, we now suggest some fundamental steps.

In the field of the moral theories related to science and technology, we mention the considerable work of Tom L. Beauchamp from the Kennedy Institute of Ethics [64.49].

Two important annual gatherings of Computer Philosophy, CEPE, Computer Ethics Philosophical Enquiry and IACAP International Association for Computing and Philosophy, to mention just two, have recently added *roboethics* as one of their key topics.

We also encourage students and scholars to consult the works and website of the renowned Center for Computing and Social Responsibility (CCSR) of DeMontfort University, Leicester, UK. The CCSR is internationally recognized for its applied research expertise on the risks and opportunities of information technology. It also organizes the International Conference on the Social and Ethical Impacts of Information and Communication Technology (ETHICOMP) every year.

Furthermore, it is very useful to follow the activity of the regulatory bodies entitled to deal with the issues of science and ethics. In accordance with what was said in Sects. 64.4, 64.5, 64.12, and 64.13 of this chapter, the person's interest should start from the general principles that are essentially accepted by most of the worlds' Nations (at least, nominally), and to come down to the specific applications in our field.

The Ethics of Science and the Technology Programme is part of UNESCO's Division of the Ethics of Science and Technology in the Social and Human Sciences Sector. COMEST is an advisory body to UN-

ESCO. The two bodies work to apply in science and technology the principles of the Universal Declaration of Human Rights.

The Unesco's Ethics of Science and Technology Programme was created in 1998 along with COMEST to provide ethical reflection on science, technology, and their applications. Currently, in accordance with Decision 3.6.1 of the 169th session of the Executive Board, UNESCO is initiating standard-setting action by drafting studies on some new technological areas.

Another body whose activity is useful to follow is the European Group on Ethics in Science and New Technologies and the Forum (EGE, European Group on Ethics in Science and New Technologies), established by the European Commission. The EGE is an independent, pluralist and multidisciplinary body that advise the European Commission on ethical aspects of science and new technologies, regarding the preparation and implementation of community legislation or policies. The forum has many complementary roles. The former body is appointed to provide high-level specialist ethical advice to the European Commission, particularly in relation to the policy arena. The latter was set up under the Framework Programme as a networking activity with the aim of sharing information and exchanging best practices on issues of ethics and science. They work on the basis of the Lisbon Declaration 2000 and the charter of fundamental rights of the European Union approved by all the member states in 2001 (Nice, France).

Concerning the role of science and technology in law, politics, and the public policy in modern democracies, there are important differences between each of the European, the American, and the – we could say – oriental approach. In the United States, the general attitude is definitely more science-based than it is in Europe. In the former case, science is said to speak the truth, and the regulatory process is based more on objective scientific data than on ethical considerations. At the same time, the subjective point of view is taken up by the courts, which are now also intervening directly in areas such as risks to society and scientific knowledge, although the current conceptual tools of jurisprudence in the field of science and technology are still very limited. Nonetheless, in the Anglo Saxon culture, *law does not speak the language of science* [64.70].

On the other hand, in Europe, against the backdrop of the ongoing process of European cohesion, regulation and legislation of science and technology is assuming the character of the foundation of a new political community – the European Union – which is centered around the relationship between science and its applications, and the

community formed by the scientists, technology producers, and citizens. We can safely assume that, given the common classical origin of jurisprudence, the latter process could be helpful in influencing other cultures, for instance, the moderate Arab world.

On the subject of science, technology, and law in America and Europe, we recommend the impressive work by Sheila Jasanoff (Kennedy School of Government Faculty, Harvard University) whose research pivots on the role of science and technology in the law, politics, and public policy in Europe, the United States, and India, with particular reference to the behavior of the American courts in the regulation of science, and to the role of experts.

There is a third way to approach issues in science and society, which could be called oriental. In fact, in Japan and in the Republic of South Korea, issues of robotics and society have been handled more smoothly and pragmatically than in Europe and in America. Due to the general confidence from these societies towards the products of science and technology, the robotics community and the ad hoc ethical committees inside these governments have started to draw up guidelines for the regulation of the use of robotic artefacts. This nonideological nonphilosophical approach has its pros and cons, but it could encourage scientists and experts in Europe and the United States to adopt a more normative position.

For those who are interested in keeping up to date on these issues, a good habit to acquire is to consult the archives and websites of the academic institutions, private associations, and professional orders where problems of science and ethics are followed on a regular basis. The Nobel Prize Pugwash Conference for World Affairs is the umbrella association for this community and NGOs concerned with these issues. The IEEE Robotics & Automation Society's Technical Committee on Roboethics was formed for the purpose of promoting and collecting research on robotics and society.

The issue of the influence and the pressure provided by the market on science and R&D is handled by applied ethics, and is known as business ethics. In this framework, corporate social responsibility is one of the ways in which enterprises can affirm ethical principles and values. This view was introduced to the United States 15 years ago (especially in the field of health care) and is still running today. Also, training in the responsible conduct of research (**RCR**) has been adopted by the United States, and is still being applied. The domain of **RCR** training does not only include the ethical dimensions of research with human

subjects, but every intricate dimension of responsible conduct in the planning, performance, analysis, and reporting of research. Difficulties here arise from the small amounts of resources allocated; see also the Organization for Economic Cooperation and Development (OECD) Guidelines for Multinational Enterprises, on the ethical paragraphs.

Concerning the philosophical and epistemological aspect of the issues in ethics and robotics, one of the main problems that people who are interested in roboethics will have to handle is the persistent confusion – ontologically, but especially linguistically – between human and artificial intelligence, as well as between other fundamental concepts of perception, consciousness, self consciousness, emotions, and so on, as applied to humans and to machines.

It must be clarified that the contemporary roboethics is human ethics as applied to robotics, which is considered nonhuman. A strong base of human roboethics is needed in order to responsibly construct the foundations of the final question, which nobody can yet answer: can robots ever become *human*?

This triaging choice, far from rendering the problem simple, renders it technically manageable and fertile of solutions useful to robotics and to society.

At the same time, the need for serious and thorough work into the concepts of intelligence, knowledge, conscience, autonomy, freedom, free will etc. is highlighted. Indeed, the heterogeneous composition of specialists often leads to incessant discussions about the meaning of words, rather than on the content of the myriad, often pressing, issues that need to be faced.

This work is in fact one of the philosophies of robotics, aiming to better define the scientific paradigm. It is important work, as robotics faces the ideal challenge of recreating life artificially and synthetically, which imposes a reopening of discussion and, in some cases, a need to redefine seemingly simple concepts, as well as the need to create new concepts. All this takes place in a multicultural context, which fuels vastly different philosophical backgrounds.

All of this leads to the necessity for the international robotics community to become the author of its own destiny, so as to face directly the task which needs defining, whilst collaborating with academics in the fields of philosophy of law, and generally with experts from the human sciences, to engage with the ethics and social aspects of their research and the applications of the former. Nor should they feel relegated to a mere technoscientific role, delegating to others the task of reflecting and taking action on moral aspects. On the other hand,

a closed-shop attitude would be damaging to the development of robotics, given the interdisciplinary nature of the much of the research undertaken in the field.

From this point of view, roboethics cannot fail to be beneficial to robotics, framing research in close connection with end users and society, and so avoiding many problems that other *sensitive* fields are now facing.

All this, and more, will be wishful thinking if engineering study curricula do not include subjects such as scientific philosophy, history of science, law, and the politics of science, as is already happening in some advanced polytechnics. Once again, we have to say that the deeper study of the history of science, for example, especially in the 19th and 20th centuries, cannot but aid a better understanding of that complex scientific galaxy which is robotics. Even a restricted knowledge of cybernetics and computer science, from Wiener, to von Neumann, to Weizenbaum, will immediately and directly demonstrate that these scientists immediately took care of the ethical and social aspects of their dis-

coverties and realizations, which marked the beginning of the field of computers and robotics.

At the same time, it is necessary that those not involved in robotics keep up to date with the field's real and scientifically predictable developments, in order to base discussions on data supported by technical and scientific reality, and not on appearances or emotions generated by science fiction. In particular, apart from this handbook, one must look to serious magazines published by recognized scientific associations, and not rely on headlines about ambiguous and scandalizing creations that do not really exist.

Ethics is a 1000-year-old human science with an impressive literature. Its application to the field of science technology is no doubt more recent, even though precedents such as the Hippocratic oath suggest an extremely ancient origin. Research on robotics is throwing light on manifold issues across science and the humanities. No wonder it will also open new and unexpected field of studies and application in ethics.

Acknowledgements

C.20 Inertial Sensors, GPS, and Odometry

by *Gregory Dudek, Michael Jenkin*

We would like to thank Sarah Jenkin for her help with the figures.

F.42 Industrial Robotics

by *Martin Hägele, Klas Nilsson, J. Norberto Pires*

The authors are indebted to James Trevelyan of The University of Western Australia for his valuable assistance.

F.44 Aerial Robotics

by *Eric Feron, Eric N. Johnson*

The authors would like to thank the reviewers for their thorough and useful comments during the development of this chapter. They would also like to acknowledge the support of the US Defense Advanced Research Projects Agency, the US Air Force Office of Scientific Research, and the US Office of Naval Research for their support.

F.48 Robotics in Hazardous Applications

by *James P. Trevelyan, Sung-Chul Kang, William R. Hamel*

James Trevelyan acknowledges Surya Singh for detailed suggestions on the original draft, and would also like to thank the many unnamed mine clearance experts who have provided guidance and comments over many years, as well as Prof. S. Hirose, Scanjack, Way Industry, and Total Marine Systems for providing photographs.

William R. Hamel would like to acknowledge the US Department of Energy's Robotics Crosscutting Program and all of his colleagues at the national laboratories and universities for many years of dealing with remote hazardous operations, and all of his collaborators at the Field Robotics Center at Carnegie Mellon University, particularly James Osborn, who were pivotal in developing ideas for future telerobots.

Sungchul Kang acknowledges Changhyun Cho, Woosub Lee, Dongsuk Ryu at KIST, Korea for their providing valuable documents and pictures. He also appreciates Munsang Kim for his leading projects that have produced many of research achievements related to Sect. 48.3 enabling technologies.

F.52 Medical Robotics

and Computer-Integrated Surgery
by *Russell H. Taylor, Arianna Menciassi, Gabor Fichtinger, Paolo Dario*

We would like to thank the many colleagues, including clinicians, fellow engineering researchers, and students with whom we have worked over the years. These experiences have provided the essential background that enabled us to write this chapter. In addition, Drs. Dario and Menciassi extend special thanks to their colleagues at the CRIM Laboratory for help in identifying appropriate citations from the rapidly expanding literature within subfields of medical robotics. Drs. Taylor and Fichtinger gratefully acknowledge the support of numerous US Government agencies and other entities that have provided partial funding for many of the research results reported here, with special thanks to the National Science Foundation for generous support of the Engineering Research Center for Computer-Integrated Surgical Systems and Technology under cooperative agreement EEC9731478. Finally, we would like to thank the reviewers for their many constructive comments and suggestions, which have greatly improved this chapter.

G.61 Evolutionary Robotics

by *Dario Floreano, Phil Husbands, Stefano Nolfi*

We thank the anonymous reviewers and Michael Arbib for constructive suggestions and Mototaka Suzuki for further corrections and editorial help. Dario Floreano was supported by the Swiss National Science Foundation.

About the Authors

Jorge Angeles

McGill University
Department of Mechanical Engineering
and Centre for Intelligent Machines
Montreal, Quebec, Canada
angeles@cim.mcgill.ca

Chapter B.10

Jorge Angeles graduated as an Electromechanical Engineer and obtained the MEng degree in Mechanical Engineering, both at Universidad Nacional Autónoma de México (UNAM), then received the PhD degree in Applied Mechanics from Stanford University. Research activities include robot kinematics, dynamics, design, and control as well as design theory and methodology. Angeles is a Fellow of ASME, CSME, IEEE and RSC, The Academies of Arts, Humanities, and Sciences of Canada, and Honorary Member of IFToMM, the International Federation for the Promotion of Mechanism and Machine Science.

Chapter F.43

Gianluca Antonelli received the Laurea degree in Electronic Engineering and the Research Doctorate in Electronic Engineering and Computer Science from the University of Naples in 1995 and 2000, respectively. He is currently an Associate Professor at the University of Cassino. His research interests include simulation and control of underwater robotic systems, force/motion control of robot manipulators, multirobot systems, and identification. He is author of the book *Underwater Robots*. He has been a Senior Member of the IEEE since June 2006.

Fumihito Arai

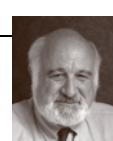

Tohoku University
Department of Bioengineering and
Robotics
Sendai, Japan
arai@imech.mech.tohoku.ac.jp

Chapter B.18

Fumihito Arai received the MS degree from Tokyo University of Science in 1988. He joined Nagoya University in 1989 as a Research Associate. He received the Dr. Eng. from Nagoya University in 1993 and was Associate Professor there from 1998 onwards. Since 2005, he has been Professor at the Department of Bioengineering and Robotics, Tohoku University. His research interests are mainly in micro- and nanorobotics.

Michael A. Arbib

University of Southern California
Computer, Neuroscience and USC Brain
Project
Los Angeles, CA, USA
arbib@usc.edu

Chapter G.62

Michael Arbib is University Professor, Fletcher Jones Professor of Computer Science, a Professor of Biological Sciences, Biomedical Engineering, Electrical Engineering, Neuroscience and Psychology, and Director of the USC Brain Project, all at the University of Southern California.

Antonio Bicchi

Università degli Studi di Pisa
Centro Interdipartimentale di Ricerca
"Enrico Piaggio" e Dipartimento di
Sistemi Elettrici e Automazione
Pisa, Italy
bicchi@ing.unipi.it

Chapter G.57

Antonio Bicchi (Laurea Mechanical Engineering, Pisa 1984, PhD 1989 Bologna) is Professor of Automatic Control and Robotics in the Department of Electrical Systems and Automation of the University of Pisa, Italy. His research interests are in robotics, control, and haptics. He currently serves as the Director of the Interdepartmental Research Center E. Piaggio of the University of Pisa, where he has lead the Automation and Robotics group since 1990. He is an IEEE Fellow and served as Vice President for Member Activities of the IEEE Robotics and Automation Society (2006–2007).

Aude Billard

Ecole Polytechnique Federale de Lausanne (EPFL)
Learning Algorithms and Systems Laboratory (LASA)
Lausanne, Switzerland
aude.billard@epfl.ch

**Chapter G.59**

Aude Billard is Associate Professor and Head of the Learning Algorithms and Systems Laboratory (LASA) at the School of Engineering at the Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, which she joined in 2002. She is an adjunct faculty member in the Department of Computer Science at the University of Southern California (USC). She received the BS (1994) and MS (1995) degrees in Physics from EPFL. She received her MS in knowledge based systems in 1996 and her PhD in artificial intelligence in 1998 from the University of Edinburgh. Prof. Billard's research interests include humanoid robotics, human–robot interactions, machine learning, and computational neuroscience.

John Billingsley

University of Southern Queensland
Faculty of Engineering and Surveying
Toowoomba, QLD, Australia
billings@usq.edu.au

**Chapter F.46**

Over 40 years, John Billingsley has led robotics and mechatronics research in the Universities of Cambridge, Portsmouth, and Southern Queensland, Australia. He holds a Chair of Mechatronic Engineering, is Technology Research Director in the National Centre for Engineering in Agriculture, and has written several textbooks. He was recently awarded an Achievement Medal by The Institution of Engineering and Technology (IET) UK.

Wayne Book

Georgia Institute of Technology
G.W. Woodruff School of Mechanical Engineering
Atlanta, GA, USA
wayne.book@me.gatech.edu

Chapter B.13

Wayne J. Book, HUSCO/Ramirez Distinguished Professor of Fluid Power and Motion Control, has taught at Georgia Institute of Technology since 1974. A Fellow of ASME and IEEE, he holds degrees from M.I.T. (MS, PhD) and The University of Texas (BS) in Mechanical Engineering. His research focuses on system dynamics of fluid power and flexible systems, robotics, and haptic human interfaces.

Cynthia Breazeal

Massachusetts Institute of Technology
The Media Lab
Cambridge, MA, USA
cynthiab@media.mit.edu

Chapter G.58

Cynthia Breazeal is an Associate Professor at the Massachusetts Institute of Technology where she founded and directs the Personal Robots Group in the Media Lab. She is a pioneer of social robotics and human–robot interaction. Her research focuses on developing the principles, techniques, and technologies for socially intelligent robots that interact and communicate with people in humancentric terms, work with humans as peers, and learn from people as an apprentice. She has developed numerous robotic creatures ranging from small hexapod robots, to creating highly expressive humanoid robots. Her recent work investigates the impact of social robots on helping people of all ages.

Oliver Brock

University of Massachusetts
Robotics and Biology Laboratory
Amherst, MA, USA
oli@cs.umass.edu

**Chapter D.26**

Oliver Brock is an Assistant Professor of Computer Science at the University of Massachusetts, Amherst. He received his Computer Science Diploma in 1993 from the Technical University of Berlin, Germany, and the Masters and PhD degrees in Computer Science from Stanford University in 1994 and 2000, respectively. At the University of Massachusetts Amherst, he is affiliated with the Robotics and Biology Laboratory and the Computational Biology Laboratory. His research focuses on autonomous mobile manipulation and structural computational biology.

Alberto Broggi

Università degli Studi di Parma
Dipartimento di Ingegneria
dell'Informazione
Parma, Italy
broggi@ce.unipr.it

**Chapter F.51**

Alberto Broggi received the Master degree in Electronic Engineering and the PhD degree in Information Technology both from the University of Parma, Italy. He is now Full Professor at the University of Parma. He is the director of VisLab (the Artificial Vision and Intelligent Systems Lab), whose main milestones are the ARGO Project (a 2000+ km test done on Italian highways in 1998 in which the ARGO vehicle drove itself in automatic mode) and the setup of the Terramax vehicle that reached the finish line of the DARPA Grand Challenge 2005.

**Heinrich H. Bülthoff**

Max-Planck-Institut für biologische
Kybernetik
Kognitive Humanpsychophysik
Tübingen, Germany
heinrich.buelthoff@tuebingen.mpg.de

Chapter G.63

Professor Heinrich H. Bülthoff is scientific member of the Max Planck Society and Director at the Max Planck Institute for Biological Cybernetics. In his department, an interdisciplinary group of 60 scientists work on psychophysical and computational aspects of higher-level visual processes in object and face recognition, sensory-motor integration, computer graphics psychophysics, and perception and behavior in virtual environments.

**Joel W. Burdick**

California Institute of Technology
Mechanical Engineering Department
Pasadena, CA, USA
jwb@robotics.caltech.edu

Chapter D.27

Joel Burdick received the PhD degree in Mechanical Engineering from Stanford University. He has been with the department of Mechanical Engineering at the California Institute of Technology since May 1988, where he has been the recipient of the NSF Presidential Young Investigator Award, the Office of Naval Research Young Investigator Award, and the Feynman Fellowship. Professor Burdick's current research interests are in sensor-based robot motion planning, multifingered robotic hand manipulation, and the application of robotics to neural prosthetics.

Wolfram Burgard

Albert-Ludwigs-Universität Freiburg
Institut für Informatik
Freiburg, Germany
burgard@informatik.uni-freiburg.de

**Chapter E.36**

Wolfram Burgard is a Professor for Computer Science at the University of Freiburg and head of the Research Laboratory for Autonomous Intelligent Systems. His research focuses on the development of probabilistic approaches to mobile robot navigation. Over the past years he and his group have developed a series of innovative probabilistic techniques for various mobile robot navigation problems including localization, map building, path planning, and exploration.

Zack Butler

Rochester Institute of Technology
Department of Computer Science
Rochester, NY, USA
zjb@cs.rit.edu

**Chapter E.39**

Zack Butler received his PhD in Robotics from Carnegie Mellon University in 2000 and is currently an Assistant Professor of Computer Science at the Rochester Institute of Technology. His research interests are in cooperative systems, self-reconfiguring robotics, and the use of robotics in education.

**Fabrizio Caccavale**

Università degli Studi della Basilicata
Dipartimento di Ingegneria e Fisica
dell'Ambiente
Potenza, Italy
fabrizio.caccavale@unibas.it

Chapter D.29

Fabrizio Caccavale received the Laurea degree and the Research Doctorate degree in Electronic Engineering from the University of Naples Federico II in 1993 and 1997, respectively. He is currently Associate Professor in the Department of Environmental Engineering and Physics of the University of Basilicata. He has published more than 80 journal and conference papers and is co-author of two books. He has been in the program committee of several international conferences and workshops.

**Sylvain Calinon**

Ecole Polytechnique Federale de Lausanne (EPFL)
Learning Algorithms and Systems Laboratory (LASA)
Lausanne, Switzerland
sylvain.calinon@epfl.ch

Chapter G.59

Sylvain Calinon is a Postdoctoral Fellow at the Learning Algorithms and Systems Laboratory (LASA), Ecole Polytechnique Federale de Lausanne (EPFL), Switzerland. He received his PhD in Robot Programming by Demonstration from LASA, EPFL in May 2007, and his BS/MS in Microengineering with specialization in robotics from the School of Engineering at EPFL in 2003. His research interests cover learning by imitation, human–robot interaction, artificial intelligence, and machine learning.

Guy Campion

Université Catholique de Louvain
Centre d'Ingénierie des Systèmes
d'Automatique et de Mécanique
Appliquée
Louvain-la-Neuve, Belgium
guy.campion@uclouvain.be

Chapter B.17

Guy Campion received the Masters and the PhD degree in Mechanical Engineering from Université Catholique de Louvain, Louvain-la-Neuve, Belgium. Since 1977 he is Research Associate (Fonds National de la Recherche Scientifique), and part-time Professor with the Centre for Systems Engineering and Applied Mechanics (CESAME) at the same University. His main research interests are in nonlinear control theory, adaptive control, modeling, and control of mechanical systems, especially in nonholonomic systems such as mobile robots.

Raja Chatila

Chapter A.9

For biographical profile, please see the section “About the Part Editors” on page XXII.

François Chaumette

INRIA/IRISA
Campus de Beaulieu
Rennes, France
francois.chaumette@irisa.fr

Chapter C.24

François Chaumette graduated from Ecole Nationale Supérieure de Mécanique, Nantes, France, in 1987. He received the PhD degree in Computer Science from the University of Rennes, France, in 1990. Since 1990, he has been with INRIA at IRISA in Rennes, where he is now Directeur de Recherches and Head of the Lagadic Group. His research interests include robotics and computer vision, especially visual servoing and active perception.

**Stefano Chiaverini**

Università degli Studi di Cassino
Dipartimento di Automazione, Ingegneria
dell'Informazione e Matematica
Industriale
Cassino, Italy
chiaverini@unicas.it

Chapter B.11

Stefano Chiaverini is a Professor of Automatic Control. His research interests include inverse kinematics techniques, redundant manipulator control, cooperative robots, force/position control, underwater robotics, and mobile robotic systems. He has published about 150 papers, is co-editor of the book *Complex Robotic Systems* and is co-author of the book *Fondamenti di Sistemi Dinamici*. He is a Senior Member of the IEEE.

**Nak Young Chong**

Japan Advanced Institute of Science and
Technology (JAIST)
School of Information Science
Ishikawa, Japan
nakyung@jaist.ac.jp

Chapter D.32

Nak-Young Chong is an Associate Professor at the Japan Advanced Institute of Science and Technology. He received the PhD degree from Hanyang University, Seoul, Korea, in 1994. He was on the research staff at Daewoo Heavy Industries, Korea, and AIST, Japan, from 1994 to 2003. He has been chair of Fujitsu Robotics Work Group and Robot Information Processing Work Group since 2004. His research interests cover human-friendly robots, teleoperation, intelligent mechanical systems, and knowledge networking robot control.

Howie Choset

Chapter F.50

Carnegie Mellon University
The Robotics Institute
Pittsburgh, PA, USA
choset@cs.cmu.edu

Howie Choset is an Associate Professor of Robotics at Carnegie Mellon University, where he conducts research in motion planning and design of serpentine mechanisms, and coverage path planning for demining. Choset directs the Undergraduate Robotics Minor at Carnegie Mellon and teaches an overview course on Robotics which uses series of custom-developed Lego Labs to complement the coursework.

Wankyun Chung

POSTECH
Department of Mechanical Engineering
Pohang, Korea
wkchung@postech.ac.kr

**Chapter A.6**

Wankyun Chung received his BS degree from Seoul National University in 1981, his MS degree in 1983, and his PhD from KAIST in 1987. He is a Professor in the School of Mechanical Engineering, POSTECH and Director of the National Research Laboratory for Intelligent Mobile Robot Navigation. He has written two books on the control of mechanical systems and published more than 60 journal papers on control and robotics. His research interests include SLAM, underwater robots, and biorobots.

**Woojin Chung**

Korea University
Department of Mechanical Engineering
Seoul, Korea
smartrobot@korea.ac.kr

Chapter B.17

Woojin Chung received the BS degree from the Seoul National University and the MS and PhD degrees from the University of Tokyo. He is currently an Assistant Professor at the Department of Mechanical Engineering, Korea University. He received the best paper awards from RSJ and IEEE Robotics and Automation Society. He works on design and control of nonholonomic systems and mobile robot navigation.

J. Edward Colgate

Northwestern University
Department of Mechanical Engineering
Segal Design Institute
Evanston, IL, USA
colgate@northwestern.edu

Chapter G.57

Ed Colgate is the Pentair–Nugent Professor in the Department of Mechanical Engineering at Northwestern University, Evanston. He has worked extensively in the areas of haptic interface and teleoperation, and he is the co-inventor of *cobots*, a class of collaborative robots. Dr. Colgate is the founder of two start-up companies and he is the founding Editor-in-Chief of the IEEE Transactions on Haptics.

Peter Corke

Commonwealth Scientific and Industrial Research Organisation (CSIRO)
ICT Centre
Kenmore, QLD, Australia
peter.corke@csiro.au

**Chapter F.49**

Peter Corke is a Chief Principal Research Scientist at CSIRO, where his research focus has been on vision-based robot control and field robotics. He is a member of the editorial board of the International Journal of Robotics Research, a founding editor of the Journal of Field Robotics, and a member of the editorial board of the Springer STAR book series.

Jock Cunningham

Commonwealth Scientific and Industrial Research Organisation (CSIRO)
Division of Exploration and Mining
Kenmore, QLD, Australia
jock.cunningham@csiro.au

**Chapter F.49**

Jock Cunningham has 20 years mining R&D experience with Mount Isa Mines: instrumentation, process control, automation for mineral processing/smelting, robotic nondestructive analysis of rocks, and process streams and teleremote control of mobile equipment. He spent 1 year with Science Applications International in the USA and has worked for CSIRO for 10 years in a range of research/management roles. His current interests include the development of a robotically implemented mining method called ROES.

**Mark R. Cutkosky**

Stanford University
Mechanical Engineering
Stanford, CA, USA
cutkosky@stanford.edu

Chapter C.19

Mark Cutkosky is a Professor in the Design Group of Mechanical Engineering at Stanford University. He received the PhD degree in 1985 from Carnegie Mellon University. His research includes haptics, tactile sensing, and bio-inspired robots. He has graduated 30 PhD students in these areas and is a former Fulbright Faculty Chair, Charles M. Pigott Chair, and NSF PYI awardee.

**Kostas Daniilidis**

University of Pennsylvania
Department of Computer and Information
Science
GRASP Laboratory
Philadelphia, PA, USA
kostas@cis.upenn.edu

Chapter C.23

Kostas Daniilidis is Associate Professor of Computer and Information Science at the University of Pennsylvania, where he is a member of the interdisciplinary GRASP laboratory. He obtained the BSE and MSE degrees in Electrical Engineering from the National Technical University of Athens (1986) and his Dr. rer.nat. in Computer Science from the University of Karlsruhe (1992). His research interests are in space and motion perception with machines with applications to navigation, panoramic vision, and immersive environments.

Paolo Dario

Scuola Superiore Sant'Anna
ARTS Lab e CRIM Lab
Pisa, Italy
paolo.dario@sssup.it

Chapter F.52

Paolo Dario received his Dr. Eng. degree in Mechanical Engineering from the University of Pisa, Italy, in 1977. He is currently Professor of Biomedical Robotics at the Scuola Superiore Sant'Anna in Pisa. His main research interest is in biorobotics and he is active in projects on the development of mechatronic and robotic systems for rehabilitation, prosthetics, surgery, and microendoscopy. He is the author of more than 200 journal papers, an IEEE Fellow, and a recipient of the Joseph Engelberger Award.

Alessandro De Luca

Università degli Studi di Roma "La Sapienza"
Dipartimento di Informatica e
Sistemistica "A. Ruberti"
Roma, Italy
deluca@dis.uniroma1.it

Chapter B.13

Alessandro De Luca has been Professor of Robotics at the Università di Roma "La Sapienza" since 2000. He has published about 140 journal/conference papers, mostly on flexible manipulators, kinematic redundancy, underactuated robots, and wheeled mobile robots. Since 2004, he has been Editor-in-Chief of the IEEE Transactions on Robotics. He was General Chair of the 2007 IEEE ICRA. In 2005, he received the Helmholtz Humboldt Research Award for foreign scientists. He is a member of the Search Committee for Technical Science of the Körber European Science Award and an IEEE Fellow.

**Joris De Schutter**

Katholieke Universiteit Leuven
Department of Mechanical Engineering
Leuven-Heverlee, Belgium
joris.deschutter@mech.kuleuven.be

Chapter A.7

Joris De Schutter obtained the PhD degree in Mechanical Engineering from K.U. Leuven in 1986. His research interests are in sensor-based robot control and programming including hybrid force/vision control and multisensor fusion, and control and optimization of mechanical and mechatronic systems. He is co-author of two volumes in the STAR book series.

**Rüdiger Dillmann**

Universität Karlsruhe
Institut für Technische Informatik
Karlsruhe, Germany
dillmann@ira.uka.de

Chapter G.59

Professor Rüdiger Dillmann received his PhD in Electrical Engineering from the University of Karlsruhe in 1980. Since 1987 he has been Professor at the Department of Computer Science and Technical Engineering (CSE) and since 2001 Director of the Industrial Applications of Informatics and Microsystems (IAIM) research group. His research interests are in interactive multimodal humanoid robots, bio-inspired robot systems, autonomous ground-based vehicles, computer-supported surgery, and augmented-reality-based simulation techniques.

**Lixin Dong**

ETH Zentrum
Institute of Robotics and Intelligent
Systems
Zürich, Switzerland
ldong@ethz.ch

Chapter B.18

Lixin Dong received the PhD degree in Microsystem Engineering from Nagoya University in 2003. He became Research Associate, Lecturer, and Associate Professor at Xi'an University of Technology in 1992, 1995, and 1998, respectively, and Assistant Professor at Nagoya University in 2003. He is Senior Research Scientist at ETH Zurich, where his main research interests include nanorobotic manipulation and related technologies including carbon nanotubes, nanofabrication, nano-mechanochemistry, nanoassembly, NEMS, and nanorobotics.

Gregory Dudek

McGill University
Department of Computer Science
Montreal, QC, Canada
dudek@cim.mcgill.ca

**Chapter C.20**

Gregory Dudek is a Professor in the McGill University School of Computer Science and a member of the McGill Research Centre for Intelligent Machines (CIM). He was named a William Dawson Scholar. He directs the McGill Mobile Robotics Laboratory, where his research interests include perception for mobile robotics, vision-based robotics, computational vision, and collaborative filtering.

Mark Dunn

University of Southern Queensland
National Centre for Engineering in
Agriculture
Toowoomba, QLD, Australia
mark.dunn@usq.edu.au

Chapter F.46

Mark Dunn has just completed his Engineering PhD entitled ‘Applications of vision sensing in agriculture’ and is investigating many diverse case studies from counting macadamia nuts with machine vision to using cameras to differentiate between sheep, goats, and feral pigs.

Hugh Durrant-Whyte

University of Sydney
ARC Centre of Excellence for Autonomous
Systems
Australian Centre for Field Robotics (ACFR)
Sydney, NSW, Australia
hugh@acfr.usyd.edu.au

Chapter C.25

Hugh Durrant-Whyte received the MSE and PhD degrees, both in Systems Engineering, from the University of Pennsylvania, USA, in 1985 and 1986, respectively. Since 1995 he has been a Professor at the University of Sydney, where he leads the Australian Centre for Field Robotics (ACFR). His research work focuses on autonomous vehicle navigation and decentralized data fusion methods with applications including automation in cargo handling, mining, defence, and marine systems.

Jan-Olof Eklundh

KTH Royal Institute of Technology
Stockholm, Sweden
joe@nada.kth.se

**Chapter C.23**

Jan-Olof Eklundh is Professor in Computer Science at KTH, Stockholm, where in 1996 he initiated the Center for Autonomous Systems. His research interests cover a broad range of topics in computational vision and robotics. He chaired ICCV 1990 and ECCV 1994. He is a member of the Royal Swedish Academy of Science, the Royal Danish Academy of Sciences and Letters, and the Royal Swedish Academy of Engineering Science.

Aydan M. Erkmen

Middle East Technical University
Department of Electrical Engineering
Ankara, Turkey
aydan@metu.edu.tr

Chapter F.50

Aydan M. Erkmen received the BS degree from Bogazici University, Istanbul, Turkey in Electrical Engineering (1978), her MS degree in Electrical and Computer Engineering from Drexel University, Philadelphia (1981) and her PhD in Information Technology and Engineering from George Mason University, Fairfax in 1989. She is full professor in the Electrical Engineering Department of the Middle East Technical University, Ankara, Turkey. Her research interests include mechatronic design, search, rescue and surveillance robotics, mobile sensor networks, biomimetic manipulation, biologically inspired control in unstructured environments, and uncertainty modeling.

**Bernard Espiau**

INRIA Rhône-Alpes
Saint-Ismier, France
bernard.espiau@inria.fr

Chapter B.16

Bernard Espiau received a PhD degree in Automatic Control (Nantes, France, 1975). He conducted research projects in robotics, in the areas of sensor-based control, visual servoing, control architectures, and bipedal locomotion. He launched the BIP (biped) robot project completed in 2000. From 2001 to 2007 he was director of INRIA Rhône-Alpes. He is presently Deputy Scientific Director of INRIA.

**Roy Featherstone**

The Australian National University
Department of Information Engineering
Canberra, ACT, Australia
roy.featherstone@anu.edu.au

Chapter A.2

Dr. Featherstone received the PhD degree from Edinburgh University in 1984. He is the inventor of the articulated-body algorithm, and the author of two books on rigid-body dynamics. He has 7 years experience in industry and was awarded an EPSRC Advanced Research Fellowship in 1992, which was held at Oxford University. He currently works on robot dynamics, control, simulation, and actuator technology.

Eric Feron

Georgia Institute of Technology
School of Aerospace Engineering
Atlanta, GA, USA
feron@gatech.edu

**Chapter F.44**

Eric Feron has been the Dutton/Ducoffe Professor of Aerospace Software Engineering at the Georgia Institute of Technology since 2005. From 1993 to 2005, he was with the Department of Aeronautics and Astronautics at the Massachusetts Institute of Technology. Eric Feron's work concentrates on control systems and optimization and their applications to aircraft dynamics, aerial robots and their certification, and transportation systems.

Gabor Fichtinger

Queen's University
School of Computing
Kingston, ON, Canada
gabor@cs.queensu.ca

**Chapter F.52**

Gabor Fichtinger received the BS and MS degrees in Electrical Engineering, and doctorate in Computer Science from the Technical University of Budapest, Hungary, in 1986, 1988, and 1990, respectively. Dr. Fichtinger's primary research area is computer-assisted surgery, with a strong accent on image-guided needle-based interventions. Further research interest is in systems for robot-assisted minimally invasive surgical procedures executed under image guidance. Primarily application areas are in cancer therapy musculoskeletal procedures.

**Paolo Fiorini**

Università degli Studi di Verona
Dipartimento di Informatica
Verona, Italy
paoletto.fiorini@univr.it

Chapter F.50

Paolo Fiorini received the Laurea degree from the University of Padova (Italy), the MS degree from the University of California at Irvine, both in Electrical Engineering, and the PhD in Mechanical Engineering from the University of California at Los Angeles. From 1985 to 2000, he was with NASA-JPL, Caltech, and since 2000 he has been an Associate Professor of Control Systems at the University of Verona.

**Robert B. Fisher**

University of Edinburgh
School of Informatics
Edinburgh, UK
rbr@inf.ed.ac.uk

Chapter C.22

Robert Fisher received the PhD degree from the University of Edinburgh in 1987 and has been, since then, an academic in Edinburgh University's School of Informatics. His research covers topics in 3-D computer vision and video analysis. He has led the development of several well-used computer vision web resources, including CVonline. He has published six books and about 200 scientific articles.

Paul Fitzpatrick

Italian Institute of Technology
Robotics, Brain, and Cognitive Sciences
Department
Genova, Italy
paul.fitzpatrick@iit.it

**Chapter G.56**

Paul Fitzpatrick received the PhD degree in Computer Science from MIT, on developmental approaches to machine perception. He worked at MIT as a postdoctoral lecturer, then held a postdoctoral position at LIRA-Lab at the University of Genoa, Italy. He is now working at the Italian Institute of Technology. His primary interest is the development of machine perception for object manipulation.

Dario Floreano

Ecole Polytechnique Federale de Lausanne (EPFL)
Laboratory of Intelligent Systems
Lausanne, Switzerland
dario.floreano@epfl.ch

**Chapter G.61**

Dario Floreano is Associate Professor in the School of Engineering at the Swiss Federal Institute of Technology in Lausanne (EPFL), Switzerland. His research activities span evolutionary robotics, swarm robotics, and biomimetic robotics, and evolvable hardware. He has contributed to the development of several biomimetic robots, such as swarms of wheeled and flying robots. He is cofounder of the International Society for Artificial Life, Inc., and a Member of the Board of Governors of the International Society for Neural Networks. He has been an IEEE Senior Member since 2005.

**Thor I. Fossen**

Norwegian University of Science and Technology (NTNU)
Department of Engineering Cybernetics
Trondheim, Norway
fossen@ieee.org

Chapter F.43

Professor Thor I. Fossen received the MS degree in Naval Architecture and PhD degree in Control Systems from the Norwegian University of Science and Technology. Professor Fossen has been instrumental in the development of several industrial autopilot and dynamic positioning systems. He founded the company Marine Cybernetics, which offers service for hardware-in-the-loop (HIL) testing of marine control systems. His work on weather optimal positioning control for marine vessels received the Automatica Prize Paper Award in 2002. Fossen is currently Head of Automatic Control at the Centre for Ships and Ocean Structures (CESOS), Norwegian Centre of Excellence.

**Li-Chen Fu**

National Taiwan University
Department of Electrical Engineering
Taipei, Taiwan, R.O.C.
lichen@ntu.edu.tw

Chapter A.6

Li-Chen Fu received the PhD degree (1987) from University of California at Berkeley, and then joined the Department of Electrical Engineering of the National Taiwan University. His research interests include robotics, control, scheduling, and home automation. His numerous awards include the Distinguished Research Awards (1995, 1998, 2000) and Distinguished Research Fellowship (2001–2007) from the National Science Council, R.O.C., and the Industry-Academia Collaboration Award (2004) from the Ministry of Education, R.O.C. He has been an IEEE Fellow since 2004.

Maxime Gautier

Université de Nantes
IRCCyN, ECN
Nantes, France
maxime.gautier@ircyn.ec-nantes.fr

**Chapter B.14**

Maxime Gautier received the Doctorat d'Etat degree in Robotics and Control Engineering from the University of Nantes, France, in 1990. Since 1991, he has been a Professor of Automatic Control at the University of Nantes. He is a member of the Robotics Team, Institut de Recherche en Communication et Cybernétique de Nantes (IRCCyN, UMR-CNRS n6597). His research topics include modeling, identification, and control of robots.

Martin A. Giese

University of Wales
Department of Psychology
Bangor, UK
martin.giese@uni-tuebingen.de

**Chapter G.63**

Martin A. Giese (PhD in Electrical Engineering), after a postdoc at CBCL (MIT), headed the HONDA Cambridge Research Laboratory. He founded the Laboratory for Action Representation and Learning at the Hertie Institute for Clinical Brain Research, Tübingen, Germany in 2001, and is now Senior Lecturer at the Department of Psychology, University of Bangor, UK. His research addresses learning in action recognition and control.

**Ken Goldberg**

University of California at Berkeley
Department of Industrial Engineering and
Operations Research
Berkeley, CA, USA
goldberg@ieor.berkeley.edu

Chapter D.32

Ken Goldberg is Professor of Industrial Engineering and Operations Research at UC Berkeley, with joint appointments in Electrical Engineering and Computer Science, and the School of Information. Goldberg was named IEEE Fellow in 2005 and serves (2006–2009) as Vice President of Technical Activities for the IEEE RAS. He is Founding Chair of the IEEE Transactions on Automation Science and Engineering (T-ASE) Advisory Board.

**Clément Gosselin**

Université Laval
Département de Génier Mécanique
Québec, QC, Canada
gosselin@gmc.ulaval.ca

Chapter B.12

Clément Gosselin received the PhD degree and the D.W. Ambridge Award from McGill University, Montreal, Quebec, Canada in 1988. Since 1997 he has been a Full Professor in the Department of Mechanical Engineering at University Laval, Quebec and a Canada Research Chair in Robotics and Mechatronics since January 2001. His research interests are kinematics, dynamics, and control of robotic mechanical systems with a particular emphasis on parallel mechanisms and robot hands. Dr. Gosselin is a Fellow of the ASME.

Agnès Guillot

Université Pierre et Marie Curie – CNRS
Institut des Systèmes Intelligents et de
Robotique
Paris, France
agnes.guillot@lip6.fr

Chapter G.60

Agnès Guillot is Assistant Professor of Psychophysiology at Paris X University. She graduated in Human and Animal Psychology, and holds PhDs in Psychophysiology and Biomathematics. Her main scientific interests are in action selection in animals and robots. She coordinates the biomimetic modeling of the Psikharpax project that aims to synthesize an artificial rat.

Martin Häggele

Fraunhofer IPA
Robot Systems
Stuttgart, Germany
mmh@ipa.fhg.de

Chapter F.42

Martin Häggele studied Mechanical Engineering and Engineering Science at the University of Stuttgart and the George Washington University. Since 1989 he is with Fraunhofer IPA and was promoted to Head of the Department Robot Systems in 1993. He received the Award of the German Association of Machine Tools Manufacturers (VDW) in 1990, the Fraunhofer IPA Innovation Award in 1995, the European Innovation and Emerging Technology Award in 1998, and the Engelberger Robotics Award in 2007.

Gregory D. Hager

Johns Hopkins University
Department of Computer Science
Baltimore, MD, USA
hager@cs.jhu.edu

Chapter A.4

Gregory D. Hager is a Professor of Computer Science at Johns Hopkins University. Prof. Hager received the MS and PhD degrees in computer science from the University of Pennsylvania in 1985 and 1988, respectively. His current research interests include visual tracking, vision-based control, medical robotics, and human-computer interaction. He is a Fellow of the IEEE for his contributions in vision-based robotics.

David Hainsworth

Commonwealth Scientific and Industrial
Research Organisation (CSIRO)
Division of Exploration and Mining
Kenmore, QLD, Australia
david.hainsworth@csiro.au

Chapter F.49

David Hainsworth holds the degrees of BE and PhD in Electrical Engineering from the University of Queensland, Australia. For the last 15 years he has been with the CSIRO Division of Exploration and Mining, where he is currently leader of the Mining Automation Research Group. His main research interests are automation for longwall coal mining and sensor development for underground navigation.

William R. Hamel

University of Tennessee
Mechanical, Aerospace, and Biomedical
Engineering
Knoxville, TN, USA
wahamel@utk.edu

**Chapter F.48**

William R. Hamel is a Professor and the Head of the Mechanical, Aerospace, and Biomedical Engineering Department at the University of Tennessee. He worked for 31 years at the Oak Ridge National Laboratory in robotics and remote systems for nuclear, military, and space applications. He is an IEEE Fellow with ongoing research in telerobotics for hazardous environments.

Blake Hannaford

University of Washington
Department of Electrical Engineering
Seattle, WA, USA
blake@ee.washington.edu

**Chapter D.30**

Blake Hannaford, PhD, is Professor of Electrical Engineering, Adjunct Professor of Bioengineering, Mechanical Engineering, and Surgery at the University of Washington, Seattle. He was awarded the National Science Foundation's Presidential Young Investigator Award, the Early Career Achievement Award from the IEEE Engineering in Medicine and Biology Society, and was named IEEE Fellow in 2005. His currently active interests include haptic displays on the Internet and surgical robotics.

**Kensuke Harada**

National Institute of Advanced Industrial
Science and Technology (AIST)
Intelligent Systems Research Institute
Tsukuba, Japan
kensuke.harada@aist.go.jp

Chapter G.56

Dr. Harada's main area of research includes mechanics and control of robotic systems such as humanoid robots and robot fingers. He received the PhD degree in 1997 from Kyoto University. From 1997 to 2002, he worked at Hiroshima University. Since 2002, he has been a researcher at AIST. From 2005 to 2006, he was also a visiting scholar at Stanford University.

**Martial Hebert**

Carnegie Mellon University
The Robotics Institute
Pittsburgh, PA, USA
hebert@ri.cmu.edu

Chapter E.36

Professor Martial Hebert's interests include computer vision, 3-D model building and recognition, and perception for mobile robots. His group has developed approaches for object recognition in images and video sequences, techniques for recognizing 3-D shapes in 3-D point clouds and for building models of 3-D objects, and for modeling the environment of autonomous robots from sensor data, and their integration into systems.

Thomas C. Henderson

University of Utah
School of Computing
Salt Lake City, UT, USA
tch@cs.utah.edu

**Chapter C.25**

Professor Thomas Henderson received the BS degree in Mathematics from Louisiana State University in 1973 and the PhD degree in Computer Science from The University of Texas at Austin in 1979. Since 1989 he has been Professor of Computer Science at the University of Utah. His current research interests concentrate on smart sensor networks, the simulation of accidental fires and explosions, on the DARPA Urban Challenge, and on technical drawing analysis.

Joachim Hertzberg

Universität Osnabrück
Institut für Informatik
Osnabrück, Germany
hertzberg@informatik.uni-osnabrueck.de

**Chapter A.9**

Joachim Hertzberg holds diploma and doctorate degrees in Informatics. He is a Full Professor for Informatics/Knowledge-Based Systems at Osnabrück University; previously, he has worked at Bonn University and Fraunhofer AIS. His areas of research are AI, action planning, robot navigation, mapping, and using semantic information in robot control.

**Hirohisa Hirukawa**

National Institute of Advanced Industrial Science and Technology (AIST)
Intelligent Systems Research Institute
Tsukuba, Japan
hiro.hirukawa@aist.go.jp

Chapter G.56

Dr. Hirukawa is a Deputy Director of Intelligent Systems Institute of AIST and a Professor at Tsukuba University. He developed a humanoid robot HRP-2 and software platform for humanoid robotics OpenHRP. His research interests include humanoid robotics and motion planning. He is a co-author of a textbook "Humanoid Robot".

**Gerd Hirzinger**

Deutsches Zentrum für Luft- und Raumfahrt (DLR) Oberpfaffenhofen
Institut für Robotik und Mechatronik
Wessling, Germany
gerd.hirzinger@dlr.de

Chapter D.31

Gerd Hirzinger received his doctor's degree from the Technical University of Munich in 1974. Since 1992 he has been Director at the DLR Institute for Robotics and Mechatronics. His institute develops innovative robot systems for space and terrestrial applications, telerobotic concepts, man-machine interfaces, sensors and actuators, sensory feedback, ultra-lightweight robot arms, articulated hands, planetary rovers, and medical technology. He was prime investigator of ROTEX, the first remotely controlled robot in space, which flew onboard shuttle COLUMBIA in April 93. He has received numerous national and international awards.

John Hollerbach

University of Utah
School of Computing
Salt Lake City, UT, USA
jmh@cs.utah.edu

**Chapter B.14**

John M. Hollerbach is Professor of Computing, Research Professor of Mechanical Engineering, and Director of the Robotics Track at the University of Utah. Previously he held faculty positions at MIT and McGill University. He received his PhD from Massachusetts Institute of Technology in 1978. He is Editor of the International Journal of Robotics Research. His research interests include haptic interfaces and virtual reality.

Robert D. Howe

Harvard University
Division of Engineering and Applied Sciences
Cambridge, MA, USA
howe@seas.harvard.edu

**Chapter C.19**

Robert D. Howe is Gordon McKay Professor of Engineering in the Harvard School of Engineering and Applied Sciences. Dr. Howe's research interests focus on manipulation, the sense of touch, and haptic interfaces. Biomedical applications include robotic and image-guided surgery. Dr. Howe earned the BA degree in Physics from Reed College and the PhD degree in Mechanical Engineering from Stanford University.

**Phil Husbands**

University of Sussex
Department of Informatics
Falmer, Brighton, UK
philh@sussex.ac.uk

Chapter G.61

Phil Husbands is Professor of Computer Science and Artificial Intelligence in the Department of Informatics and Co-director of the Centre for Computational Neuroscience and Robotics at the University of Sussex. His research interests include biologically inspired adaptive robotics, evolutionary systems, computational neuroscience, and creative systems.

**Seth Hutchinson**

University of Illinois
Department of Electrical and Computer Engineering
Urbana, IL, USA
seth@uiuc.edu

Chapter C.24

After receiving the PhD degree from Purdue University, Seth Hutchinson joined the University of Illinois in Urbana-Champaign, where he is currently a Professor in the Department of Electrical and Computer Engineering. He has published more than 150 papers in the area of sensor-based robotics, and is co-author of the books *Principles of Robot Motion: Theory, Algorithms, and Implementations* and *Robot Modeling and Control*.

Adam Jacoff

National Institute of Standards and Technology
Intelligent Systems Division
Gaithersburg, MD, USA
adam.jacoff@nist.gov

**Chapter F.50**

Adam Jacoff has directed technology readiness level assessments of autonomous mobility for the US Army, developed standard performance test methods for emergency response robots through ASTM International, and chaired international RoboCupRescue robot competitions since 2001. He received the BS degree in Mechanical Engineering from the University of Maryland and the MS degree in Computer Science from Johns Hopkins University.

Michael Jenkin

York University
Computer Science and Engineering
Toronto, Ontario, Canada
jenkin@cse.yorku.ca

**Chapter C.20**

Michael Jenkin is a Professor of Computer Science and Engineering at York University, Canada. Working in the areas of virtual reality and visually guided autonomous robots, he is the co-author with G. Dudek of *Computational Principles of Mobile*. He has worked on a number of large robotics projects including the ARK and AQUA Robotic Systems and is also one of the designers of IVY – a six-sided immersive projective environment.

**Eric N. Johnson**

Georgia Institute of Technology
Daniel Guggenheim School of Aerospace Engineering
Atlanta, GA, USA
eric.johnson@ae.gatech.edu

Chapter F.44

Eric Johnson is the Lockheed Martin Associate Professor of Avionics Integration in the School of Aerospace Engineering at Georgia Tech. His research includes fault-tolerant estimation and flight control as well as digital avionics systems. He was awarded the PhD degree from Georgia Tech, the MS degrees from MIT and The George Washington University, and the BS degree from the University of Washington.

**Shuuji Kajita**

National Institute of Advanced Industrial Science and Technology (AIST)
Intelligent Systems Research Institute
Tsukuba, Japan
s.kajita@aist.go.jp

Chapter B.16

Shuuji Kajita received the Dr. degree in Control Engineering from the Tokyo Institute of Technology, Tokyo, Japan, in 1996. In 1985, he joined the Mechanical Engineering Laboratory, National Institute of Advanced Industrial Science and Technology (AIST). During 1996–1997, he was a Visiting Researcher at the California Institute of Technology. Since 2007, he has been the Leader of the Humanoid Robotics Group of Intelligent Systems Research Institute, AIST, Japan.

Makoto Kaneko**Chapter B.15**

For biographical profile, please see the section “About the Part Editors” on page XXII.

Sung-Chul Kang

Korea Institute of Science and Technology
Cognitive Robotics Research Center
Seoul, Korea
kasch@kist.re.kr

**Chapter F.48**

Sung-Chul Kang is a Principal Research Scientist in the Intelligent Robotics Research Center of the Korea Institute of Science and Technology (KIST). His research interests are in intelligent dependable manipulation, field service robot for rescue, military and hazardous application, haptics, tactile interfaces, and small indoor airship design, control, and application. He has a PhD in Mechanical Design and Production Engineering from the Seoul National University, Seoul, Korea.

Imin Kao

State University of New York at Stony Brook
Department of Mechanical Engineering
Stony Brook, NY, USA
imin.kao@stonybrook.edu

**Chapter D.27**

Being the Director of the Manufacturing Automation Laboratory (MAL) at SUNY Stony Brook, Professor Kao conducts research in robotics and manufacturing, specialized in the modeling of contact interface. He integrates his study with MEMS transducers to study intelligent contact interface that augments the capability of robots and humans. The soft-contact theory he proposed, which correlates the growth of contact radius with normal force, subsumes the well-known Hertzian model.

**Lydia E. Kavraki**

Rice University
Department of Computer Science, MS 132
Houston, TX, USA
kavraki@rice.edu

Chapter A.5

Lydia E. Kavraki is the Noah Harding Professor of Computer Science and Professor of Bioengineering at Rice University. She earned the PhD degree in Computer Science from Stanford University. Kavraki's research is in physical algorithms and their applications in robotics and structural bioinformatics. Her recent work has focused on motion planning with realistic physical constraints, robot coordination, and hybrid systems. Her awards include the Grace Murray Hopper Award from the Association for Computing Machinery.

Homayoon Kazerooni

University of California at Berkeley
Berkeley Robotics and Human
Engineering Laboratory
Berkeley, CA, USA
kazerooni@berkeley.edu

Chapter D.33

Dr. Kazerooni holds a Doctorate from MIT and is currently a Professor in the Mechanical Engineering Department at the University of California, Berkeley. He is the Director of the Berkeley Robotics and Human Engineering Laboratory. His research activities have spanned many aspects of human-machine systems, control sciences, robotics, orthotics, prosthetics, mechatronics, and electromechanical design. His latest work on lower extremity exoskeletons resulted in the creation of the very first energetically autonomous orthotic lower extremity exoskeleton.

Charles C. Kemp

Georgia Institute of Technology and
Emory University
The Wallace H. Coulter Department of
Biomedical Engineering
Atlanta, GA, USA
charlie.kemp@bme.gatech.edu

Chapter G.56

Charles C. Kemp is an Assistant Professor in the Department of Biomedical Engineering at Georgia Tech and Emory University. He is Director of the Center for Healthcare Robotics in the Health Systems Institute. He received a Doctorate in Electrical Engineering and Computer Science from MIT in 2005. His current research focuses on autonomous robot manipulation and human-robot interaction for healthcare.

Wisama Khalil

Université de Nantes
IRCCyN, ECN
Nantes, France
wisama.khalil@ircyn.ec-nantes.fr

Chapter B.14

Wisama Khalil received the PhD and the Doctorat d'Etat degrees in Robotics and Control Engineering from Montpellier, France, in 1976 and 1978, respectively. Since 1983 he has been Professor of Robotics in the Ecole Centrale de Nantes. He carries out his research within the Robotics team of the IRCCyN (Institut de recherche en Communication et Cybernétique de Nantes-UMR-CNRS n6597). His research interest includes, kinematics, dynamics, calibration, identification, and control of robots.

Lindsay Kleeman

Monash University
Department of Electrical and Computer
Systems Engineering
Monash, VIC, Australia
kleeman@eng.monash.edu.au

Chapter C.21

Lindsay Kleeman received the bachelor degrees in Electrical Engineering and Mathematics both with university medals, and, in 1986, the PhD degree from the University of Newcastle. He is currently an Associate Professor at Monash University, Australia with over 100 publications including a best paper award at IROS99. His research interests include mobile robotics, ultrasonic sensing, and digital systems.

Tetsunori Kobayashi

Waseda University
Department of Computer Science
Tokyo, Japan
koba@waseda.jp

Chapter G.58

Tetsunori Kobayashi received the BE, ME, and PhD degrees from Waseda University in 1980, 1982, and 1985, respectively. He worked at Hosei University as a Lecturer and Associate Professor from 1985. In 1991, he joined Waseda University and has been a Professor there since 1997. His research interests include human-computer interaction using linguistic and paralinguistic information, as well as fundamentals of pattern recognition.

Kurt Konolige

SRI International
Artificial Intelligence Center
Menlo Park, CA, USA
konolige@ai.sri.com

**Chapter C.22**

Kurt Konolige is a Principal Computer Scientist at the Artificial Intelligence Center of SRI International, a Consulting Professor of Computer Science at Stanford University, and a Fellow of the AAAI. He received the PhD degree in Computer Science from Stanford University in 1984. His recent research has concentrated on real-time perception and navigation for mobile robots. He teaches a course in mobile robotics at Stanford University, and codeveloped the Pioneer and AmigoBot robot lines.

David Kortenkamp

TRACLabs Inc.
Houston, TX, USA
korten@traclabs.com

**Chapter A.8**

David Kortenkamp is a Senior Scientist with TRACLabs, Inc. supporting NASA Johnson Space Center's Automation, Robotics, and Simulation Division. He received the BS degree in Computer Science from the University of Minnesota and the MS and PhD degrees in Computer Science from the University of Michigan. His research at NASA focuses on intelligent control architectures, human–robot interaction, and autonomous execution systems.

Kazuhiro Kosuge

Tohoku University
Department of Bioengineering and
Robotics
Graduate School of Engineering
Sendai, Japan
kosuge@irs.mech.tohoku.ac.jp

Chapter F.54

Professor Kazuhiro Kosuge received the BE, ME, and PhD degrees in Control Engineering from the Tokyo Institute of Technology, in 1978, 1980, and 1988, respectively. From 1980 to 1982, he was with Denso Co. Ltd. After serving as a Research Associate at Tokyo Institute of Technology and as an Associate Professor at Nagoya University, he has been a Professor at Tohoku University since 1995, and is currently with the Department of Bioengineering and Robotics.

Roman Kuc

Yale University
Department of Electrical Engineering
New Haven, CT, USA
kuc@yale.edu

Chapter C.21

Dr. Kuc is Director of Educational Affairs in Engineering and Director of the Intelligent Sensors Laboratory at Yale University. He received the BSEE degree from the Illinois Institute of Technology, Chicago, in 1968, and the PhD degree in Electrical Engineering from Columbia University, New York, in 1977. His interests cover digital signal processing with applications to bioengineering, robotics and telecommunications, inverse problems, intelligent sensors, modeling biological systems, as well as embedded systems.

James Kuffner

Carnegie Mellon University
The Robotics Institute
Pittsburgh, PA, USA
kuffner@cs.cmu.edu

**Chapter D.26**

James Kuffner received the PhD degree in Computer Science from Stanford University in 1999. He was a Japan Society for the Promotion of Science Postdoctoral Research Fellow at the University of Tokyo until 2001. He joined the faculty at Carnegie Mellon University in 2002 and is currently an Assistant Professor. He has published over 100 technical papers and received the Okawa Foundation Award for Young Researchers in 2007.

Vijay Kumar

University of Pennsylvania
Department of Mechanical Engineering
and Applied Mechanics
Philadelphia, PA, USA
kumar@grasp.upenn.edu

**Chapter E.41**

Vijay Kumar is the UPS Foundation Professor and the Chairman of the Department of Mechanical Engineering and Applied Mechanics at the University of Pennsylvania. He received his PhD from the Ohio State University. He won the NSF Presidential Young Investigator Award in 1991, the Lindback Award for Distinguished Teaching in 1996, and the IEEE ICRA Kawamori Best Paper Award in 2004. He is a Fellow of the ASME and the IEEE.

**Florent Lamiraux**

LAAS-CNRS
Toulouse, France
florent@laas.fr

Chapter E.35

Florent Lamiraux graduated from the Ecole Polytechnique Paris in 1993. He received the PhD degree in Computer Science from the Institut National Polytechnique de Toulouse in 1997 for his research on Mobile Robots. He spent two years at Rice University as a Research Associate and is currently Chargé de Recherche at LAAS-CNRS, where he has worked for years on nonholonomic mobile robots. His interest is now on humanoid robots.

**Jean-Paul Laumond**

LAAS-CNRS
Toulouse, France
jpl@laas.fr

Chapter E.35

Jean-Paul Laumond, PhD 1984, IEEE Fellow and 2006–2007 Distinguished Lecturer, is Directeur de Recherche at LAAS-CNRS in Toulouse, France. His research is on robot motion planning and control. In 2001 he created Kineo CAM, a spin-off company devoted to market motion planning technology (2005 IEEE-IFR prize). He is currently co-director of the French–Japanese laboratory JRL. He has published more than 100 papers in computer science, automatic control, robotics, and neuroscience.

Steven M. LaValle

University of Illinois
Department of Computer Science
Urbana, IL, USA
lavalle@cs.uiuc.edu

Chapter A.5

Steve LaValle is an Associate Professor of Computer Science at the University of Illinois. His interests include motion planning, geometric algorithms, control theory, and sensing. He recently authored the book (free online) *Planning Algorithms*.

John J. Leonard

Massachusetts Institute of Technology
Department of Mechanical Engineering
Cambridge, MA, USA
jleonard@mit.edu

Chapter E.37

John J. Leonard is Professor of Mechanical and Ocean Engineering in the MIT Department of Mechanical Engineering. He is also a member of the MIT Computer Science and Artificial Intelligence Laboratory. He holds the degrees of BSE in Electrical Engineering and Science from the University of Pennsylvania (1987) and PhD in Engineering Science from the University of Oxford (1994). His research addresses the problems of navigation, mapping, and persistent autonomy for autonomous mobile robots.

**Kevin Lynch**

Northwestern University
Mechanical Engineering Department
Evanston, IL, USA
kmlynch@northwestern.edu

Chapter D.27

Kevin Lynch received the PhD degree in Robotics from Carnegie Mellon University in 1996. Since 1997 he has been faculty in the Mechanical Engineering Department of Northwestern University, where he is a McCormick Professor of Teaching Excellence. His research interests include robotic manipulation, motion planning, underactuated dynamic systems, human–robot interaction, and self-organizing systems. He received the 2001 IEEE Early Academic Career Award in Robotics and Automation.

**Alan M. Lytle**

National Institute of Standards and
Technology
Construction Metrology and Automation
Group
Gaithersburg, MD, USA
alan.lytle@nist.gov

Chapter F.47

Alan Lytle leads the Construction Metrology and Automation Group, National Institute of Standards and Technology (NIST). He received the BS degree in Electrical Engineering and the MS degree in Environmental Engineering from Virginia Tech in 1986 and 1994, respectively. Current work includes research towards automated construction, on-site component tracking, and construction object recognition using 3-D imaging systems. Awards include the 1993 SAME Bliss Medal for teaching excellence, Department of Commerce Bronze Medal, and the SPAR Achievement Award.

Maja J. Matarić

University of Southern California
Computer Science Department
Los Angeles, CA, USA
mataric@usc.edu

**Chapter E.38**

Maja Matarić is Professor of Computer Science and Neuroscience at the University of Southern California and Founding Director of the USC Center for Robotics and Embedded Systems. She received the PhD and MS degrees from MIT in Computer Science and AI in 1994 and 1990. She is a recipient of numerous awards and is featured in the movie “Me & Isaac Newton”. Her research into socially assistive robotics is aimed at endowing robots with the ability to help people through individual assistance and team cooperation.

Yoshio Matsumoto

Osaka University
Department of Adaptive Machine
Systems Graduate School of Engineering
Suita, Osaka, Japan
matsumoto@ams.eng.osaka-u.ac.jp

**Chapter G.56**

Dr. Yoshio Matsumoto received the PhD degree from the University of Tokyo in 1998. He then joined the Australian National University, where he developed a real-time vision system for gaze measurement. He moved to Nara Institute of Science and Technology in 1999, and is a Professor at Osaka University since 2007. His research interests include real-time vision, human–robot interaction, and mobile robotics.

J. Michael McCarthy

University of California at Irvine
Department of Mechanical and Aerospace
Engineering
Irvine, CA, USA
jmmccart@uci.edu

Chapter A.3

J. Michael McCarthy received the PhD degree from Stanford University in 1979, and joined the faculty at the University of California, Irvine in 1986. He is the author of two books *Introduction to Theoretical Kinematics* and *Geometric Design of Linkages*, and has served as Editor of the ASME Journal of Mechanical Design and is the Founding Editor of the ASME Journal of Mechanisms and Robotics.

Claudio Melchiorri

Università degli Studi di Bologna
Dipartimento di Elettronica Informatica e
Sistemistica
Bologna, Italy
claudio.melchiorri@unibo.it

Chapter B.15

Claudio Melchiorri is Professor of Robotics at the University of Bologna, Italy. He has served in the organization of several international conferences, and was Chair of the NOC of SYROCO 2006. He has published about 200 scientific papers, three books on digital control, and is co-editor of three books on robotics. His research interests include dexterous manipulation, haptics, telemanipulation, nonlinear control. He is a Senior Member of the IEEE.

Arianna Menciassi

Scuola Superiore Sant'Anna
CRIM Lab
Pisa, Italy
arianna@sssup.it

**Chapter F.52**

Arianna Menciassi received the Laurea degree in physics from the Pisa University and the PhD degree in Bioengineering from the Scuola Superiore Sant'Anna (SSSA), Pisa, Italy, in 1995 and 1999, respectively. She is an Associate Professor of Biomedical Robotics at SSSA. She also teaches at Pisa University. Her research interests include biomedical micro- and nanorobotics, microsystem technologies, and micromechatronics. She was awarded the Best Manipulation Paper Award at ICRA in 2001.

Jean-Pierre Merlet

INRIA Sophia-Antipolis
Sophia-Antipolis, France
jean-pierre.merlet@sophia.inria.fr

**Chapter B.12**

J.-P. Merlet is senior researcher at INRIA, where he works on interval analysis and robotics. He is the author of a book on parallel robots and of over 200 papers in robotics, mechanism theory, and numerical analysis. He is the chair of IFToMM France and has received the Altran Award and the “Micron d'Or” Award for his microrobot for surgical endoscopy.

**Giorgio Metta**

Italian Institute of Technology
Department of Robotics, Brain and
Cognitive Sciences
Genova, Italy
pasa@liralab.it

Chapter G.62

Giorgio Metta is Senior Scientist at the Italian Institute of Technology and Assistant Professor at the University of Genoa. His research activities are in the fields of biologically motivated and humanoid robotics developed in collaboration with leading European and international scientists from different disciplines such as neuroscience and psychology. He also worked at MIT on various humanoid robots.

**Jean-Arcady Meyer**

Université Pierre et Marie Curie – CNRS
Institut des Systèmes Intelligents et de
Robotique
Paris, France
jean-arcady.meyer@lip6.fr

Chapter G.60

Jean-Arcady Meyer is Emeritus Research Director at CNRS. He is trained as an Engineer, graduated in Human and Animal Psychology, and received a PhD in Biology. He is the founder of the journal Adaptive Behavior, and his primary scientific interests are in adaptive behaviors in natural and artificial systems. He is the main coordinator of the Psikharpax project.

François Michaud

Université de Sherbrooke
Department of Electrical Engineering and
Computer Engineering
Sherbrooke, Québec, Canada
francois.michaud@usherbrooke.ca

Chapter E.38

François Michaud is the Canada Research Chairholder in Mobile Robots and Autonomous Intelligent Systems at the Université de Sherbrooke, Québec, Canada. In 2003, he received the Young Engineer Achievement Award from the Canadian Council of Professional Engineers. His research interests are in architectural methodologies for intelligent decision-making, design of autonomous mobile robotics, social robotics, human–robot interaction, robot learning, and intelligent systems.

David P. Miller

University of Oklahoma
School of Aerospace and Mechanical
Engineering
Norman, OK, USA
dpmiller@ou.edu

Chapter F.55

David P. Miller is the Wilkerson Chair Professor of Intelligent Systems at the University of Oklahoma. His teaching and research span the schools of Aerospace and Mechanical Engineering, Computer Science, and Bioengineering. His primary research areas are planetary rovers, assistive technology, and robots for STEM education. He is a co-founder of the KISS Institute for Practical Robotics, which produces educational robotics programs.

**Javier Minguez**

Universidad de Zaragoza
Departamento de Informática e
Ingeniería de Sistemas Centro Politécnico
Superior
Zaragoza, Spain
jminguez@unizar.es

Chapter E.35

Javier Minguez received the physics degree in 1996 from the Universidad Complutense de Madrid, Spain, and the PhD degree in computer science and systems engineering in 2002 from the University of Zaragoza, Spain. He is currently a full-time Researcher in the Robotics Group at the University of Zaragoza. His research interests are mobile robots and human–machine interaction.

**Pascal Morin**

INRIA Sophia-Antipolis
Sophia-Antipolis, France
pascal.morin@inria.fr

Chapter E.34

Pascal Morin obtained the PhD degree from Ecole des Mines de Paris, France, in 1996, and then spent one year as a Postdoctoral Fellow at the California Institute of Technology, Pasadena, USA. Since 1997, he has been Chargé de Recherche at the French research institute INRIA. His research interests include control of nonlinear systems and its applications to mechanical systems.

Robin R. Murphy

University of South Florida
Computer Science and Engineering
Tampa, FL, USA
murphy@cse.usf.edu

**Chapter F.50**

Robin Roberson Murphy is director of the Institute for Safety, Security, and Rescue Technology at the University of South Florida. She received the BME degree in Mechanical Engineering, and the MS and the PhD degrees in Computer Science in 1980, 1989, and 1992, respectively, from Georgia Tech. She received the NIUSR Eagle Award for her work at the World Trade Center.

Daniele Nardi

Università degli Studi di Roma "La Sapienza"
Dipartimento di Informatica e Sistemistica "A. Ruberti"
Roma, Italy
nardi@dis.uniroma1.it

**Chapter F.50**

Dr. Daniele Nardi is Full Professor at the Engineering Faculty of the University "Sapienza" Rome. He received the Laurea degree in Electronic Engineering from Politecnico, Torino in 1981 and the Master degree in Computer and System Engineering from Sapienza Università di Roma in 1984. His research interests are in artificial intelligence and cognitive robotics. He is Trustee of the RoboCup Federation and Director of the Research Laboratory Intelligent Systems for Emergency and Civil Defense at the Istituto Superiore Antincendi, Roma.

Bradley J. Nelson

ETH Zentrum
Institute of Robotics and Intelligent Systems
Zürich, Switzerland
bnelson@ethz.ch

**Chapter B.18**

Brad Nelson received the PhD in Robotics from Carnegie Mellon University in 1995. He became Assistant Professor at the University of Illinois-Chicago in 1995, Associate Professor at the University of Minnesota in 1998, and Professor of Robotics and Intelligent Systems at ETH Zurich in 2002. His research involves microrobotics and nanorobotics.

Günter Niemeyer

Stanford University
Department of Mechanical Engineering
Design Group, Terman Engineering Center
Stanford, CA, USA
gunter.niemeyer@stanford.edu

**Chapter D.31**

Dr. Günter Niemeyer directs the Stanford Telerobotics Laboratory, where he studies the dynamics and control of physical human–robot interactions, in particular haptic perception and teleoperation under time delay. Applications range from telerobotic surgery to remote satellite servicing. He received the MS and PhD degrees from MIT and helped develop Intuitive Surgical's daVinci system, now in use at hundreds of hospitals worldwide.

Klas Nilsson

Lund University
Department of Computer Science
Lund, Sweden
klas@cs.lu.se

**Chapter F.42**

Working as an Associate Professor at the Department of Computer Science, Dr. Nilsson is involved in several research projects and teaching in real-time programming. His research includes robot control systems and related software technologies, considering implementation and industrially relevant test cases. The Laboratory for Application Languages and the Real-Time Garbage Collector developed within his group have been used for programming and real-time control of industrial robots from ABB.

Stefano Nolfi

Consiglio Nazionale delle Ricerche (CNR)
Istituto di Scienze e Tecnologie della Cognizione
Roma, Italy
stefano.nolfi@istc.cnr.it

**Chapter G.61**

Dr. Stefano Nolfi is Director of the Laboratory of Autonomous Robots and Artificial Life within the Institute of Cognitive Sciences and Technologies of the Italian National Research Council (CNR-ISTC). His research activities focus on evolutionary robotics, collective robotics, adaptive behavior, complex systems, and embodied cognitive sciences.

**Illah R. Nourbakhsh**

Carnegie Mellon University
The Robotics Institute
Pittsburgh, PA, USA
illah@cs.cmu.edu

Chapter F.55

Illah R. Nourbakhsh is an Associate Professor of Robotics and head of the Robotics Masters Program in The Robotics Institute at Carnegie Mellon University. He is co-founder of the Toy Robots Initiative, Director of the Center for Innovative Robotics, and Director of the Community Robotics, Education and Technology Empowerment Lab. He co-authored the textbook *Introduction to Autonomous Mobile Robots*.

**Jonathan B. O'Brien**

University of New South Wales
School of Civil and Environmental
Engineering
Sydney, Australia
j.obrien@unsw.edu.au

Chapter F.47

Jonathan O'Brien is the Founder of Construction Robotics Ltd. in the UK and a former President of the International Association for Automation and Robotics in Construction. He is Professor in Civil and Environmental Engineering at the University of NSW in Sydney, Australia. He is a pioneer of construction robotics in Australia.

Allison M. Okamura

The Johns Hopkins University
Department of Mechanical Engineering
Baltimore, MD, USA
aokamura@jhu.edu

Chapter D.30

Allison Okamura received the PhD degree from Stanford University in 2000 and is currently an Associate Professor of Mechanical Engineering at Johns Hopkins University. Her awards include the 2004 NSF CAREER Award, and the 2005 IEEE Robotics and Automation Society Early Academic Career Award. Her research interests are haptics, teleoperation, virtual environments, medical robotics, smart prosthetics, rehabilitation engineering, and engineering education.

Fiorella Opero

Scuola di Robotica
Sampierdarena, Genova, Italy
operto@scuoladirobotica.it

Chapter G.64

Dr. Opero is a scholar of the Philosophy of Science and of Science Ethics. She has acquired specific experience in science dissemination and popularization. She contributed to the birth of the scientific book series "I Dialoghi". She has cooperated with the Italian National Research Council in promoting the knowledge and understanding of robotics. In 2000 she cofounded the Association School of Robotics and is contributing to the development of roboethics.

David E. Orin

Chapter A.2

For biographical profile, please see the section "About the Part Editors" on page XXI.

**Giuseppe Oriolo**

Università degli Studi di Roma "La Sapienza"
Dipartimento di Informatica e
Sistemistica "A.Ruberti"
Roma, Italy
oriolo@dis.uniroma1.it

Chapter B.11

Giuseppe Oriolo is an Associate Professor of Automatic Control at the Dipartimento di Informatica e Sistemistica of the Università di Roma "La Sapienza" and the Coordinator of the DIS Robotics Laboratory. His research interests are in the area of nonlinear control and robotics, and in particular in robot control, motion planning, trajectory planning, redundant robotic systems, control of underactuated and nonholonomic systems, sensor-based localization, navigation, and perception for mobile robots. He is a Senior Member of the IEEE.

**Michel Parent**

INRIA Rocquencourt
Le Chesnay, France
michel.parent@inria.fr

Chapter F.51

Michel Parent is currently the Program Manager at INRIA of the R&D team on advanced road transport (IMARA research group). This group focuses on research and development of new forms of road transport and in particular on fully automated vehicles (the cybercars). Michel Parent has an engineering degree from the French Aeronautics School (ENSAE), the Masters degree in Operation Research, and the PhD in Computer Science, both from Case Western Reserve University, Cleveland, OH.

Frank C. Park

Chapter B.10

For biographical profile, please see the section “About the Part Editors” on page XXI.

Lynne E. Parker

University of Tennessee
Department of Electrical Engineering and
Computer Science
Knoxville, TN, USA
parker@eecs.utk.edu

Chapter E.40

Dr. Parker is a Professor in the Department of Electrical Engineering and Computer Science at the University of Tennessee, Knoxville. She received the PhD degree from the Massachusetts Institute of Technology. Her research is in the areas of distributed multi-robot systems, sensor networks, and artificial intelligence. She received the Presidential Early Career Award for Scientists and Engineers (PECASE) Award in 2000.

Michael A. Peshkin

Northwestern University
Department of Mechanical Engineering
Evanston, IL, USA
peshkin@northwestern.edu

Chapter G.57

Michael Peshkin received the doctorate in Physics from Carnegie Mellon University in 1988. His current research interests include human–machine physical interaction, human motion control, and novel sensors and actuators. He is cofounder of three companies: Mako Surgical in image guided surgery, Cobotics in industrial material handling, and Kinea Design in rehabilitation robotics, prosthetics, assistive devices, and other human-interactive applications of robotics.

**J. Norberto Pires**

Universidade de Coimbra
Departamento de Engenharia Mecânica
Coimbra, Portugal
norberto@robotics.dem.uc.pt

Chapter F.42

J. Norberto Pires received the PhD degree in 1999 in Robotics and Automation from the University of Coimbra, Portugal. Since 1991 he has been with the Mechanical Engineering staff of the University of Coimbra, where he currently serves as Auxiliary Professor. His research interests include force control, industrial robotics, object-oriented and distributed programming, flexible manufacturing systems, and human-machine interfaces. He is an IEEE Senior Member and Vice President of the IEEE-PT branch.

**Erwin Prassler**

Fachhochschule Bonn-Rhein-Sieg
Fachbereich Informatik
Sankt Augustin, Germany
erwin.prassler@fh-brs.de

Chapter F.54

Dr. Prassler received a Master’s degree in Computer Science from the Technical University of Munich in 1985. In 1989, he joined the Research Institute for Applied Knowledge Processing in Ulm, where he headed a research group working in the field of mobile robots and service robotics where he received his PhD in Computer Science in 1996. In 2004, Dr. Prassler was appointed Associate Professor at the University of Applied Science Bonn-Rhein-Sieg.

Domenico Prattichizzo

Università degli Studi di Siena
Dipartimento di Ingegneria
dell’Informazione
Siena, Italy
prattichizzo@ing.unisi.it

Chapter D.28

Domenico Prattichizzo received the MS degree in Electronics Engineering and the PhD degree in Robotics and Automation from the University of Pisa, Italy in 1991 and 1995, respectively. Since 2002 he has been an Associate Professor of Robotics and Automation at the University of Siena. In 1994, he was Visiting Scientist at the Artificial Intelligence Laboratory at MIT, Cambridge. His research interests are in the area of robotic grasping, haptics, distance learning, visual servoing, geometric control, and distance learning.

Carsten Preusche

Deutsches Zentrum für Luft- und Raumfahrt (DLR) Oberpfaffenhofen
Institut für Robotik und Mechatronik
Wessling, Germany
carsten.preusche@dlr.de

**Chapter D.31**

Carsten Preusche became a Scientist at the Institute of Robotics and Mechatronics, German Aerospace Center (DLR) in 1999. Since 2004 he is head of the telepresence and telerobotic group. His work is mainly focused on the control of time-delayed telerobotic systems and the design of multimodal human–system interfaces.

William R. Provancher

University of Utah
Department of Mechanical Engineering
Salt Lake City, UT, USA
wil@mech.utah.edu

Chapter C.19

Dr. Provancher holds the BS degree in Mechanical Engineering and the MS degree in Materials Science both from the University of Michigan, and the PhD degree in Mechanical Engineering from Stanford University. He is currently an Assistant Professor in the Department of Mechanical Engineering at the University of Utah. His active areas of research include haptics, tactile sensing and feedback, and the design of novel climbing robots.

David J. Reinkensmeyer

University of California at Irvine
Mechanical and Aerospace Engineering
Irvine, CA, USA
dreinken@uci.edu

Chapter F.53

David Reinkensmeyer received the PhD degree in Electrical Engineering from the University of California at Berkeley in 1993, and was a Postdoctoral Fellow at the Rehabilitation Institute of Chicago. He is currently a Professor in the Department of Mechanical and Aerospace Engineering at the University of California, Irvine. His research interests are in neuromuscular control, motor learning, robotics, and neurorehabilitation.

Alfred Rizzi

Boston Dynamics
Waltham, MA, USA
arizzi@bostondynamics.com

**Chapter E.39**

Dr. Alfred Rizzi is the Lead Robotics Scientist at Boston Dynamics. He served as an Associate Research Professor in the Robotics Institute at Carnegie Mellon University from 1998–2006 where he directed research projects focused on hybrid sensor-based control of complex and distributed dynamical systems. These projects included the development of embedded software systems and automated behaviors for novel legged mobile robots. Dr. Rizzi received the MS and PhD degrees from Yale University in 1990 and 1994, respectively.

Jonathan Roberts

Commonwealth Scientific and Industrial Research Organisation (CSIRO)
ICT Centre, Autonomous Systems Laboratory
Kenmore, QLD, Australia
jonathan.roberts@csiro.au

Chapter F.49

Jonathan Roberts completed an honours degree in Aerospace Engineering and the PhD degree in Computer Vision, both at the University of Southampton, UK. In 1995, he joined CSIRO in Australia to work in the area of field robotics including UAVs, AUVs, and large AGVs for mining and metal production. In 2006 Jonathan was elected President of the Australian Robotics and Automation Association.

Daniela Rus**Chapter E.41**

For biographical profile, please see the section “About the Part Editors” on page XXII.

Kamel S. Saidi

National Institute of Standards and Technology
Building and Fire Research Laboratory
Gaithersburg, MD, USA
kamel.saidi@nist.gov

Chapter F.47

Dr. Saidi holds the PhD degree in Civil Engineering from the University of Texas at Austin (UT), where he co-invented an electric power-plant boiler maintenance robot. Dr. Saidi is currently a UT researcher and a National Institute of Standards and Technology Guest Researcher. He is developing the NIST Intelligent and Automated Construction Job Site Research Testbed and standards for 3-D imaging systems.

**Claude Samson**

INRIA Sophia-Antipolis
Sophia-Antipolis, France
cclaude.samson@inria.fr

Chapter E.34

Claude Samson is Directeur de Recherche at the French research institute INRIA. Much of his research concerns robotics and automatic control, with a particular interest in the control of nonlinear mechanical systems. He has published the book *Robot Control. The Task-Function Approach* with his colleagues Bernard Espiau and Michel Leborgne.

Stefan Schaal

University of Southern California
Computer Science and Neuroscience
Los Angeles, CA, USA
sschaal@usc.edu

**Chapter G.59**

Stefan Schaal is an Associate Professor in Computer Science and Neuroscience at the University of Southern California. He has previously held positions as postdoctoral fellow at MIT, as Head of the Computational Learning Group in a Japanese ERATO project, and Adjunct Assistant Professorships at the Georgia Tech and the Pennsylvania State University. Dr. Schaal's research interests include topics of statistical and machine learning, neural networks, computational neuroscience, functional brain imaging, nonlinear dynamics and control theory, and biomimetic robotics.

Victor Scheinman

Stanford University
Department of Mechanical Engineering
Stanford, CA, USA
vds@stanford.edu

**Chapter A.3**

Victor Scheinman is a Consulting Professor in Mechanical Engineering at Stanford University. He has engineering degrees from MIT and Stanford. He was a founder of Automatix Inc. and Vicarm Inc. He designed and developed the Unimation PUMA robot, the Automatix/Yaskawa Robotworld, the Scheinman/Stanford Arm, and the Scheinman/MIT robot arms. He is a recipient of the ASME's Leonardo DaVinci Award for Design Engineering and the RIA's Joseph F. Engelberger Award for Robotics Technology.

**James Schmiedeler**

The Ohio State University
Department of Mechanical Engineering
Columbus, OH, USA
schmiedeler.2@osu.edu

Chapter A.1

James Schmiedeler is an Assistant Professor in the Department of Mechanical Engineering at The Ohio State University. His current research activities involve biped robot locomotion, human motor coordination, robot-assisted rehabilitation, human biomechanics, and design of morphing systems. His research was recognized with a National Science Foundation Presidential Early Career Award for Scientists and Engineers (PECASE) in 2007.

**Roland Siegwart**

ETH Zentrum
Department of Mechanical and Process Engineering
Zürich, Switzerland
rsiegwart@ethz.ch

Chapter F.55

Roland Siegwart is Full Professor for Autonomous Systems at ETH Zürich. He was formerly Professor (1996–2006) and Vice Dean (2002–06) at EPFL, R&D Director at MECOS Traxler AG (1991–96), and held postdoc and visiting positions at Stanford University (1989/90, 2005) and NASA Ames (2006). He was Vice President for Technical Activities (2004/05) and Distinguished Lecturer (2006/08) of the IEEE Robotics and Automation Society. He is cofounder of several spin-off companies.

Reid Simmons

Carnegie Mellon University
The Robotics Institute
School of Computer Science
Pittsburgh, PA, USA
reids@cs.cmu.edu

**Chapter A.8**

Reid Simmons received the PhD degree in Artificial Intelligence from MIT in 1988. His research focuses on autonomous, self-reliant robots, which involves issues of robot control architectures, probabilistic planning and reasoning, robot navigation, multirobot coordination, automated assembly, and human–robot social interaction. Dr. Simmons has developed over a dozen autonomous robots, receiving the Newell Award for Research Excellence in 2004.

Dezhen Song

Texas A&M University
Department of Computer Science
College Station, TX, USA
dzsong@cs.tamu.edu

**Chapter D.32**

Dezhen Song received the PhD degree in Engineering from the University of California, Berkeley, in 2004. Currently, he is an Assistant Professor with Texas A&M University, College Station. His research area is networked robotics, computer vision, optimization, and stochastic modeling. Dr. Song received the Kayamori Best Paper Award of the 2005 IEEE International Conference on Robotics and Automation (with J. Yi and S. Ding) and the NSF Faculty Early Career Development (CAREER) Award in 2007.

**Gaurav S. Sukhatme**

University of Southern California
Department of Computer Science
Los Angeles, CA, USA
gaurav@usc.edu

Chapter E.41

Gaurav S. Sukhatme is an Associate Professor of Computer Science at the University of Southern California (USC). He earned the MS and PhD degrees in Computer Science from USC. He is the co-director of the USC Robotics Research Laboratory and the director of the USC Robotic Embedded Systems Laboratory, which he founded in 2000. His research interests are in multirobot systems and sensor/actuator networks. He is a recipient of the NSF CAREER award and the Okawa foundation research award.

**Satoshi Tadokoro**

Tohoku University
Graduate School of Information Sciences
Sendai, Japan
tadokoro@rm.is.tohoku.ac.jp

Chapter F.50

Satoshi Tadokoro was an Associate Professor of Kobe University in 1993–2005, and has been a Professor of Tohoku University since 2005. He established the International Rescue System Institute in 2002, where he is a President. He was a project leader of MEXT DDT Project on rescue robotics 2002–2007. He is a Trustee of The RoboCup Federation and founded RoboCupRescue.

Atsuo Takanishi

Waseda University
Department of Modern Mechanical
Engineering
Tokyo, Japan
takanisi@waseda.jp

**Chapter G.58**

Atsuo Takanishi is a Professor in the Department of Mechanical Engineering, Waseda University and a concurrent Professor and one of the core members of the Humanoid Robotics Institute (HRI), Waseda University. He received the MSE degree in 1982 and the PhD degree in 1988 in Mechanical Engineering from Waseda University. His current researches are related to humanoid robots and cyborgs, such as the WABIAN series (WAseda BiPpedal humANoid), Waseda Leg, the Waseda Jaw, the Waseda Yamanashi, the fWaseda Flutist, the Waseda Eye, and the Waseda Talker.

Russell H. Taylor

The Johns Hopkins University
Department of Computer Science
Baltimore, MD, USA
rht@jhu.edu

**Chapter F.52**

Russell H. Taylor received the PhD degree in Computer Science from Stanford in 1976. He joined IBM Research in 1976, where he developed the AML robot language and managed the Computer-Assisted Surgery Group before moving in 1995 to Johns Hopkins, where he is as a Professor of Computer Science with joint appointments in Mechanical Engineering, Radiology, and Surgery. He is Director of the NSF Engineering Research Center for Computer-Integrated Surgical Systems and Technology.

**Charles E. Thorpe**

Carnegie Mellon University in Qatar
Qatar Office SMC 1070
Pittsburgh, PA, USA
thorpe@qatar.cmu.edu

Chapter F.51

Chuck Thorpe is Dean of the Carnegie Mellon University campus in Doha, Qatar. Prior to being appointed Dean, Thorpe was Director of the Robotics Institute at Carnegie Mellon University, where he led a research group that developed autonomous vehicles. Thorpe received the PhD degree in Computer Science from Carnegie Mellon University in 1984. In addition to serving as Dean, Thorpe is a member of the faculty, teaching Introduction to Mobile Robotics.

**Sebastian Thrun**

Stanford University
Department of Computer Science Artificial
Intelligence Laboratory
Stanford, CA, USA
thrun@stanford.edu

Chapter E.37

Sebastian Thrun is Professor of Computer Science and Electrical Engineering at Stanford University, where he directs the Stanford Artificial Intelligence Laboratory. Professor Thrun has published over 300 scientific articles and 11 books. He won numerous awards, including the 2005 DARPA Grand Challenge, the Braunschweig Research Prize, the World Technology Network Award, the Olympus Award, and numerous best paper awards. Thrun has been elected into the National Academy of Engineering, the Leopoldina, and he is an elected Fellow of the AAAI, ECCAI, and WTN.

James P. Trevelyan

The University of Western Australia
School of Mechanical Engineering
Perth, Western Australia, Australia
james.trevelyan@uwa.edu.au

**Chapter F.48**

James Trevelyan pioneered sheep shearing robots between 1976 and 1993, then worked on remote access laboratories, landmine clearance, and understanding engineering practice. He received the Joseph Engelberger award for contributions to robotics science in 1993, two JIRA awards, and numerous awards for distinguished teaching. He is a Fellow of Engineers Australia and an Elected Member of the IFTOMM Executive Council.

Jeffrey C. Trinkle

Rensselaer Polytechnic Institute
Department of Computer Science
Troy, NY, USA
trink@cs.rpi.edu

**Chapter D.28**

Jeffrey C. Trinkle received the PhD degree from the Department of Systems Engineering at the University of Pennsylvania. Since 1987, he has held faculty positions at the University of Arizona and at Texas A&M University. From 1998 to 2003 he was at Sandia National Labs in Albuquerque, New Mexico. He is now Professor of Computer Science at Rensselaer Polytechnic Institute in Troy, New York. Professor Trinkle's primary research interests are in the areas of robotic manipulation, multibody dynamics, and automated manufacturing.

**Masaru Uchiyama**

Tohoku University
Department of Aerospace Engineering
Sendai, Japan
uchiyama@space.mech.tohoku.ac.jp

Chapter D.29

Masaru Uchiyama received the BE, ME, and PhD degrees from the University of Tokyo, Tokyo, Japan, in 1972, 1974, and 1977, respectively, all in Mechanical Engineering for Production. Since 1977, he has been with the School of Engineering, Tohoku University, Sendai, Japan and is currently a Professor of the Space Machines Laboratory, Department of Aerospace Engineering. His research interests include robotics, automatic control and their application to aerospace engineering.

**H.F. Machiel Van der Loos**

University of British Columbia
Department of Mechanical Engineering
Vancouver, BC, Canada
vdl@mech.ubc.ca

Chapter F.53

Dr. Machiel Van der Loos is Adjunct Professor in Mechanical Engineering at UBC, Vancouver, Canada. Until 2007, he was with the VA Rehabilitation R&D Center, Palo Alto, California, focusing on rehabilitation robotics. He is Consulting Associate Professor in Mechanical Engineering at Stanford University, collaborating on design coaching and thesis advising. He received the Ingénieur Mécanicien degree from the Swiss Federal Institute of Technology, Lausanne (1979), and an Engineer's Degree (1984) and PhD (1992) from Stanford University.

Patrick van der Smagt

Deutsches Zentrum für Luft- und
Raumfahrt (DLR) Oberpfaffenhofen
Institut für Robotik und Mechatronik
Wessling, Germany
smagt@dlr.de

**Chapter G.62**

Patrick van der Smagt is head of the bionics group at the Institute of Robotics and Mechatronics, German Aerospace Center (DLR). His award-winning group is inspired by biological systems and uses it to build the most advanced robotic and sensor concepts, as well as the control thereof. As Auden had Tom Rakewell say: "to follow nature as my teacher".

Gianmarco Veruggio

Consiglio Nazionale delle Ricerche
Istituto di Elettronica e di Ingegneria
dell'Informazione e delle
Telecomunicazioni
Genova, Italy
gianmarco@veruggio.it

Chapter G.64

Dr. Veruggio received the degree in Electronic Engineering from Genoa University, Italy, in 1980. He is Senior Research Scientist at IEIIT of Italian National Research Council. His research interest focuses on experimental robotics in extreme environment, and he led several underwater robotics campaigns in Antarctica and in the Arctic. In 2000 he founded the association "School of Robotics" to promote this new science among young people and the society at large. In 2002 he coined the word, and proposed the concept of Roboethics, to which he is dedicating increasing resources.

**Luigi Villani**

Università degli Studi di Napoli Federico II
Dipartimento di Informatica e
Sistemistica, PRISMA Lab
Napoli, Italy
luigi.villani@unina.it

Chapter A.7

Luigi Villani received the PhD degree in Electrical Engineering and Computer Science from the University of Naples in 1996, where he is Associate Professor of Automatic Control since 2002. His research interests include robot force/motion control, cooperative robots, visual servoing. He has co-authored three books and more than 100 journal and conference papers. He is Associate Editor of the IEEE Transactions on Control Systems Technology and the IEEE Transactions on Robotics.

**Arto Visala**

Helsinki University of Technology (TKK)
Department of Automation and Systems
Technology
Helsinki, Finland
arto.visala@tkk.fi

Chapter F.46

Arto Visala, Professor at TKK Helsinki since 2000, has an extensive experience in control engineering, automation technology, and robotics. During the last 10 years, he has been working on modelling of nonlinear dynamical systems with NN Wiener-type models, mobile multirobot systems for environment monitoring, working machine automation, machine vision systems for industry, and machine perception for mobile robots and working machines.

Kenneth Waldron

Stanford University
Department of Mechanical Engineering
Stanford, CA, USA
kwaldron@stanford.edu

Chapter A.1

Kenneth Waldron is a Professor (Research) in the Department of Mechanical Engineering of Stanford University. He has occupied academic positions at the University of New South Wales, the University of Houston, Ohio State University, and the University of Technology, Sydney, in addition to Stanford. He is President of IFToMM, the International Federation for Promotion of Mechanism and Machine Science.

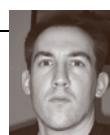

Ian D. Walker

Clemson University
Department of Electrical and Computer
Engineering
Clemson, SC, USA
ianw@ces.clemson.edu

Chapter B.11

Ian D. Walker received the BS from the University of Hull, England, in 1983 and the MS and PhD degrees from the University of Texas, Austin, in 1985 and 1989, respectively. He is currently a Professor at Clemson University. His research centers on robotics, particularly novel manipulators and manipulation. He conducts research in biologically inspired "trunk, tentacle, and worm" robots.

**Christian Wallraven**

Max-Planck-Institut für biologische
Kybernetik
Kognitive Humanpsychophysik
Tübingen, Germany
christian.wallraven@tuebingen.mpg.de

Chapter G.63

Christian Wallraven (PhD in Physics) is a research scientist at the Max-Planck-Institute for Biological Cybernetics, Tübingen, Germany. His research addresses the fusion of cognitive psychophysics, computer graphics, and computer vision to understand fundamental perceptual processes as well as to open up new applications in the field of computer science.

**Brian Wilcox**

California Institute of Technology
Jet Propulsion Laboratory
Pasadena, CA, USA
brian.h.wilcox@jpl.nasa.gov

Chapter F.45

Brian Wilcox is at the Jet Propulsion Laboratory and is the Principal Investigator for the ATHLETE robot. He was the Supervisor of the Robotic Vehicles Group at JPL from 1985–2005, leading the development of rover technology leading to the Sojourner rover in 1997 and subsequent Mars rovers. He holds six patents and has received the NASA Exceptional Engineering Achievement Medal.

Jing Xiao

University of North Carolina
Department of Computer Science
Charlotte, NC, USA
xiao@uncc.edu

**Chapter D.26**

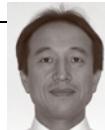

Jing Xiao received the PhD degree from the University of Michigan in 1990. She is currently a Professor of Computer Science at the University of North Carolina, Charlotte. She served as the Director of the Robotics and Human Augmentation Program at the U.S. National Science Foundation from 1998 to 2000. Her research covers robotics and haptics, and she has about 100 publications.

Dana R. Yoerger

Woods Hole Oceanographic Institution
Department of Applied Ocean Physics
and Engineering
Woods Hole, MA, USA
dyoerger@whoi.edu

**Chapter F.43**

Dana Yoerger's research interests include underwater vehicle dynamics and control, vehicle design, and autonomous scientific survey. He has contributed to the design and control systems of the Jason remotely operated vehicles, the Autonomous Benthic Explorer, and the Nereus vehicle, designed to operate to 11000 m depth. He has participated in over 50 oceanographic research cruises, and conducted 210 autonomous vehicle dives.

**Kazuhito Yokoi**

National Institute of Advanced Industrial
Science and Technology (AIST)
Intelligent Systems Research Institute
Tsukuba, Japan
kazuhito.yokoi@aist.go.jp

Chapter G.56

Kazuhito Yokoi received the PhD degree from the Tokyo Institute of Technology. He is currently a co-director of AIST-CNRS Joint Robotics Laboratory (JRL), Intelligent Systems Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), at Tsukuba, Japan. He is also an Adjunct Professor of Cooperative Graduate School at University of Tsukuba. His research interests include humanoids and human-centered robotics.

**Kazuya Yoshida**

Tohoku University
Department of Aerospace Engineering
Sendai, Japan
yoshida@astro.mech.tohoku.ac.jp

Chapter F.45

Kazuya Yoshida received his Dr. Eng. from the Tokyo Institute of Technology in 1990. Since 2003 he has been Professor in the Department of Aerospace Engineering, Tohoku University, Japan. He is also serving as a Visiting Lecturer at the International Space University in Strasbourg, France, since 1998. His research activities include dynamics and control of space robots covering from free-flying robots to planetary exploration rovers.

Alexander Zelinsky**Chapter F.51**

For biographical profile, please see the section "About the Part Editors" on page XXII.
